The **local action of chloral** is sufficiently irritant to allow its use as a rubefacient. Its action on the stomach is consequently prominent; it must be largely diluted with water before administration, else it may produce vomiting. Large doses are liable to show after-effects, referable to a gastritis. Solutions of chloral hydrate are *antiseptic;* 5 per cent prevents putrefaction (Claude Bernard).

Acute Chloral Poisoning.—The lighter grades show the narcotic phenomena, together with gastric irritation and vomiting, sometimes followed by icterus and albuminuria, skin lesions and ataxia. In severe cases (as by "knockout drops") there is prompt collapse or delirium; pulse scarcely perceptible; severe fall of temperature; cyanosis; dyspnea or very slow respiration. In fatal cases, death is rarely delayed beyond five hours and may be almost immediate. Fatal relapses, after apparent recovery, have been reported (Purdy, 1889). Large doses may kill the fetus *in utero* (Jung, 1914). The *fatal dose* averages about 10 Gm., but varies greatly. Death has been reported after 1 to 3 Gm., and recovery after 10 to 28 Gm. (Lewin). Doses above 3 Gm. must be used cautiously. (The dosage for cats was studied by Sollmann and Hatcher, 1908.) The popular impression that the effects of chloral are potentiated by alcohol ("Mickey Finn" knock-out drops) is not borne out by animal experiments (W. L. Adams, 1943). The *treatment* of chloral poisoning consists in gastric lavage; emetics would often be ineffective. The patient should be kept warm. Metrazol and ephedrine are useful. Artificial respiration is given as needed. *Cerebral stimulants* are of little avail against toxic doses. Light chloral sleep, however, is easily broken by caffeine, cocaine or tetrahydronaphylamine (Airila, 1913).

Chronic chloral poisoning is not rare. It presents the symptoms and degenerations of chronic alcoholism, with more severe gastric and cutaneous manifestations. The tolerance is only moderately increased, and sudden death is not infrequent. Chloral habit is treated in the same general manner as other drug habits.

Habituation of animals to hypnotics occurs with chloral, amylene hydrate, paraldehyde and others of the fatty series, but not with urethane, bromural or sulfonal (Biberfeld, 1918). Chronic chloral poisoning was studied in dogs by Wallace, 1912. Habituation to morphine does not confer tolerance for chloral (H. B. Myers, 1917).

Growth.—Chronic chloral poisoning arrests the growth of young rats, which remain permanently stunted even after the chloral is discontinued (Sollmann, 1924).

Fate.—Chloral is readily absorbed from all mucous membranes. It is excreted by the urine, in one and one-half to eighteen hours as the nontoxic trichlorethyl-glycuronic acid (urochloralic or chloraluric acid) (v. Mering, 1881). This reduces Fehling's solution, and thus gave rise to the erroneous belief that chloral causes glycosuria. It polarizes to the left, but does not ferment. True hyperglycemia may occur in profound narcosis, analogous to chloroform (Jacobson, 1913). It is generally stated that trichlorethyl alcohol, $CCl_3.CH_2OH$, is formed as an intermediate product, but this is questionable, since the conjugation of the latter is slower (G. Lehmann, 1938).

A small part of the chloral is excreted unchanged; this is greater if the liver is injured, as by carbon tetrachloride (Mukerji and Ghose, 1941).Minimal traces, if any, are exexcreted as inorganic chlorides and chloroform.

Liebreich's Theory.—Liebreich, 1869, was led to try chloral by the assumption that it would be converted into chloroform in the organism, as it is by alkalis in the test tube. The theory was disproved: the blood and expired air contain no chloroform, or at most insignificant traces (Nicloux, 1906). Liebreich also stated that a fraction is excreted as chloride; this was contradicted by Kast, 1887.

Concentration in Blood and Tissues.—In light chloral anesthesia of dogs, the blood contains 30 to 50 mg. per 100 cc.; in deep anesthesia, 50 to 70 mg. With just fatal doses, the brain contains 57 to 58 mg. per 100 Gm. (Archangelski, 1901; Olszewski and Renescu, 1932).

***Chloral Hydrate,** U.S.P., Chloral; $CCl_3CH(OH)_2$. Colorless crystals, of aromatic odor and acrid taste. Slowly volatilized when exposed to air. Very sol. in water (1:0.25); freely sol. in alc. (1:1.3) or eth. and oils, fixed or volatile. *Incompatible* with alkalis, carbonates, antipyrine and alcoholic liquids containing between 10 and 50 per cent of alcohol (Hargreaves, 1932). Average dose, 0.06 Gm., 10 grains.

Bromal hydrate does not induce typical sleep, but causes coma and death, in doses much smaller than does chloral hydrate. It is also much more toxic to the heart and uterine muscle (Ken Ito, 1926).

OTHER CHLORINATED HYPNOTICS

Many of these have been suggested as substitutes for chloral, but they are not seriously superior. Several owe their activity to the liberation of chloral. Since promptness of action is generally desirable, the slow and uncertain liberation is a disadvantage.

Butyl-chloral Hydrate, Croton Chloral Hydrate, $CH_3.CHCl.CCl_2.CH(OH)_2$, was also introduced by Liebreich, 1871. Its action is more powerful but shorter than that of chloral (v. Mering, 1875). It has been used especially in facial neuralgia. Sol. in water (1:40); very sol. in alc. or glyc. Dose, 0.3 to 1.2 Gm., 5 to 20 grains. The *hypnotic trihalogen butyl alcohols* were investigated by Aldrich, 1916.

Chlorobutanol, U.S.P.; Chlorbutol, B.P.; acetone chloroform; *Chloretone*, $CCl_3.C(OH)CH_2CH_3$, occurs as a colorless crystalline powder, of odor and taste reminding of camphor; sparingly soluble in water (1:125); freely soluble in organic solvents. It acts similarly to chloral, and is probably rather more toxic (Impens, 1901); severe poisoning, but with recovery, is reported from 6 Gm. The therapeutic dosage is 0.3 to 1.2 Gm., 5 to 20 grains. The saturated solution (0.6 per cent) acts as a mild local anesthetic, antiseptic and preservative for hypodermic solutions. Chlorobutanol appears in the mother's milk after the continued administration of large doses, but not after therapeutic doses (Blanner, 1919).

Chlorobutanol is used as an *anesthetic for laboratory animals*, as it allows of long operations without requiring any attention. The dogs are given the usual dose of morphine. As soon as vomiting has occurred, 0.2 Gm. of chlorobutanol per kilogram of animal is administered by stomach tube or peritoneally (Rowe, 1916). The chlorobutanol is previously dissolved in the smallest possible amount of alcohol. The anesthesia is complete in fifteen to twenty minutes, and lasts several hours. The blood pressure falls rapidly in rabbits, slowly in dogs. In unanesthetized dogs it decreases the response of the respiratory center to carbon dioxide (Voegtlin and Wiggers, 1918). Chlorobutanol is inadvisable when it is wished to have the animal recover.

Excised intestines are depressed by chlorobutanol. This may lead to false results in testing epinephrine or pituitary solutions preserved by this drug (G. B. Roth; E. L. Blackman, 1922).

Chloralformamidum (Chloral Formam.) (*Chloralamid*), CCl_3.CH(OH).NH.COH, was introduced by v. Mering, 1889, with the idea that the formamide ($CHONH_2$) would counteract the medullary depression of the chloral. This was not realized; it is merely a less active hypnotic, being probably slowly decomposed into chloral. Sol. in water, freely in alc.

Chloralose, a compound of chloral and glucose, was introduced by Heffter, 1888 and 1893. It is often contaminated with the nonhypnotic but toxic parachloralose (Mosso, 1893). It is used chiefly in physiologic experimentation. Restricted doses paralyze motor and sensory spinal centers without interfering with reflexes (review, M. Kochmann, 1936). It reinforces epinephrine stimulation of the uterus and excised intestine; and decreases response to parasympathetic stimulation; for instance, vagus reflexes, or pilocarpine on intestine or uterus. The blood pressure falls, according to Hamet, 1928, and rises, according to Vincent and Thompson, 1928.

Isopral, trichlorisopropyl alcohol, is over twice as potent as chloral, and its action is prompter. Impens, 1903, claimed that it is safer than chloral, but Sollmann and Hatcher, 1908, showed this claim to be unjustified. Clinically, it is also uncertain and dangerous (Kleinschmidt, 1914).

PARALDEHYDE

Paraldehyde $(CH_3CHO)_3$, a polymer of acetaldehyde, was introduced by Cervello, 1882. Its actions are fundamentally similar to those of alcohol (Kraepelin, 1892), but the hypnotic effect is more powerful, and sets in promptly, so that the patient may be asleep in ten to fifteen minutes. The sleep is normal and, with ordinary doses, without aftereffects. The drug is less certain and less powerful than chloral, but therapeutic doses do not tend to depress the heart and respiration. Its principal disadvantages are the disagreeable pungent taste; fusel-oil odor of the breath, persisting over a day; irritation of the throat and stomach; dizziness and faintness. Tolerance is generally acquired (also by guinea pigs; E. B. Carmichael *et al.*, 1942) and addiction is not infrequent. This presents the phenomena of chronic alcoholism, including delirium tremens (Fornaca and Querelli, 1912; William Hartz, 1912).

Other Aldehydes.—Simple aldehydes are not narcotic, but become so by chlorination (chloral) and by polymerization (paraldehydes), provided that they are soluble in water. Of the polymeric aldehydes from formaldehyde to butylaldehyde, only the paracetaldehyde is practically suitable for narcosis; the others are too toxic, too insoluble, or not sufficiently hypnotic (Knoefel, 1933). Other aliphatic aldehydes are reported to produce arterial disease in rabbits (Denny and Frothingham, 1914). *Acetaldehdye* intravenously produces a pressor response similar to that from epinephrine. The action is peripheral, with marked potentiation by cocaine (E. E. Nelson, 1943).

Indications and Administration.—Paraldehyde is used to *secure sleep*, particularly in delirium tremens (Theunisan, 1915); in the insane; in alternation with other hypnotics. The ordinary dose is 3 cc., raised in severe cases to 5 to 15 cc. or, better, a teaspoonful every hour, until effective. It is best given in iced water, tea or claret. As it acts promptly, the patient should be in bed before the drug is administered. It should not be injected hypodermically, as it is quite irritant.

Slow intravenous injection of 1 cc. of undiluted paraldehyde is advised by I. S. Wechsler, 1940. It generally puts the patient to sleep immediately and stops the convulsions of status epilepticus. It may be repeated when the patient awakens. One would fear intravascular precipitation, but Wechsler states that he has not seen any ill effects.

Paraldehyde may be used for *basal anesthetic*, preparatory to ether, intravenously (0.15 to 0.2 cc. per Kg. of body weight, as 6 to 8 per cent in isotonic dextrose solution, injected in eight to ten minutes; Nitzescu and Iacobovici, 1934) or by rectum (0.5 cc. per Kg. as 10 per cent in normal saline; Foote, 1935; Whigman, 1935). It is reported to be highly effective for *obstetric amnesia*, without producing uterine inertia or fetal apnea, and with a minimum of restlessness. Its toxicity varies widely, however, and death has occurred occasionally from doses within this range.

In parturition, 30 cc. of paraldehyde in 60 cc. of olive oil may be administered by mouth or rectum. Its concentration in the blood reaches 11 to 33 mg. per 100 cc. Amnesia is incomplete below 20 mg. per cent; with the higher concentrations it is complete for about ten hours. The concentration in the fetal blood is about the same as in the mother's (H. L. Gardner *et al.*, 1940). H. F. Kane and Roth, 1936, advise a rectal technic, with a cleansing enema at the beginning of labor, followed by a saline enema, and this by the paraldehyde, 1.2 cc. per 10 pounds of body weight, mixed with 1.5 cc. of benzyl alcohol (regardless of body weight), and followed by 30 cc. of normal saline to diminish local irritation. Proctitis does not occur (H. F. Kane and Roth, 1936).

Metabolism.—Hypnotic doses (in dogs) lower the blood sugar, but have no effect on the nitrogen excretion. Anesthetic doses cause considerable hyperglycemia and glycosuria, and a decrease of nitrogen excretion (Powell, 1914).

The **acute toxicity** of paraldehyde is usually low, so that 100 Gm. generally produce only prolonged sleep; 150 Gm. have been survived, but the susceptibility varies, and the few recorded deaths occurred from moderate doses, 25, 52 and 31 Gm. or cc. by mouth (Kotz *et al.*, 1938), and 12 cc. by rectum (C. L. Burstein, 1943). Formation of large blisters has been reported. Anatomic and histologic lesions were described by P. Schneider, 1929. *The margin of safety* on intravenous injection is narrow in animals. *Autopsy lesions* consist in pulmonary congestion, edema and massive hemorrhage, and dilated right heart (C. L. Burstein, 1943).

Large doses of paraldehyde which lower the systemic blood pressure thereby also lower the cerebrospinal fluid pressure; smaller doses do not affect it (T. H. B. Bedford, 1946).

Fate.—From 70 to 88 per cent of the paraldehyde is destroyed. The destruction is materially decreased in hepatic insufficiency. The unoxidized fraction, 11 to 28 per cent, is excreted chiefly by the lungs; only 0.1 to 2.5 per cent by the urine (H. Levine *et al.*, 1940). *Acetaldehyde* is destroyed four times as rapidly as paraldehyde, and is not affected by liver injury (P. Hitchcock and Nelson, 1943).

Hepatic insufficiency causes a longer and higher blood-concentration curve of paraldehyde, presumably by slowing the destruction. The narcotic effect is therefore increased, although a given level of blood concentration produces the normal narcotic effect.

***Paraldehyde**, U.S.P. $(CH_3CHO)_3$, is a colorless transparent liquid, of strong characteristic odor and burning taste. Sol. in water (1:8), freely miscible with alc. Dose, 2 to 8 cc., ½ to 2 drachms.

ETHYLSULFONE HYPNOTICS

These were introduced by Baumann and Kast, 1888 Sulfonal has the formula $(CH_3)_2.C(SO_2.C_2H_5)_2$. Baumann and Kast believed that the hypnotic action is connected with the ethyl radicals, and is further enhanced by replacing the remaining methyl radicals with ethyl (*trional*, one replaced; *tetronal*, both replaced), but this has not been confirmed (Burger).

Sulfonal, Sulfonmethane, occurs as a white crystalline powder of bitter taste, slightly soluble in water (1:365), freely soluble in boiling water. It is a rather powerful hypnotic, but a weak analgetic. Its absorption and therefore its effects are slow, sleep occurring only after one to five hours, and its administration must be properly timed. The sleep lasts six to eight hours, and the effect persists somewhat during the next day, with vertigo, lassitude, drowsiness and depression. This is due to the delayed excretion, which is even slower than the absorption; thus it tends to cumulative effects and dangerous poisoning, if the administration is continued over longer periods. Sulfonal is therefore unsuitable for prolonged use. It does not induce tolerance, but may probably cause addiction.

The symptoms of *acute poisoning* consist in prolonged and profound sleep, with gradual failure of the circulation and respiration. Death occurs usually after several days. It has been reported from 5 to 30 Gm. (Knaggs, 1890); while 100 Gm. have been survived (Neisser, 1891).

Chronic poisoning has been produced even by ordinary therapeutic doses, when continued for some weeks. The symptoms develop slowly and consist in nervous depression, gastro-intestinal disturbances and urinary changes. The appearance of hematoporphyrin in the urine (dark cherry color) is particularly characteristic. Skin eruptions are sometimes seen. If the drug is stopped when the symptoms are light, recovery occurs, but is slow. After the urine changes have set in, the prognosis is discouraging; death occurs after some weeks by general exhaustion. The autopsy is generally negative. The occurrence of *hematoporphyrin* was described by Stokvis, 1889. It is rarely seen in acute poisoning, but is frequent and fairly early in chronic poisoning. It can be produced in rabbits, but not in dogs (Neubauer, 1900). Hematoporphyrin is also found in the bile (Pfoertner, 1914). With rabbits, hematoporphyrin appears in the urine after four to six days of daily administration of 0.375 Gm. of sulfonal per Kg of body weight. The greater part is excreted as a proporphyrin, which is converted into porphyrin by mineral acids (Laubender and Monden, 1938). There is no evidence of nephritis in rabbits (Polson, 1927).

Urticaria may be produced by local application to the scarified skin (Sollmann, 1917).

Excretion.—Sulfonal is excreted partly as ethylsulfonic acid, partly unchanged, by the urine and intestines.

Administration.—The ordinary doses, 0.75 to 1 Gm., 10 to 15 grains, or in severe cases 2 Gm., are taken in hot milk at least four hours before bedtime. A smaller dose may be taken the second night. The administration should not be continued beyond a week, when an intermission must be made. It is generally advisable to prescribe cathartics, alkalis and plenty of water.

Trional, Sulfonethylmethane, $(CH_3)(C_2H_5)C(SO_2C_2H_5)_2$, is more effective than sulfonal; being more soluble, its absorption and action are prompter, producing sleep in one-half to one hour. It has the same dangers as sulfonal, and the latter is more commonly used. A case of chronic trional poisoning is described by v. Noorden, 1916. Trional occurs as colorless, odorless, crystalline scales; bitter taste. Slightly sol. in water (1:200); sol. in alc. Dose, 0.3 to 1.2 Gm., 5 to 20 grains, as powder.

Tetronal.—Tetronal is less soluble, and therefore slow.

URETHANES

These are derived from urethane (ethyl carbamate), $H_2N.CO.OC_2H_5$. They have been disappointing clinically. The hypnotic action is feeble and patients soon become immune. The efficiency increases with the magnitude of the alkyl radicals (Binet). There is also a decided diuretic effect.

Urethane (Ethyl Carbamate) acts more satisfactorily on animals than on man, producing a rapid and profound narcosis, with little change in the circulation or respiration (Schmiedeberg, 1885). It is therefore employed as a laboratory anesthetic. The CO_2 threshold of the respiratory center is somewhat raised (Wieland, 1915). It decreases the oxygen consumption (Winterstein, 1914). Large doses cause in rabbits a vacuolar degeneration of the hepatic epithelium (Sollmann) and severe damage to the portal veins and sinusoidal capillaries in rats (Doljanski and Rosin, 1944). In mice, repeated urethane anesthesias are often followed by *pulmonary adenomas* (Henshaw and Meyer, 1944). Intraperitoneal injection into rats (0.1 Gm. per 100 Gm.) arrests *mitosis* in the cornea at all stages, not merely in the metaphase as does colchicine. Most of these animals later develop adenomatous lung tumors (M. F. Guyer and Claus, 1947). In a strain of mice, weekly administration produced *anasarca* with glomerular lesions; this does not occur with other strains or in rabbits (T. B. Dunn and Larsen, 1946; A. Kirschbaum and Bell, 1947).

It also lowers the phenol-s.-phthalein output (Whipple and Speed, 1915). Large doses produce *hyperglycemia*, independent of the quantity of liver glycogen and epinephrine, and unaffected by pituitary. Bang, 1914, believed that it acts through pancreatic degeneration. It is excreted as urea.

The pendular movements of *excised intestines* of rabbits are weakened by 0.3 to 2 per cent urethane (Hecht, 1926).

Urethane inhibits the *oxygen uptake* of mammalian tissue, but accelerates it in yeast. The permeability of the *capillaries* is increased (S. M. Landis, 1927). Application to the scarified skin produces a *wheal* (Sollmann, 1917) and dilatation of the capillaries and arterioles (Carrier, 1922).

Urethane, U.S.P. (Ethyl Carbamate), forms colorless, odorless crystals of saline taste. It is very sol. in water (1:0.5) and in alc. (1:0.8). Dose, 1 to 4 Gm., 15 to 60 grains. It is used to *increase the solubility of certain substances*, for instance, quinine hydrochloride.

Hedonal, methyl-propyl-carbinol-urethane, is twice as active as urethane (Dreser, 1899). It has the same general effects, its absorption is relatively slow and it is more toxic. Its dose is about double that of chloral. It has been used intravenously for anesthesia (Page, 1912); a 0.75 per cent solution in normal saline is injected at the rate of 100 cc. per five minutes, reduced to 50 cc. when anesthesia is attained. Its use is dangerous.

Alkoxyethyl Carbamates were reported as to narcotic potency by G. A. Emerson and Abreu, 1938.

CARBAMIDES

These are acylic ureides, with one H of the urea ($H_2N.CO.NH_2$) replaced by an acid radical to give a simple acyl urea, usually with a Br in the acid residue. The principal representatives are carbromal and bromural. They are rather feeble hypnotics and sedatives. Their therapeutic field is similar to that of the bromides, except that they are not used in epilepsy.

Carbromal (Bromdiethylacetylurea, Uradal, Adalin), $C(C_2H_5)_2Br.CONH.CONH_2$.—A white crystalline odorless powder. Very slightly sol. in water (1:3000); sol. in alc. (1:18). It is administered in powder or tablets. The sedative dosage is 0.3 to 0.6 Gm., 5 to 10 grains, three or four times daily; the hypnotic dose is 0.6 to 1.3 Gm., 10 to 20 grains. It is used against nervous insomnia. Poisoning by 15 Gm. was reported by Kirschberg, 1919.

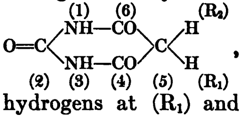
Bromural, monobrom-isovalerianyl-urea, is a prompt but mild hypnotic, effective only in slight nervous insomnias. It is not analgetic, and is rendered ineffective by cough or delirium (v. d. Eeckhout, 1907; Sollmann and Hatcher, 1908). In man, 0.3 to 0.9 Gm. is effective in five to twenty-five minutes, producing a natural sleep lasting three to five hours, without excitement (Krieger and v. d. Velden). It dissolves in hot water, but not in cold.

Sedormid is allyl-isopropyl-acetyl-carbamide. In hypersensitive patients theraputic doses may cause *thrombocytopenic purpura* and temporary inhibition of the maturation of the megakaryocytes in the bone marrow, probably by acting on some platelet-regulating center (S. Moeschlin, 1942; A. M. Hoffmann, Kahn and Fitzgibbon, 1938; McGovern and Wright, 1939).

BARBITURATES

These have largely displaced the older hypnotics and sedatives, as they are effective and ordinarily without serious side actions. They are derivable from urea 
$$O{=}C\langle^{NH_2}_{NH_2}$$

, through malonylurea or barbituric acid



, by replacing both hydrogens at (R_1) and (R_2) with alkyl or aryl groups. Numberless derivatives of this pattern are easily produced, differing chiefly in potency and in rapidity of action. Many of these have been placed on the market since the introduction of diethyl barbituric acid ("veronal," barbital) by Emil Fischer and von Mering, 1903 (review, A. L. Tatum, 1939). Replacement of the CO of the urea by CS leads to a parallel series of hypnotics, the *thiobarbiturates*. Replacement of NH at (1) by CH gives the *pyridine* type of hypnotics, represented by *navigan*. The *hydantoins*, which are used in epilepsy, drop the CO at (6).

Barbituric acid and its substitute derivatives act as weak acids and form soluble salts of alkaline reaction, probably by trans-position into a lactim,  The "acids" are only sparingly soluble in water, but may be dissolved by conversion into the salts, or by addition of diethylamine or urethane. The salts form unstable solutions, decomposing gradually or rapidly with formation of ammonia and other products. Boiling hydrolyzes the solution with precipitation of the free acid, so that sterile solutions can only be prepared by sterilizing the dry acid before solution.

Constitution and Action.—The numerous barbiturates have in general the same actions, and in a therapeutic sense may be considered as different preparations of one substance. They differ in dosage, in duration of action, and somewhat in the breadth of the therapeutic zone (fatal dose: therapeutic dose). The relation of the substituted groups to the degree of pharmacologic action appears complex, as they are determined not only by the solubility coefficient and surface tension, but by the decomposition in the body.

Tatum, 1939, lists the following relations: (*a*) To be effective, both H atoms at (R_1) and (R_2) must be replaced by an alkyl or aryl group. (*b*) Increasing the length of the chains up to five or six carbons increases the potency. (*c*) Branched chains are likely to give briefer action than straight. (*d*) Unsaturated short chains are generally briefer than saturated chains. (*e*) Alkyl groups in ($_1$) and ($_3$) shorten depression and may produce stimulation. (*f*) Replacement of oxygen in ($_2$) by sulfur increases instability and shortens the action. Cyclic groups tend to render the compound inert, and benzyl groups make it convulsive. Tetra-alkyl barbituric acids have brief actions (M. T. Bush and Butler, 1937).

Duration of action is practically the most significant distinction of the barbiturates. The more important compounds (with their substituted groups) may be classified in order of decreasing duration (Gruber, 1941) as:

Long:

Phenobarbital = ethyl-phenyl
Barbital = ethyl-ethyl

Intermediate:

Neonal = ethyl-n-butyl
Dial = allyl-allyl
Ipral = ethyl-isopropyl
Alurate = allyl-isopropyl
Nostal = β-bromallyl-isopropyl
Amytal = ethyl-isoamyl
Sandoptal = allyl-isobutyl

Short:

Pentobarbital = ethyl-1-methylbutyl
Phanodorn = ethyl-cyclohexenyl
Ortal = ethyl-n-hexyl

Ultrashort:

Seconal = allyl-1-methylbutyl
Evipal = methyl-cyclohexenyl
Thiopental (Pentothal) = ethyl-1-methyl-butyl-2 thio.

A posological table for animals is furnished by Tatum, 1939.

Fate.—The excretion of the barbiturates occurs practically exclusively by the urine; the feces contain only traces. In the urine they occur partly unchanged (microscopic identification, O. Ehrismann and Joachimoglu, 1928), partly more or less split (J. Halberkann and Reiche, 1927), or conjugated with sulfuric acid or metabolized to urea (Stakol and Cerecedo, 1933). A part may disappear completely, probably by oxidation. The fate varies materially for the various derivatives, and these differences are chiefly responsible for the varying duration of the action (M. Reinert, 1928) which determines the therapeutic scope of these drugs; differences in the speed of absorption also play a part (Fitch, 1931). The shortest acting barbiturates are generally easily oxidized (Weese, 1936). Thiobarbiturates are destroyed rapidly.

Destruction in the Body.—Barbital and phenobarbital are the only barbiturates that appear consistently in the urine with ordinary therapeutic doses; the others only if the dosage is heavy (Herwick, 1931; Shonle, Keltsch *et al.*, 1933).

The site of detoxication, as judged by duration after excision of kidneys, or partial excision of liver (Masson and Belano, 1944), is chiefly in the *kidneys* with barbital; in the *liver* with amytal, evipal, ipral, pentobarbital, seconal, and most of the others; about *equally in liver and kidneys*, with dial, neonal and phanodorn; *chiefly in other tissues* with thiobarbiturates. Injury of the *liver*, for instance by chloroform, prolongs the action of the brief duration barbiturates (Pratt, 1933). *Ascorbic acid deficiency* impairs the production of enzymes connected with the destruction of the pentobarbital series, but not of barbital or of the thiobarbiturates (Kueter *et al.*, 1941; R. K. Richards *et al.*, 1941).

The "*biuret reaction*," under conditions which exclude confusion with others, is given by all barbiturates, but not by their decomposition products. It is a convenient qualitative and quantitative test if conditions are modified to exclude confusion with other biuret-reacting substances. Such tests are described by Herwick, 1934; Koppanyi, Murphy *et al.*, 1934; Brundage and Gruber, 1936. The urine must be examined promptly, as barbituric acid decomposes markedly on standing twenty-four hours (Ashe and Agricola, 1935).

Quantitative Urinary Excretion of Barbital (di-ethyl barbituric acid).—Clinically, 70 to 90 per cent can be recovered from the urine within a week (Koppanyi *et al.*, 1934); but the excretion is slow: for instance, 8 per cent in twelve hours, 20 per cent in a day, 36 per cent in two days; and traces are present for nine days (F. Reiche, 1926; Reinert, 1928). This slow excretion may give rise to cumulative action. The percentage excretion is not altered by habituation. The excretion is more prolonged with continued administration; a single dose of 0.3 Gm. required three days for elimination, but seven days were required after the same dosage had been continued daily for seven days. *Nephritic* patients require longer, six to eleven days; nephrosis, however, only the normal time (Arakawa, 1935; Argy *et al.*, 1936). In rabbits, the excretion is delayed by glomerular, but not by tubular, poisons, indicating that the excretion occurs in the glomeruli (Arakawa, 1935). With dogs, the normal excretion (74 to 82 per cent in seven to eight days) is increased by *theobromine* to 90 to 95 per cent in five days (Frostig and Engelberg, 1933). The rate and extent of its excretion vary in different kinds of animals: Rabbits excrete only half, dogs and cats relatively more (Koppanyi, Dille and Krop, 1934).

Excretion of barbiturate into breast milk can be demonstrated, but the quantity is generally too small to affect the nursling (Tyson *et al.*, 1938).

Placental Transmission with Soporific Doses.—Traces of barbiturate may be demonstrated in the amniotic fluid, placenta and fetus of rabbits receiving sodium barbital (Dille, 1936).

The *distribution in the body* was studied by G. Coronedi, 1928, for different compounds, as also their absorption and excretion. Data on the organ content in clinical poisoning and in rabbits are given by M. A. Jazzi-Mancini, 1923. Koppanyi, Murphy and Krop, 1934, found the barbiturate content highest in the liver, skeletal muscle and kidneys. The brain concentration was not high. The concentration in the blood corpuscles was a third that of the plasma. Kozelka, Tatum and Nelson, 1938, report that the ratio shifts with time. Ehrismann, 1928, reported on the concentration of barbiturates and ureid hypnotics in various *parts of the brain* by a sublimation method.

Therapeutic Uses.—The sedative action of the barbiturates is used to secure sleep, to dull worry and apprehension, and to calm nervousness and obtain tranquillity and rest in conditions ranging from "overwrought nerves" through drug addictions, hyperthyroidism, mania, chorea and epilepsy; the narcotic action is used to produce partial or complete unconsciousness in anesthesia, amnesia in parturition; and a hypnotic state suitable for psychiatric analysis. The effects can be readily graded in intensity by dosage, and in duration by the selection of the appropriate barbiturate. The barbituric acids may be administered by mouth as capsules; the sodium salts may be dispensed as capsules or powders, and dissolved in hot water, milk or a little tea. Administration by hypodermic and intravenous injection is especially important in obstreperous and maniacal patients (see, for instance, Blackwenn, 1930). With some patients considerable excitement precedes the sedative effect. Man is two or three times more susceptible than animals to the barbiturates, but there are marked individual variations to the identical dose, depending upon the nervous state: sensory and motor excitement require larger doses than depressed states (S. Weiss, 1929).

Advantages of the Barbiturates.—The effect is prompt, securing dreamless sleep in twenty to thirty minutes after oral administration, and immediately with intravenous injection. Even full anesthetic dosage produces little if any disturbance of other functions; the respiration, circulation, metabolism and the smooth muscles remain quite or practically normal until the fatal dosage is approached. There is no serious local irritation, so that the drugs may be administered by all channels, by mouth or rectum, hypodermically or by vein. There is no dangerous cumulation, and practically no habituation, no need for increase of dosage, and relatively small liability of addiction, beyond that entailed by the desire for easy sleep. The *disadvantages* are that the response is rather variable, markedly so in some individuals. The hypnotic effect is often preceded by considerable excitement, inebriation and even delirium; and the sleep and hebetude may be undesirably prolonged. Collapse occurs exceptionally. Severe cholera-like diarrhea has been reported. In some individuals, the barbiturates produce marked *skin reactions*, resembling urticaria, purpura, measles or scarlatina (Luce and Feigl, 1918). Moderate therapeutic doses of phenobarbital may aggravate the rigidity of parkinsonian conditions and are therefore contraindicated in this complex (Ziskind and Ziskind, 1937).

The *location of the central depression* is in the cerebral cortex and probably also in the subcortical ganglia (E. and J. Keeser, 1927), especially the hypothalamic portion of the diencephalon. Electroencephalogram effects of intravenous injection are described by Brazier and Finesinger, 1945. The bulbo-spinal reflexes are little affected (Pearcy and Weaver, 1927).

Use as Somnifacient.—The hypnotic dosage of barbital or phenobarbital, or their sodium salt, at bedtime, generally insures a natural, dreamless sleep, beginning in twenty to thirty minutes and lasting six to eight hours. The patient awakens refreshed, but may not be so alert as usual, and some lassitude persists during the day. With the other barbiturates, the duration of the sleep and of the after-inertia is shorter. Most subjects soon learn to compensate against the depression. Sodium barbital and phenobarbital are adequate for most somnifacient indications. With pentobarbital, the total action lasts only three to six hours, which is often too brief. The ordinary *hypnotic dosage*, taken half an hour to an hour before sleep is desired, is: barbital, 0.5 Gm.; phenobarbital, 0.03 Gm.; dial, 0.1 to 0.3 Gm.; ipral, 0.12 to 0.25 Gm; neonal, 0.05 to 0.1 Gm.; phanodorn, 0.1 to 0.3 Gm.; amytal, 0.1 to 0.3 Gm.; pentobarbital, 0.1 to 0.2 Gm.

Analgetic Action.—Ordinary hypnotic doses are analgetic to a rather limited degree. They have no effect on sensations other than pain (Wikler *et al.*, 1945). In normal men, the sensory irritability to faradic stimulation appears somewhat depressed (Hale and Grabfield, 1923). Clinically, satisfactory relief has been reported in severe burns, and in syphilitic gastric crises, by pentobarbital, 0.5 to 0.8 Gm. (Lundy, 1929). Migraine and other paroxysmal and recurrent *headaches* respond fairly well to phenobarbital, 0.03 to 0.045 Gm., three times daily; it may be necessary to continue the medication over long periods (Harris, 1922). In the treatment of headaches, and neuralgic and neuritic pain, the barbiturates are often prescribed together with the antipyretic analgetics. *Mixtures with aminopyrine* have been exploited under coined names, "veramon" or "peralga" with barbital; "allonal" with allyl-isopropyl barbituric acid. Their use has diminished greatly since it became recognized that they were the most frequent source of fatal aminopyrine neutropenia. Sedative doses of any barbiturate, or indeed any other hypnotic, may be prescribed extemporaneously, with analgetic doses of any antipyretic analgetic, including salicylates, acetophenetidin, and the like. Although objective clinical experiments are difficult to devise, it may be presumed that the tranquilizing effect of the hypnotics renders the patient more amenable to the analgetic action of the antipyretics, so as to constitute a kind of potentiation. Experiments on animals indicate summation of the narcotic, sedative, hypnotic as well as analgetic effects, and antagonism of the acute toxicity; *i. e.*, of the convulsant action of the antipyretics by the sedative action of the hypnotics. The details are complex, and the transfer of the animal data to the clinic is problematical (Kaer and Loewe, 1928; Starkenstein, 1925).

Use as Sedative.—This field is similar to that of the bromides, but the barbiturates act much more promptly, are less subject to untoward actions, and may be pushed to more profound effects. Skin eruptions occur only in especially susceptible individuals. In temperamental excitability or in emotional stress, barbiturates should be avoided, for fear of habituation. Sudden withdrawal of sedation sometimes leads to convulsions. They are useful in *toxic goiters* to lower the nervous excitability, the muscular activity and the basal metabolism; they allay the apprehension, and reduce the risk of operation (Rowley, 1921). They delay, more than ether, shock from exposure and manipulation of the intestines, but not hemorrhage shock (H. K. Beecher *et al.*, 1942). The barbiturates have been used successfully against the nervous *vomiting of pregnancy*, especially phenobarbital, 0.06 to 0.12 Gm., an hour before each meal and at bedtime, or hypodermically every four hours (Linkart, 1923; Miller, 1924). *Infantile pylorospasm*, pyloric stenosis and severe colic have been treated successfully with 0.008 to 0.015 Gm. of phenobarbital, crushed and given before or with each cereal feeding (Barnett, 1930). The usual *sedative doses* of the barbiturates are as follows, repeated at intervals of four to six hours, if needed: barbital, 0.1 to 0.15 Gm.; phenobarbital, 0.015 to 0.1 Gm.; amytal or pentobarbital, 0.02 to 0.04 Gm. Larger doses may be used if the patient is under close medical supervision; for instance, sodium amytal, to 0.2 Gm. every six hours or 0.4 Gm. every twelve hours. Barbiturates of brief duration are less suitable for sedation.

Considerably larger doses may be needed in *maniacal conditions*, in delirium tremens and in morphine withdrawal: phenobarbital, 0.6 Gm.; amytal, 0.4 to 0.8 Gm.; pentobarbital, 0.25 to 0.5 Gm. There may be some risk in repeating the larger doses within twenty-four hours. Sodium amytal or pentobarbital may be administered intravenously in these doses to delirious or maniacal patients. This has the advantage that the dosage can be adjusted to the response (C. B. Wilbur, 1944). Prolonged deep narcosis by sodium amytal has been used successfully in combat neurosis (Erb and Bond, 1945). M. M. Harris *et al.*, 1939, report transient amelioration in most schizophrenic patients who are subsequently benefited by insulin, indicating some prognostic significance. Sodium amytal, 0.25 to 0.5 Gm. hypodermically or by vein, may be used to break down the refusal of food by schizophrenic and other psychiatric patients; they often eat spontaneously immediately after the injection (Foley and Rossignoli, 1937).

Use in Epilepsy.—Barbiturates diminish the number and severity of the attacks, especially of the motor type, and thus indirectly improve the mental and physical condition of the patient. The improvement persists only during the medication. Acute attacks are controlled more efficiently than chronic or mild seizures (Grinker, 1922): idiopathic and traumatic epilepsies are more amenable than the senile and syphilitic. The effects and the efficiency are about the same as with bromides or dilantin, but one may succeed when the other has become ineffective. Combined medication with phenobarbital and dilantin is far more effective than either alone (B. Cohen *et al.*, 1940). Bromide may be added to phenobarbital to reduce the dosage of both (I. A. Darling, 1923). The barbiturates have several advantages over bromide in that the improvement is more rapid, and the undesirable side actions are less; they avoid the progressive psychoses of bromide, and the acne, fetid breath and dietary restriction. *Phenobarbital*, the first barbiturate to be introduced for this purpose (by A. A. Friedlander, 1912, and by A. Hauptmann, 1912), appears to be more active than other hypnotics, although these are somewhat effective (van Wert, 1920). It is not subject to serious idiosyncrasies, and does not appear to produce mental deterioration, even when 0.2 to 0.3 Gm. has been taken daily for two years (Somerfeld-Ziskind and Ziskind, 1940). The antiepileptic effect is not caused by the hypnotic action, for it is obtained undiminished when the phenobarbital is given with sufficient amphetamine sulfate (5 to 20 mg. by mouth) to prevent the hebetude and drowsiness (B. Cohen and Myerson, 1938; L. J. Robinson, 1941). The initial dosage of phenobarbital is 0.1 to 0.15 Gm. at night; increased by an additional dose in the afternoon and morning, if necessary, until increase of the dose does not further improve the condition. This averages about 0.2 Gm. (3 grains) per day, but ranges from 0.065 to 0.5 Gm. per day. Up to 0.7 Gm. (11 grains) per day may safely be taken over prolonged periods. It does not produce tolerance or addiction in epileptic patients. Severe attacks may be controlled immediately by intravenous injection of sodium phenobarbital (B. Cohen, Showstack and Myerson, 1940; L. J. Robinson and Osgood, 1940; W. G. Lennox, 1940).

Anticonvulsant Action.—The barbiturates may be used clinically as well as experimentally to suppress most if not all varieties of convulsions of central origin: traumatic tetanus (R. Spaeth, 1940), strychnine poisoning, meningitis, chorea, status epilepticus, tetany, eclampsia, cocaine poisoning, insulin overdosage. They are effective against convulsions induced experimentally from all central locations, the cerebrum, medulla or spinal cord (E. E. Stranson, 1932). They are highly successful against strychnine convulsions, good against metrazol, picrotoxin and coramine. They are also successful against cocaine convulsions. Their efficiency in developed cocaine poisoning depends on whether this takes the form of convulsions or of collapse.

Phenobarbital may be used prophylactically before local anesthesia, especially in hypersensitive subjects. Pentobarbital is the most potent of the commonly used convulsant antidotes; but amytal, avertin and chloral are also effective (Barlow *et al.*). The *anticonvulsant dosage* for pentobarbital is 0.25 to 0.5 Gm.; amytal, 0.4 to 0.8 Gm.; pernoston, 2 to 6 cc. of 10 per cent solution. The administration should be by slow intravenous injection. Relaxation and hypnosis occur in forty-five to ninety seconds. In the persistent convulsive states the dosage is repeated, by mouth, when the action wears off. Patients should not be kept continuously unconscious for more than twenty-four hours; if a longer action is necessary, the patient should be allowed to recover consciousness between the convulsions. In chorea and tetany the administration is as with epilepsy.

The antagonism of barbiturates against *acute cocaine poisoning* and other local anesthetic drugs was shown on dogs and monkeys by Tatum and Collins, 1925. Sulfonal and trional are also effective (Mendola, 1927). Not only are the convulsions suppressed, but the respiratory depression is decreased, and the minimal fatal dose is materially increased. Similar observations have been made on man (Guttman, 1926).

Antagonism to Insulin Convulsions.—Although the barbiturates have little effect on the insulin hypoglycemia, they suppress insulin convulsions and raise the fatal dose materially (I. H. Page, 1923; E. L. Jackson, 1931). Insulin or epinephrine administration before evipal *prolongs the sleep*, as compared with control mice (J. F. Reinhard, 1945).

Efficacy against Electric Convulsions in Cats.—Convulsions produced by the passage of an alternating current through the brain form a convenient means of testing the efficacy of anticonvulsants. Sodium bromide, 2 Gm., a dosage sufficient to prevent the cat from walking, raised the convulsant threshold by only one-half. Phenobarbital, 0.1 Gm., a dosage producing similar symptoms, raised the threshold to three or four times the normal. Comparable doses of other barbiturates had little anticonvulsant action. The highest ratio of anticonvulsant: hypnotic potency occurred with diphenylhydantoin, acetophenone and benzophenone (Putnam and Merritt, 1937). The *chronaxia of the nervous centers* is increased by barbiturates, decreased by strychnine, with mutual antagonism (Chauchard, 1934).

Barbiturates in Anesthesia.—Since the central effects of the barbiturates do not differ in principle from those of other aliphatic narcotics, they may be used alone, or in combination, to secure general anesthesia (Fredet and Perlis, 1924); or as premedication to anesthesia (Brumm, 1927); or for obstetric amnesia (Drabkin *et al.*, 1929). The chief difference from ether lies in their nonvolatility; they cannot, of course, be administered by inhalation; only by mouth, rectum, hypodermically, or by vein. The nonvolatility also precludes their excretion by the lungs and entails a more prolonged and continuous action. This secures steadiness of anesthesia, but restricts flexibility if the effect is too profound, as may easily happen, since the individual response varies considerably. This is especially serious, as deep barbiturate narcosis suppresses the response of the respiratory center to carbon dioxide so completely that breathing is continued only by the much less sensitive stimulation of anoxemia (E. K. Marshall and Rosenfeld, 1936; Y. Henderson, 1940). Safety can only be insured by doses which require to be supplemented by volatile anesthetics; or by adjusting the rate of intravenous injection to the effect, which is difficult since the full effect does not occur immediately. The duration of the postanesthetic stupor is also a serious objection to full anesthesia by barbiturates except for those of ultra brief action. *Barbiturates in conjunction with inhalation anesthesia* are a definite accession to anesthetic technic. They may be administered simply to assure sleep on the night preceding the operation; to tranquilize the patient, to remove nervousness and apprehension, and to secure smoother induction; or finally, to take a share in the anesthesia itself.

Laboratory Anesthesia.—Barbiturate anesthesia is used increasingly in laboratory technic, often supplemented by morphine and ether to maintain more constant conditions than is practical with inhalation anesthesia. As compared with other fixed dose anesthetics, they cause less disturbance of the circulation and respiration, of the reflexes, of the gastro-intestinal tract and of the blood sugar level; the recovery is much better. The duration of the coma is from three to five hours for pentobarbital and pernoston; twenty-four to thirty-six hours for barbital (Barlow, 1930). The barbiturates were originally administered by stomach tube, but they are now ordinarily given hypodermically or intraperitoneally (M. G. Mulinos, 1928) or, best, intravenously (Page and Coryllos, 1927). Rectal injection of pentobarbital is the most successful method of anesthetizing *chimpanzees* (J. H. Elder, 1937).

Preliminary Tranquilization.—In this field the barbiturates compete with morphine, and their action may be graded through a much wider scale, but perferably so that the patient is actually in a normal sleep when the inhalation is started. In emergencies, such as painful accidents or cesarean section, this sleep may be secured immediately by intravenous injection. In *local anesthesia*, the barbiturates have the additional advantage of being prophylactic against cocaine or procaine convulsions. Pentobarbital sodium, 0.2 Gm., 3 grains, by mouth, one and one-half to two and one-half hours before lumbar puncture, diminishes the pain and promotes the cooperation of the patient (S. H. Epstein and Marvin, 1932). Morphine is often added to enhance the sedative action, before and during the operation, diminishing the after-pain, and lessening the tendency to excitement during recovery from the anesthetic. It materially prolongs the depressant action (Lundy, 1930). It is inadvisable to use morphine with pernoston, because the additional depression of respiration may become dangerous.

Qualitative changes in the pernoston actions occur in mice if other drugs are added: with morphine, a characteristic posture of the hind legs develops, with abduction of the thigh and extreme flexion of the knee and hip; with benzedrine (as little as 0.05 mg.) there are fits of convulsive jumping; with coramine or metrazol, seminal ejaculation occurs (S. Loewe, 1938).

For basal anesthesia, with dosages that give the barbiturates a more or less equal share in the anesthesia, they diminish correspondingly the amount of the inhalation agent, and therefore diminish the undesirable side actions. The induction is tranquil, even more so than after morphine; the blood pressure, heart and respiration remain more nearly normal than with any other anesthesia (except for the tendency to respiratory depression with pernoston). Nitrous oxide is potentiated, so that surgical anesthesia may be maintained with an 80:20 mixture, allowing sufficient oxygen to prevent anoxia and to secure adequate relaxation. The reduction in the ether helps to prevent vomiting and postanesthetic nausea. The long sleep and amnesia after the operation ease the ordeal for the patient; those who have been subjected to several anesthesias generally prefer the barbiturate and nitrous oxide or ether sequence. The chief disadvantage of barbiturates consists in the varying susceptibility to the depression, particularly in occasional excitement; and in the duration of the postanesthetic stupor. When this is not too prolonged, it may be a positive advantage by resting the patient, as with pentobarbital, but it limits the use of barbital and phenobarbital; amytal and pernoston are intermediate.

Choice of Preparations.—This involves chiefly the duration of the effects; toxicity, *i. e.*, the margin between the therapeutic and fatal dose; and the personal experience of the physician with the drug. This last is an important element, and it is better to intensify one's experience by confining it to the agents which offer substantial advantages. Of these, the duration of action is clinically more important than the margin of safety, since the differences in the latter are not sufficiently large to appear practically important.

The experimental and clinical data as to the *duration of narcosis* vary considerably for want of a sharp end point, especially when comparing the results of different investigators. The dosage is an important factor. Fitch and Tatum, 1932, used 60 per cent of that dose which was fatal to 50 per cent of the animals. J. Pinkhof, 1930, employed a more complicated procedure, involving chiefly the time when half of the original dose must be injected to reproduce the original depth of anesthesia (a light narcosis). The *temperature of the room* has considerable effect on the response of mice (Raventos, 1938); these also show some seasonal variations of susceptibility to the somnifacient action and in the duration of anesthesia, but not in the toxicity (De Beer *et al.*, 1939). *Repetition* of dial anesthesia in dogs shortened the duration of the narcosis from eight hours to one hour; with phenobarbital anesthesia, repetition had little effect on the duration (G. H. Ettinger, 1938).

Procedure for Basal Anesthesia.—The administration of the barbiturate is begun on the evening preceding the operation, to insure rest. If pentobarbital sodium is chosen, this is given in capsules, 0.1 Gm. (1½ grains). A second dose of 0.1 to 0.2 Gm. (1½ to 3 grains) is given two hours before the operation, and repeated an hour before the operation. If sodium amytal is used, these doses are doubled. The last dose is generally accompanied by 10 mg. (⅙ grain) of morphine, and 0.4 mg. (1/150 grain) of atropine, hypodermically (Barlow, Fife and Hodgkins, 1934). The amount of the barbiturate should not produce deep narcosis, to avoid respiratory depression, especially if ether is used to complete the anesthesia (Lundy, 1932). The morphine dosage should be somewhat less than if barbiturate were not given; and barbiturates should not be used after large doses of morphine.

Effects of the Preanesthetic Dosage.—In the series of Barlow, Fife and Hodgins, 1934, about a fourth of the patients were asleep on arrival at the *operating room;* most of the others were drowsy; a few were inebriated, but were quickly calmed by nitrous oxide analgesia. The respiration was generally unchanged in rate, slightly reduced in depth, as by sleep. The pulse rate and blood pressure were generally practically unchanged. About a fifth of the patients had some conjunctival congestion, resembling that produced by alcohol, lasting about an hour. The *induction of surgical anesthesia with nitrous oxide:oxygen* was completed in three to six minutes. It was easily established and maintained, with a wider margin of safety. Respiratory depression occurred only if the dosage of pentobarbital exceeded 0.4 Gm. on the operative days. The *postoperative sleep* varied widely in duration, from a few minutes to ten hours, depending largely on personal factors and on the nature and duration of the anesthesia. The patient should lie on his side during the sleep, to prevent obstruction of the airway by the tongue. After the return of consciousness, the patient remains drowsy and sleeps much for a day or two; after amytal, there may be amnesia during this period (Zerfas and McCallum, 1929). *Postoperative restlessness and excitement,* tossing and incoherent talking, occurred in nearly a third of the patients, depending chiefly on their personality. It is generally inverse to the duration of the postoperative sleep, and can usually be controlled by small doses of morphine. *Nausea and vomiting* depend entirely on the supplementary anesthetic; they do not occur with local anesthesia. The *urine output* is decreased proportional to the water intake. Albumin is present in less than 4 per cent. Casts are rare.

Obstetric Amnesia.—This aims to induce a condition in which the patient is not actually unconscious, but is tranquilized and drowsy, so that she drops to sleep between pains, and the pains, although of undiminished force, are but little felt and not remembered. Morphine may be omitted or reduced to half. The uterine contractions are not weakened, even by fairly large doses (Dodek, 1932), and the better cooperation tends actually to shorten labor. The circulation, respiration and temperature remain normal, the babies are not notably narcotized and breathe promptly (Robbins *et al.*, 1925; Galloway *et al.*, 1936). However, some patients develop marked restlessness, and constant supervision of both mother and baby is essential. C. O. McCormick, 1932, reported that pentobarbital produces less delirium, greater amnesia and less protracted sleep than does amytal.

J. M. Dille, 1934, found the concentration of *barbiturate in the fetus* considerably higher than that of the mother's blood, uterus, placenta and amniotic fluid. Y. Henderson, 1937, warns that the dosage should be adjusted so that the barbiturate action has virtually ended before the third stage of labor is reached, since it would interfere with the carbon-dioxide response which normally initiates the respiration of the infant. Complete anesthesia of pregnant cats with pentobarbital profoundly narcotizes the fetus, so that most of these die within two hours. In rabbits, it appeared rather to increase the resistance of the newborn to asphyxia (F. F. Snyder, 1946).

Dosage for Obstetric Amnesia.—Pentobarbital sodium, 0.1 to 0.2 Gm. (1½ to 3 grains), or double this amount of sodium amytal, is administered when the patient is definitely in labor, with regular pains and beginning dilatation of the cervix. These doses may be repeated at intervals as needed, but the total should not exceed 0.5 Gm. (7½ grains) of pentobarbital or 1 Gm. of amytal (except against eclamptic convulsions). Barbiturates may also be used with scopolamine (O. S. Krebs *et al.*, 1936; P. P. Volpitto, 1946) and with the Gwathmey rectal anesthesia mixtures.

Barbiturate Narco-Diagnosis.—The inebriation grade of narcosis facilitates psychic control and renders the patient responsive to questioning, analogous to the "hypnotic state." This is utilized in the analysis of psychoses and in the treatment of schizophrenic patients. The brief-acting barbiturates are best suited to this purpose (Tatum, 1939; J. S. Horsley, 1943; Oxford University Press).

The inception and development of narco-diagnosis is sketched by H. K. Beecher, 1947; its present status is discussed by P. H. Hoch, 1946.

Thiopental (pentothal) sodium is most widely used, injecting 0.25 Gm. slowly by vein (R. G. Grinker, 1944). W. L. Hart *et al.*, 1945, prefer sodium amytal as giving a longer period for questioning; they inject a solution of 1 Gm. in 30 cc. of water at the rate of 0.06 Gm. or less per minute. At the end of the interview they inject 0.5 Gm. of caffeine-sodium benzoate hypodermically to facilitate return of awareness. Narco-analysis may also be practiced with *nitrous oxide inhalation* (C. H. Rogerson, 1944) and with *scopolamine;* but the greater tendency of the latter to produce delirium makes it undesirable.

Surgical anesthesia by intravenous barbiturates is convenient for brief operations, but is subject to serious risks. The pentothal death rate in the U. S. Army was about 1:5500. It is not suitable for office practice. It calls for special experience, rigid technic, and preparedness to deal with respiratory depression and oxygen: carbon dioxide imbalance, to which it is especially liable. It should be confined to the barbiturates with ultrashort duration: evipal, seconal and pentothal, preferably the last because it is briefest (R. C. Adams, 1944).

Intravenous barbiturate anesthesia is particularly dangerous in morphine overdosage, shock, liver damage, myocardial degeneration and in operations that interfere with the airway; it is not satisfactory for most abdominal operations or where highly excitable reflexes are involved.

Thiopental (Pentothal) Intravenous Dosage.—An injection of 4 to 6 cc. of fresh 2.5 per cent thiopental sodium solution (corresponding to 0.1 to 0.15 Gm.) is made in ten to fifteen seconds. This generally puts the patient to sleep. The injection is stopped for thirty to thirty-five seconds to permit the development of the full effect, and is then resumed at the rate of 4 to 8 cc. in one to three minutes, to a total of 14 to 25 cc. (0.35 to 0.625 Gm.), before starting the surgery. Relaxation need not be complete. The respiration is shallow, abdominal, with slight to moderate cyanosis. It is advisable to administer oxygen throughout the operation. Thiopental is rapidly destroyed in the body, so that it may be repeated as needed. Half of the usual dosage suffices for patients in shock, with or without hemorrhage (H. B. C. Sandiford, 1944). Debilitated and toxemic patients have a lowered tolerance.

Parenteral administration of barbiturates should be confined to direct anesthesia and pressing emergenices. Otherwise, oral administration should always be chosen, for safety, although the slower absorption entails the disadvantages of greater variability of response and longer duration of excitement.

Rectal and hypodermic injections are not often used, since the alkaline solutions are irritant. With intramuscular administration of the more potent barbiturates, the local irritation is usually slight (because of the smaller dosage), and there is less risk than with intravenous injection. The intramuscular dosage of sodium amytal is 0.1 to 0.5 Gm. (1½ to 7½ grains), as 10 per cent solution, and not more than 5 cc. should be injected at one site. *Intraperitoneal injection* is used in animal experiments, but necrotic ulcers may result if the injection should lodge in the walls of the stomach or intestines (Kistler, 1933).

Intravenous injection offers the tempting advantage of immediate effect and better control of immediate dosage. This, however, holds only for the more rapidly acting barbiturates. With barbital or pentobarbital there is an unexplained delay, up to twenty minutes, until the action is fully developed (T. Koppanyi, 1945; Kepmesch, 1933), so that there is danger of underestimating the eventual depression by the immediate response, and unless the injection is made slowly there may be an alarming fall of blood pressure to shock level, but usually of short duration. This is probably due to precipitation of the barbituric acids on contact of the strong solutions with the blood. It may be minimized by alkalizing the solutions with a buffer, but best by injecting slowly.

Sloughing may result if the strongly alkaline solution escapes into the subcutaneous tissue. In such an event, the site should be infiltrated with procaine hydrochloride solution (1 per cent in isotonic saline), which presumably acts as a buffer (Elder and Harrison, 1944).

Intravenous barbiturate anesthesia of experimental animals is convenient for avoiding abrupt changes in the anesthesia, with their disturbance of the circulation and respiration (C. J. Wiggers, 1942). Dogs receive a hypodermic injection of morphine sulfate, 3 mg. per Kg. In half an hour about two-thirds of the calculated anesthetic dose of the barbiturate (for barbital sodium, 175 mg. per Kg.) is injected into a leg vein during five minutes. The remainder is injected more and more slowly until the animal just fails to respond to cutaneous stimulation. The corneal and tendon reflexes are exaggerated.

Thiobarbiturates have the urea-oxygen of barbiturates replaced by sulfur. Their action is generally similar, but much shorter, since they undergo rapid *destruction* in the body, an hour being the maximum in dogs. They are more potent than the corresponding barbiturates, and larger doses cause injury of the liver, kidneys and brain (Gruhzit *et al.*, 1937); but these do not occur clinically (Tabern and Volwiler, 1935; Pratt, Tatum *et al.*, 1936; C. M. Gruber, 1937). Intravenous pentothal anesthesia has been discussed above.

Evipal, n-methyl cyclohexenylmethyl barbiturate of sodium (hexobarbital, evipan), was introduced especially for intravenous anesthesia, as its action is brief. It is destroyed in the liver, only 1.2 to 4.5 per cent appearing in the urine, in man. However, a number of deaths by depression of both respiration and circulation have been reported, and it must be used with discrimination. It may be employed with fair safety in a relatively narrow field, for analgesia, for induction and for brief anesthesia. It is generally aimed to produce merely inebriation, where mentality is confused and the consciousness of pain is lost. It has been employed especially in obstetrics (report of Council on Pharmacy and Chemistry, 1937, J.A.M.A., *108*). Consciousness returns in fifteen to thirty minutes, with the usual *dosage* of 2 to 4 cc. of fresh 10 per cent solution, injected at the rate of 1 cc. per ten seconds. It is dangerous to exceed a total of 10 cc.

Pharmacologic data for a variety of animals were reported by W. P. Kennedy, 1934. The dosage for full anesthesia is about 30 mg. per Kg. for cats, 35 mg. per Kg. for dogs. The M.F.D. is 100 to 110 mg. per Kg. The blood pressure generally falls, regardless of the rate of injection or the reaction of the solution. The fall is explained partly by peripheral vasodilatation, partly by cardiac depression (S. C. Daas, 1941). The hypnotic action is materially potentiated by acetylsalicylic acid, aminopyrine, demerol and morphine (Barlow *et al.*, 1942). The narcosis is prolonged by epinephrine, but not by insulin (J. F. Reinhard, 1945). Dallemagne claimed production of *profound anemia* in dogs, but Beecher, 1938, found no blood changes even when a dog was anesthetized twenty-two times with weekly intervals.

Seconal and sodium amytal are also administered intravenously, although their chief use is oral.

One gram of *seconal* intravenously in humans produces complete surgical anesthesia for one hour; the return to consciousness is complete in six to seven hours.

Sodium amytal is used as 10 per cent solution, freshly prepared within half an hour of its use from the anhydrous (not the ordinary) salt. This should not be injected faster than 1 cc. per minute. The single dose usually need not exceed 0.5 to 0.6 Gm. and should never be more than 1 Gm. The patient becomes drowsy when 0.1 to 0.2 Gm. has been injected. The speech becomes slurred, and at 0.35 Gm. sleep sets in, perhaps in the middle of a word. When the dosage exceeds 0.6 Gm., the anesthesia becomes profound: the pupils are contracted, fixed, sometimes irresponsive to light; the corneal reflex is diminished; the gagging reflex is usually present, the knee jerk exaggerated (Mason and Baker, 1930). With 0.65 to 1 Gm. of amytal the patient stays unconscious for one to six hours, sometimes longer, and then remains drowsy and sleeps at intervals, but cooperates in taking food and fluids. Restlessness may occur in the post-anesthetic period, and can generally be controlled by morphine.

The *pernoston* technic is exclusively intravenous. The maximal dose is set at 1 cc. of the 10 per cent aqueous solution per 12½ Kg. of body weight, *i. e.*, a total of 0.3 to 0.8 Gm. The injection is begun about fifteen minutes before the operation, and stopped as soon as the patient drops asleep, so that only a part of the dose may be required. The inhalation anesthetic is then administered. It is not advisable to give morphine with pernoston.

Side Actions of Barbiturates.—A considerable inconvenience of the barbiturates is the marked *variations of the central response* with different individuals, including delayed effects, extreme depression, excitement, even mania. These clear up eventually, but are seriously objectionable while they last (Bourne, 1934).

Relative Excitant Action of Various Barbiturates.—With trained dogs, Quigley, Barlow and Himmelsbach, 1934, found psychic excitement and restlessness more frequent with amytal than with barbital, and less frequent with pentobarbital than with either of the others. They also found it more frequent with small than with moderate doses. 5,5(1,3 *dimethyl-butyl*), *ethyl barbituric acid* is not depressant, but purely convulsant, resembling picrotoxin more than strychnine; its convulsions are suppressed by amytal (Swanson and Chen, 1939).

Respiration.—With oral administration, hypnotic doses produce slight slowing, chiefly through the sleep. Larger doses depress the respiratory center directly, reducing the depth and rate, often with irregularities (Page and Coryllos, 1926). The decreased oxygen saturation of the arterial blood after pentobarbital and amytal anesthesia may persist for four hours (Schnedorf, 1939). The respiratory depression is markedly accentuated by morphine and the supplementary inhalation anesthetics. With intravenous injection of clinical doses, the respiration becomes more shallow, and often slightly accelerated; but it remains regular (Zerfas and McCallum). Even hypnotic doses may paralyze the respiratory center, if they are injected too rapidly.

Intravenous injection of the short-acting barbiturates tends to produce adduction of the vocal chords, *increased laryngeal reflexes*, and coughing. It is attributed to central vagus stimulation. This may be temporarily relieved by epinephrine; atropine tends to prevent it (C. L. Burstein and Rovenstine, 1938).

Relative Respiratory Depression by Sedative Drugs.—Barlow and Gledhill, 1933, found that the tranquilizing dose of various sedatives required to quiet the struggling movements of dorsally bound rats, decreased the minute volume of respiration by the following average percentages: morphine, 30 to 45; pentobarbital, 40; avertin with amylene hydrate, 46; amytal, 70. Kleindorfer and Halsey, 1931, reported that dial and allurate cause markedly greater respiratory depression in cats than do amytal or avertin.

Respiratory Synergism with Morphine.—In rats the respiratory depression is but little greater (at most a third) than the simple summation of the effect of the morphine and of the amytal, pentobarbital or avertin. It is of about the same order of magnitude as the summation of their tranquilizing effects (Barlow and Gledhill, 1933).

Circulation.—Anesthetic doses cause no significant change in the circulation, clinically or in animals, with oral, hypodermic or slow intravenous administration. The blood pressure remains normal; the heart rate may be slightly quickened; the color of the skin is generally unchanged, sometimes pale or slightly cyanotic. Sedative doses significantly decrease the *loss of fluid* from burned tissue (Beecher and McCarrell, 1943).

Barbiturized animals are likely to respond to *vasomotor reflexes* (sciatic stimulation, Lacey, 1932; carbon dioxide inhalation, C. E. King, 1933) by fall of blood pressure, in contrast to the rise which these stimuli generally cause under other anesthesias, including chloral and avertin. The fall is partly vagal, partly vascular. On the other hand, barbiturates, especially amytal, decrease the response of the heart to *stimulation of the cardiac vagus* (Lieb and Mulinos, 1929; G. D. Shafer, Underwood and Gaynor, 1930). Acetylcholine and pilocarpine remain effective, suggesting that the action is on the vagus ganglia (Koppanyi, Linegar and Dille, 1935).

With rapid intravenous injection there is a prompt fall of blood pressure, averaging 30 mm. in clinical cases, generally with prompt recovery to the normal level. It is probably due to the temporary flocculation of the sparingly soluble barbituric acids, at the reaction of the blood; it may therefore be prevented by slow injection of dilute and alkalinized solutions (Zerfas and McCallum, 1929; Mason and Baker, 1930). Comparative studies on a series of barbiturates were made by Vogt, 1930.

With excessive doses, the pressure may remain low (Gruber and Basket, 1926), probably due to a direct action on the blood vessels, perhaps analogous to that of arsenic (Jacobi and Roemer, 1911; Jacobi, 1920). The spleen tends to become engorged so as to contain nearly a third of the red blood corpuscles (P. F. Hahn *et al.*, 1943). Peripheral vasodilatation can be demonstrated in dogs by the changes of the local temperature (Richter and Oughterson, 1932). This may also account for the *exanthemata*. *Urticaria* is produced by the local application of barbital to the scarified skin (Sollmann, 1917). *Perfused vessels* (cerebral) are dilated (Gruber and Roberts, 1926). Perfused frog legs are slightly constricted, and sensitized to epinephrine (O. Arnell, 1928). Dial lowers the susceptibility to ventricular fibrillation in response to galvanic stimulation (Rojas *et al.*, 1942). The *perfused rat heart* is depressed by the barbiturates (G. B. Roth, 1935). Relatively small doses increase the diastolic phase in heart-lung preparations (Olmsted and Ogden, 1930). Excised *frog heart* is depressed by all barbiturates, but with considerable differences of potency. The response of the *turtle heart* to vagus nerve stimulation is also depressed (C. M. Gruber and Keyser, 1946). The depression of perfused turtle heart is antagonized more effectively by theophylline than by coramine, metrazol, glycocoll or atropine (R. L. Johnston, 1938).

Smooth muscle is depressed by large doses, but in varying degree. Clinical doses do not produce significant effects; and even in full anesthesia, the depression is much less than with ether (Jackson, 1922; C. M. Gruber, 1925). The *uterus* is relatively resistant (Arnell, 1928). The parturient contractions are not affected by the full analgetic dosage (for instance, amytal, 0.018 Gm. per Kg. by vein, within two hours, Zerfas and McCallum, 1929; Drabkin *et al.*, 1929; Dodek, 1932). The uterine response to pituitary remains normal.

Ureteral contractions are depressed by anesthetic doses, and the contractor response of epinephrine is diminished (Gruber, 1928); but distention or pilocarpine produces peristalsis.

The motility of the *gastro-intestinal tract* is significantly reduced, and the emptying time of the stomach is markedly delayed (J. M. D. Olmsted and Giragossintz, 1929); an average of 20 per cent in normal man by 0.2 Gm. of sodium amytal (Van Liere and Northup, 1941); but adequate stimuli, such as distention or pilocarpine, evoke normal peristalsis.

With unanesthetized trained dogs, intravenous injections of barbiturates depress the motor activity of the stomach, ileum and colon. With equivalent anesthetic doses, the degree of the depressant action of amytal averages about $\frac{4}{10}$ that of barbital, and pentobarbital about $\frac{1}{4}$ of amytal. The gastro-intestinal depression is much shorter than the somnifacient action, but the different barbiturates range in the same order, pentobarbital lasting a third, and amytal two-thirds as long as barbital (Quigley *et al.*, 1934). The depressant effect occurs equally after decerebration, so that the action is peripheral (Quigley and Phelps, 1934). C. L. Burstein, 1939, claims that intravenous injection of clinical doses of barbiturates into dogs with Thiry-Vella fistula of the jejunum produces only a transitory depression, followed in five to fifteen minutes by increased tonus and motility lasting from ten minutes to two hours. *Excised* intestines of various animals are relaxed and depressed by the barbiturates; but thiobarbiturates produce a sequence of stimulation and depression (C. M. Gruber and Gruber, 1939). The *gastric and pancreatic secretion* of dogs are decreased by barbital (Barlow, 1927). Amytal also interferes with the response of the gastric and salivary secretion to parasympathetic stimulation (Macleod).

The *urine output* is not affected by hypnotic doses. It is generally decreased in basal anesthesia (Emge and Hoffmann, 1931). Anuria may occur with toxic doses. The suppression appears to be due to the lowered blood pressure and may be antagonized by epinephrine (H. Silvette, 1942). Increased excretion of *urates* has been reported for anesthetic dosages (Zerfas and McCallum, 1929). *Hematoporphyrin* occurs exceptionally in the urine of rabbits after barbital, but not after nostal or phanodorn (Laubender and Monden, 1938).

The **temperature** is lowered slightly by sedative doses, and markedly so in coma, owing partly to depression of the medullary centers, partly to diminution of movement. The fall is greater in animals, because of their relatively larger body surface (M. M. Ellis and Barlow, 1924; Deuel, Chambers and Milhorat, 1926; N. B. Eddy, 1929).

Basal metabolism is not significantly changed even by full hypnotic doses.

Deuel, Chambers and Milhorat, 1926, found no distinct change in patients, despite a fall of temperature of 2 or 3 degrees If shivering occurs, in animals, the basal metabolism increases. In the obstetric use of amytal, the maternal metabolism remains within the normal limits (Zerfas and McCallum, 1929; Robbins *et al.*, 1929). The variations reported for sedative doses of different barbitals in man, by Anderson, Chen and Leake, 1930, also appear within the normal range of variability.

Blood Sugar Level.—Contradictory results have been reported, depending partly on conditions, especially the diet. Anesthetic doses, according to most observers, cause no change in the blood sugar level of normal fasting animals (Dresbach and Randels, 1931; E. S. Jackson, 1931). A few have reported marked hyperglycemia (Soma Weiss, 1926; H. Jacoby, 1930). Olmsted and Giragossintz, 1931, who found no change in the sugar level of dogs when fed on meat, obtained hyperglycemia in dogs fed on a diet rich in carbohydrate. This is due to decreased rapidity of the assimilation of the circulating glucose, for injection of glucose produces greater hyperglycemia in barbital animals (Wierzuchowski and Gadomska, 1927). Amytal is said to prevent morphine hyperglycemia (Olmsted and Giragossintz, 1931). Barbital does not influence the effects of *insulin* on the blood sugar level, although it suppresses the insulin convulsions (E. L. Jackson, 1931). In the period *following barbiturate anesthesia*, the blood sugar falls, apparently by diminished hepatic glycogenolysis, diminishing the response to epinephrine. This effect is similar to that of chloroform and probably indicates incipient liver damage (Hrubetz and Blackberg, 1938).

Other Blood Constituents.—Bourne *et al.*, 1930, reported for dogs under amytal, concentration of the blood, decrease of *p*H, decreased blood alkali reserve and increased CO_2 combining power. Zerfas and McCallum, 1929, found no significant change in CO_2 binding power. The *coagulation time of the blood* is shortened in cats and pigeons (Ellis and Barlow, 1925). Ordinary doses had no significant effects on *liver function* in dogs (Bourne *et al.*, 1930). Toxic dosage produced changes indistinguishable from those of infectious diseases.

Serum choline esterase was lowered to a fourth by continuing barbiturate administration to patients for some weeks (F. Schultz, 1943).

Toxicology.—Barbiturates as a group are now the most common suicidal poisons, excepting carbon monoxide. In 1940, there were 545 barbiturate deaths reported in the United States (Klumpp). One-seventh of all cases of poisoning (exclusive of CO) treated in recent years in hospitals of the large cities of the United States were barbiturates. About 7.3 per cent of these proved fatal (Hambourger, 1940); but recovery may sometimes occur after four to six days of coma. Nearly all cases are suicidal, although not always intentional, additional doses being taken in the confused state induced by the therapeutic dosage. Some deaths are due to therapeutic overdosage. Hypersusceptibility is rare. The chief *phenomenon* of barbiturate poisoning is profound and prolonged coma (sometimes preceded by excitement); marked fall of blood pressure, depression and eventual paralysis of respiration.

The symptoms of barbiturate poisoning have been confused with those of uremia, epidemic encephalitis and opium poisoning. The reflexes are preserved, but greatly impaired. The muscle tonus is generally diminished; but with severe intoxication there may be parkinsonian katatonus (Meerloo, 1933) and tremors. Nystagmus is frequent, and diplopia has been reported. The pupils are generally dilated, but in severe poisoning they may be constricted and unequal (Roemer, 1919), until the final asphyxial dilatation. Skin eruptions are often associated with sharp febrile reactions, mucous membrane involvement and glandular swelling (Haubrich, 1934; Messinger, 1928). A few instances of fatal exfoliative dermatitis have been reported for phenobarbital (U. J. Wile and Benson, 1940; Sexton *et al.*, 1941). Some patients have marked jaundice. The temperature falls in the acute coma, but may then rise to a high fever. Such patients often develop bronchial pheumonia, sometimes even after the consciousness has improved (Chang and Tainter, 1936). Hypersusceptibility to therapeutic doses was charged for about 2 per cent of the toxic cases of Hambourger's series. Pneumonia after complete recovery from nostal is common in rats, and may occur with subnarcotic doses, in contrast to other barbiturates (Holck and Cannon, 1936).

Histologically, two fatal phenobarbital cases showed widespread degenerative changes in the central nervous system, and fatty degeneration in the liver, kidneys and capillaries (Jankovitch and Fazekas, 1932). Renal necrosis was reported by Rommel, 1912.

Clinical Fatal Dosage of Barbiturates.—The following tabulation of minimal dose reported as fatal (min.), and maximal dose reported as survived (max.), has been constructed from the data compiled by W. E. Hambourger, 1940, Pohlisch and Panse, 1934, and miscellaneous sources. No distinction is made between the free barbituric acids and their sodium salts. Highly questionable reports are omitted. *Allonal:* (min., 36 tablets; max., 40 tablets). *Alurate elixir:* max., six ounces. *Amytal:* min., 1.6 Gm.; max., 7 Gm. *Barbital:* min., 2 Gm.; median, 6 Gm.; max., 33 Gm. *Dial:* max., 2.4 Gm. *Phenobarbital:* min., 1.7 Gm.; max., 9 Gm. The wide margin for phenobarbital is probably a statistical accident. G. F. Kempf, 1946, concludes that death from oral administration of *barbital* or *phenobarbital* rarely results in adults unless the dose reached 6.5 to 10 Gm.; that 6 Gm. of amytal are not fatal unless complications develop; and that *pentobarbital* and *seconal* are not fatal with less than 3.25 Gm.

The LD_{50} *of oral administration to cats* is reported for several barbiturates by S. Krop and Gold, 1946.

Weight, Age and Sex on Barbiturate Toxicity in Animals.—Bazett and Erb, 1933, reported a logarithmic relation for pentobarbital with the *size* of dogs and cats, the per Kg. dose being smaller for large than for small animals. Most of the toxicity determinations have been made on albino rats, where the size becomes subordinate to the age and sex. Carmichael, 1937, found young rats (four weeks to nine months) more resistant than those more than nine months old; the M.F.D. of pentobarbital per Kg. with intraperitoneal injection was about a fifth higher for the young rats than for the older. For newborn rats, however, the M.F.D. per Kg. is only a third lower than for adults (Etsten *et al.*, 1943). As to sex, Holck reports that adult male rats are much more resistant than females to pentobarbital and to evipal. Different results were claimed by Moir and Waddell, 1938, for young rats. Nicholas and Barren, 1932, found gravid females twice as sensitive as males to amytal. Prolonged administration of testosterone to rats produces complicated changes in their susceptibility to barbiturates (H. G. O. Holck *et al.*, 1942). *Acute liver damage* by CCl_4 greatly increases the susceptibility of rats to the quickly acting barbiturates, pentobarbital and evipal, even before histological damage is present, probably by impairment of the detoxicating mechanism. This passes off quickly when the liver regenerates (Cameron and de Saram, 1939).

Alcohol is additive to barbiturate narcosis, materially increasing the toxicity (H. Ramsey and Haag, 1946).

The **treatment of barbiturate poisoning** is the same as for other hypnotic drugs. Gastric lavage is the first indication in recent oral cases. Emetics should not be used if the patient is comatose. The patient should be protected against overcooling. Artificial respiration should be administered if natural breathing fails. Deep barbiturate coma tends to poor pulmonary ventilation, atelectasis and eventually pulmonary edema, disposing to pneumonia. A free airway should be maintained, by frequently changing the patient's position and administering oxygen against anoxemia. Diuresis is best maintained by intravenous fluid. Prolonged coma lessens the chance of recovery, and if the patient is greatly depressed, and especially if the reflexes are absent, picrotoxin should be administered to improve the muscular tonus, reflexes, respiration and blood pressure, without aiming to restore full consciousness (D. L. Burdick and Rovenstine, 1946).

Picrotoxin, metrazol or coriamyrtin, in nearly convulsive doses, have a limited efficiency, mainly by stimulating the respiration, especially if used together with ephedrine (Maloney, 1931); but the dosage of the convulsants must be large to be effective, and somewhat excessive amounts increase the fatality. Artificial respiration alone may save from twice the fatal dose, and helps the other analeptics (Barlow, 1935). Nasal oxygen therapy is helpful (Schnedorf, 1939). Caffeine, camphor and carbon dioxide aid but little.

Amphetamine sulfate, intravenously, awakened patients who had received 0.5 Gm. of amytal, but some remained drowsy until a third injection of 10 mg. had been made, with fifteen minute intervals (Reifenstein and Davidoff, 1938). Freireich and Landsberg, 1946, recommend 10 to 40 mg. of amphetamine, as 1 per cent solution intravenously, followed every half hour by 10 to 20 mg. as needed. A total of 400 mg. appeared harmless.

Metrazol is fairly effective against the respiratory depression of overdosage with sodium pentothal, but does not raise the fatal dose or shorten the duration of sleep (R. W. Whitehead *et al.*, 1946).

The *picrotoxin* should be injected intravenously at the rate of 3 mg. in 1 cc. of saline per minute, until the corneal reflexes reappear and the patient can be roused by pain stimuli; then sufficient to keep the patient somewhat restless, about 3 to 6 mg. per hour. Severe cases require 100 to 150 mg., mostly during the first day (J. P. Anderson, 1941), but sometimes as high as 1820 mg.

The proof of the effectiveness of convulsants against barbiturates is based on *animal experiments.* It is difficult to demonstrate by direct evidence that picrotoxin has saved human lives, because the fatality of untreated cases varies widely and overlaps that of treated cases. Maloney, 1933, showed that optimal dosage of picrotoxin (3 mg. per Kg., intravenously for rabbits) is more effective against barbiturates than optimal doses of strychnine (1 mg. per Kg., vein), or cocaine (20 mg. per Kg., hypodermically). Barlow, 1935, found that picrotoxin (usually in 5 or 6 doses) saved 60 per cent of the rabbits poisoned with two and a half times the normally fatal intravenous dose of pentobarbital and 30 per cent with three and a half fatal doses. In those that died, the time to death was lengthened to four or five times the untreated. All analeptic agents caused symptomatic improvement of pentobarbital, chloral and avertin narcosis. The superiority of picrotoxin over the other analeptics is probably due to its more prolonged stimulation of the respiration, lasting for one-half to three hours with picrotoxin, one-quarter to three-quarter hour with metrazol (Barlow, 1938).

Intracisternal injection of picrotoxin (0.023 to 1.2 mg. per Kg.), in dogs, was reported by Rice and Isenberger, 1936 and 1937, more effective than intravenous injection against the narcosis and respiratory paralysis produced by intracisternal injection of sodium amytal (2.6 to 7.8 mg. per Kg.); ephedrine sulfate, 1.3 to 2.9 mg. per Kg., was also much more effective cisternally than by vein; but coramine and metrazol were not effective antagonists by this route.

Succinate of sodium has been reported an effective antidote to barbiturate narcosis (Soskin and Taubenhaus, 1943; Pinschmidt *et al.*, 1945). Others report discordant results. K. H. Beyer and Latven, 1944, found little effect. It has no effect on dogs; in cats it apparently rather increases the toxicity and narcosis (S. Krop, 1946). It does not antagonize chronic phenobarbital intoxication (P. J. Hanzlik, 1945). *Clinically,* it is reported to produce dramatic awakening from deep pentothal anesthesia. Intravenous injection of 2 to 200 cc. of 30 per cent solution of disodium succinate hexahydrate causes the patients to cough within fifteen to thirty seconds; the skin flushes deeply in thirty to 120 seconds; the respiration is temporarily increased; the patient is awake and oriented in ten to fifteen minutes if the dosage was adequate. There were no untoward symptoms. Succinate has also proved effective in attempted suicide by other barbiturates and by morphine. Intravenous injection of 5 cc. of 10 per cent succinate solution into normal subjects causes flushing, sometimes succeeded by pallor; and a feeling of suffocation twenty to thirty seconds after the injection (C. J. Campbell *et al.*, 1946). The trial of succinate was based on the observation of Quastel and Wheatley that the oxidation of succinate by brain mash is not depressed by barbital, as is that of dextrose, lactate and pyruvate.

Data on rabbits indicate an inverse relation of the *pyruvate level* of the blood and barbiturate depression. The antagonism appears to be functional, as the rate of destruction is not decreased (B. A. Westfall, 1946).

Diuretic Treatment.—The slow and prolonged excretion of barbital prompted the trial of sodium chloride and glucose diuresis, but they proved ineffective intravenously (Gower and Tatum, 1929), and only slightly more effective by mouth (Gower and Van de Erve, 1933). Intravenous ammonium chloride greatly accelerates the elimination of barbiturate, but it has little effect on the narcosis (Koppanyi and Murphy, 1934).

Habitual Use of Barbiturates.—The use of somnifacient, sedative or excitant drugs may become habitual with persons of a certain neurotic disposition, and this bent may take the direction of morphine, alcohol, chloral or barbiturates or all of these, according to circumstances. Chronic insomnia is the most common occasion for starting the use of barbiturates; a considerable number employ them for tranquilization or euphoria; a few for "sprees." A certain amount of psychical adaptation is readily acquired, as with alcohol; but there is little real tolerance for large doses; nor are they liable to the severe withdrawal reactions characteristic of morphine, although about a third of the subjects develop craving if the drug is withheld (Hambourger, 1940). The dependence is psychic, not physical (Tatum, 1939). Prolonged use may develop psychical degeneration and mania, as with alcohol, but these are often absent after long-continued daily administration. The minor grades of mental aberration seriously increase industrial hazards (Drysdale, 1939). Somewhat over half of the states have enacted laws regulating the sale of barbiturates, and these generally include chloral, sulfonal and their derivatives.

The prevalence of barbiturate addiction is difficult to judge, except by its widespread consumption, but a large part of this is used occasionally rather than habitually. However, a single druggist sentenced in New York had sold 50,000 tablets in three years as intoxicant "goof pills" (Federation Bulletin, 1944, *30*:212). The survey by Hambourger, 1940, indicates that barbiturates constituted 10 per cent of all addiction cases, exclusive of alcohol, admitted to the selected group of larger general hospitals; but pronounced addiction is still a curiosity. Acute poisoning by overdosage, generally suicidal, is fairly frequent among the addicted (Taddei, 1913).

Tolerance by Habituation.—Considerable adaptation to the narcotic effects develops rather rapidly, in man and in animals, the sleep being shortened by a third to a half, and the subsequent hebetude is much lighter. The lethal dose, however, is not altered materially (C. M. Gruber and Freedman, 1945; Ettinger, 1938; Stanton, 1936). Sleep-tolerance induced by one barbiturate generally extends to the others. It is rapidly lost on discontinuing the administration (C. M. Gruber and Keyser, 1946).

Withdrawal Symptoms.—After administering barbiturates to rats daily for seven weeks, Stanton, 1936, found no increase of restlessness in withdrawal, in contrast to morphine; indeed, the animals accustomed to barbiturates were less resentful to tying. Seconal and amytal were similarly negative (Phatak and Hill, 1941). A few patients, especially those with marked addiction, have one to three *convulsive seizures* after sudden or gradual withdrawal, but without permanent ill effects (C. W. Osgood, 1947).

Chronic barbiturate poisoning may produce nervous abnormalities: vertigo, ataxia, nystagmus, mild dementia, visual hallucinations, motor paralyses, tremor; and gastro-intestinal irritation, anemia and tremor, hematoporphyrinuria (Krep, 1905; A. Lambert, 1915). It may also reveal partly controlled mental aberrations and thus simulate encephalitis, acute psychic depression or delirium tremens. The mental symptoms improve on withdrawal, but ten weeks may be required to clear them completely (S. Weiss, 1936; Seevers and Tatum). Prolonged administration of large doses of phenobarbital to rats has no measurable effect on maze learning and retention (M. R. Jones and Jones, 1942), unless the effects approach the fatal (G. W. Williams and O'Brien, 1937). Depressant doses, however, stunt the growth more than does diphenylhydantoin (Hanzlik, 1945).

PREPARATIONS.—The barbiturates occur as white crystalline powders of somewhat bitter taste. The free acids are but slightly soluble in cold water, fairly soluble in hot water, and soluble in alcohol. They may be taken by mouth, in capsules, tablets, or dissolved in hot liquids. The sodium salts are freely soluble in water, but the solutions decompose on standing.

The following lists the more common barbiturates in alphabetic order:

Alurate, allylisopropyl barbituric acid. Dose, 65 to 130 mg.; *Tablets*, 65 mg. *Alurate sodium tablets*, for preanesthetic, equivalent to 0.2 Gm.

Amytal, isoamylethyl barbituric acid; tablets of 8, 16, 50 and 100 mg. Dose, as sedative, 20 to 40 mg. two or three times daily; as hypnotic, 0.1 to 0.3 Gm.; preanesthetic, 0.2 to 0.6 Gm.; tetanus, 0.4 to 0.8 Gm. *Sodium Amytal*, also suitable for intravenous injection; *ampuls* of 0.065, 0.125, 0.25, 0.5 and 1 Gm.; "*pulvules*" of 0.06 and 0.2 Gm.; *suppositories* of 0.2 Gm.

Barbital, U.S.P., diethylbarbituric acid (*veronal*, *barbitone*). Dose, as hypnotic, 0.3 Gm. *Barbital Tablets*, U.S.P.; usually 0.3 Gm. *Barbital Sodium*, U.S.P. (*medinal*); *Tablets*, U.S.P.; usually 0.3 Gm.

Dial, diallylbarbituric acid. Dose, as sedative, 30 mg.; as hypnotic, 0.1 to 0.3 Gm.; *Tablets*, 30 and 100 mg.

Hexobarbital Soluble, *Evipal Sodium*, evipan, cyclural, endodorm; N-methylcyclohexenyl methyl barbiturate. Dose: see under intravenous anesthesia. *Ampuls* contain 0.5 or 1 Gm. as powder.

Ipral Calcium, ethylisopropyl barbiturate. Dose, 0.12 and 0.25 Gm. *Tablets* of 50 and 120 mg. *Ipral Sodium Tablets* of 0.25 Gm.

Neonal, n-butylethyl barbituric acid. Dose, 0.05 to 0.4 Gm. *Tablets* of 0.1 Gm.

Nostal, isopropyl bromallyl barbituric acid. Dose, as sedative, 50 to 100 mg.; as hypnotic, 0.1 to 0.3 Gm. *Tablets* of 0.1 Gm.

Ortal Sodium, n-hexylethyl barbiturate. Dose, 0.2 to 0.4 Gm. *Capsules* of 0.05, 0.2 and 0.3 Gm.

***Pentobarbital Sodium**, U.S.P., ethyl (1-methyl-butyl) barbiturate (*nembutal*). Dose, as hypnotic, 0.1 Gm.; preanesthetic, 0.2 Gm. *Capsules*, U.S.P.; usually 30 and 100 mg.

***Pentothal Sodium** (See Thiopental Sodium, U.S.P.)

Pernoston, butyl-B-bromallyl barbituric acid. Dose, as hypnotic, 0.2 Gm. *Tablets* of 0.2 Gm. *Pernoston Sodium.* Dose; see under intravenous anesthesia. *Ampuls* of 2 cc. of 10 per cent.

Phanodorn, cyclohexenyl ethyl barbituric acid (cyclobarbital). Dose, as hypnotic, 0.1 to 0.4 Gm. *Tablets* of 0.2 Gm.

***Phenobarbital**, U.S.P., phenyl ethyl barbituric acid (*luminal*). Dose, 0.015 to 0.2 Gm. *Tablets*, U.S.P.; usually 15, 30 and 100 mg. *Elixir*, U.S.P., with 17.5 per cent of alcohol. Dose, 4 cc., contains 16 mg. of phenobarbital. *Phenobarbital Sodium*, U.S.P.; *Tablets*, U.S.P., usually 30 and 100 mg.

Sandoptal, isobutyl allyl barbituric acid. Dose, as hypnotic, 0.2 to 0.8 Gm. *Tablets* of 0.2 Gm.

***Seconal Sodium**, allyl (methyl propyl carbonyl) barbiturate. Dose, as hypnotic, 0.1 to 0.2 Gm.; preanesthetic, 0.2 to 0.3 Gm. "*Pulvules*" of 0.05 and 1 Gm.; *suppositories* of 0.13 Gm.

***Thiopental Sodium**, U.S.P. (**Pentothal Sodium**, Thiopentanone), ethyl (1-methylbutyl) thiobarbiturate; soluble in water, but the solution decomposes on standing. Dose; see under intravenous anesthesia. *Sterile Thiopental Sodium*, U.S.P., a mixture of thiopental sodium and anhydrous sodium carbonate as buffer, containing at least 91.7 per cent of thiopental sodium. Usually available in ampuls of 0.5, 1.0 and 5 Gm.

Navigan is a sedative pyridine derivative, with actions similar to the barbiturates (Krautwald *et al.*, 1939).

HYDANTOINS

These differ from the barbiturates in having an acetic instead of a malonic acid residue. The only two of importance at present are phenylethyl hydantoin (nirvanol), which has been used in chorea; and diphenylhydantoin (phenytoin, N. N. R., dilantin), which is used against epileptic convulsions. Both may produce marked side actions, apparently with capillary injury, which restricts their application.

Phenytoin Sodium (*diphenylhydantoinate, dilantin, epanutin*)

is an effective anticonvulsant with relatively weak somnifacient action. It was introduced by Merritt and Putnam, 1938, for the treatment of epilepsy, originally on the basis of its anticonvulsant action in animals. Clinically, it controls grand mal, including the jacksonian, more effectively than petit mal, preventing the convulsive seizures or decreasing their number and severity, without causing hebetude or lethargy, differing in this respect from barbiturates or bromide. It is therefore less disturbing, and it succeeds in many cases where these sedatives and ketogenic diet have failed; but it does not effect a cure. The effects disappear within two days after its administration is stopped. It must be continued indefinitely, and this is often difficult because of its side actions. It should be used only under close medical supervision after milder measures have failed. It is more effective if it is given along with phenobarbital. It has no effect on chorea (O. P. Kimball, 1939). Schizophrenia and nonepileptic psychoses may be improved by diminished excitement and irritability, but only during the administration (Kalinowsky and Putnam, 1943).

The *anticonvulsant actions of sedatives* were compared by Merritt and Putnam, 1938, on cats convulsed by an interrupted electric current passing from the mouth to the occiput. These convulsions closely resemble those of grand mal, and remain constant from day to day, in untreated animals. Phenobarbital proved effective, but more favorable ratios of anticonvulsant:soporific effect were found with several newer drugs, especially diphenylhydantoin, acetophenone, acetophenoneoxime, benzophenone and propiophenone. A series of nonhypnotic sulfoxides and sulfones was found effective against electric convulsions in cats, but appeared without material advantage over diphenylhydantoin (Merritt, Putnam and Bywater, 1945). Barbiturates other than phenobarbital were but little effective, as was also bromide in doses which proved fatal on continued administration (Merritt, Putnam and Schwab, 1938). Morphine and acetylsalicylic acid do not change the threshold in rabbits (Tainter *et al.*, 1943). With this technic, Knoefel, 1940, found the threshold for convulsions raised 50 per cent by phenyl-hydantoin in $\frac{1}{10}$ of the fatal dose. Other studies of anticonvulsant series are reported by Knoefel and Lehman, 1942; Kozelka *et al.*, 1942; L. Goodman and Toman, 1945.

Phenytoin materially raises the threshold for convulsions that follow reduction of high barometric pressure (E. C. Hoff and Yahn, 1944). It has little if any effect on petit mal seizures in patients, and does not raise the threshold to metrazol seizures, nor does it prevent electroencephalographic dysrhythmia of subconvulsive metrazol doses or electric shock (Goodman, Swinyard and Toman, 1946). Its action appears to be cortical, for it does not raise the threshold for electric convulsions in decerebrate cats (Knoefel and Lehman, 1942). The spinal reflexes are augmented. Cocaine and strychnine convulsions are not antagonized. Large doses may cause convulsions followed by prolonged extensor rigidity (Knoefel, 1940).

The abolition of the tonic phase of the major seizures of electroshock is a better criterion of clinical antiepileptic efficiency than is the raising of the convulsive threshold (J. E. P. Toman *et al.*, 1946).

Isopropyl alcohol increases the effectiveness of diphenylhydantoin against electroconvulsions (R. L. Driver, 1947). Among a considerable series of derivatives, the *diisobutyl-hydantoin* approached the diphenyl in potency (W. C. Chu and Driver, 1947). Methyl phenylethyl hydantoin, "mesantoin," is clinically equivalent to diphenylhydantoin against grand mal, without producing muscular incoordination or gingival hypertrophy; but many patients develop a generalized rash and somnolence (W. G. Lennox, 1946).

Administration in Epilepsy.—Phenytoin sodium has a bitter taste. It is administered in capsules with a glass of water after meals. The dosage should be the smallest that prevents the seizures, as determined by individual trial, beginning with 0.1 Gm. three times daily and increasing gradually, if necessary, to double this dosage (W. G. Lennox, 1942).

Minor side actions occur in almost all patients, generally between the third and tenth day of treatment. They are chiefly nervous, such as ataxia, vertigo, blurred vision, nystagmus, tremors, dysphagia, insomnia or somnolence, irritable temper, sometimes mental confusion and hallucinations. Electrocardiogram changes also appear in the majority, but disappear on discontinuing. The strongly alkaline reaction of the drug may produce gastric irritation (Finkelman and Arieff, 1943). These symptoms call for temporary reduction of dosage; some patients must be kept below 0.4 Gm. daily.

Hyperplastic gingivitis (first reported by O. P. Kimball, 1939) develops in about half the patients under long-continued phenytoin treatment. It is a low grade inflammation, beginning with warty rippling of the gingivamucosal surface, and progressing to a firm, painless hyperplasia, with proliferation of the capillaries and connective tissue and round cell infiltration. It is a progressive complication, which returns but slowly to normal. It is rarely sufficient, however, to necessitate discontinuance of the drug. It may be treated by excision. Dental care helps, but does not prevent (L. Stern *et al.*, 1943). It differs from the gingivitis of scurvy, which is not hyperplastic (Ziskin *et al.*, 1941), and it is not due to deficiency of *ascorbic acid* (Merritt and Foster, 1940), nor has it any significant effect on the utilization of ascorbic acid (Emmett *et al.*, 1943).

More serious toxic reactions consist chiefly in dermatitis, dry skin, itching, rash and purpura. Morbilliform or scarlatinous dermatitis occurs in 5 to 15 per cent of the patients after nine to fourteen days of administration. It calls for temporary withdrawal, but generally no harm results if the drug is continued. Serious exfoliative dermatitis has occurred after forty days, but is rare. Purpura has been observed in a patient after two months of treatment. No changes of liver or kidney functions or blood cell count have been found, but caution is advised in its use in cardiorenal and debilitated patients (Merritt and Putnam, 1938; Kimball, 1938).

Other Effects of Phenyl-hydantoin on Animals.—The toxicity is much greater by vein than by mouth. Intravenous injection of 25 mg. per Kg. for rabbits produces marked fall of blood pressure (also in spinal dogs), depression of the vagus nerve and respiration, and death by respiratory paralysis. Uterine movements are inhibited; excised uterus of nonpregnant rabbits is relaxed by 1:150,000. Parenteral injection of excessive doses into mice, rats, rabbits and dogs causes erethismus, spastic gait, exophthalmos, accelerated respiration and convulsions (M. E. Drake *et al.*, 1939; Haury and Drake, 1940; C. M. Gruber *et al.*, 1940). *Continued feeding* to rats is less injurious than is phenobarbital (Hanzlik, 1945).

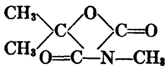
The *concentration of phenytoin in the blood* of patients receiving 300 mg. daily amounts to 3 to 6 mg. per 100 cc. The concentration *in the tissues* of rabbits injected intravenously with 50 mg. per Kg. is highest in the liver, decreasing in the sequence of brain, kidney, blood and muscle (Kozelka and Hine, 1938). In man and dog, about two-thirds of the administered quantity is completely destroyed; only 1 to 4 per cent is excreted unchanged in the urine; small quantities are metabolized to the corresponding hydantoic and amino acid (Kozelka and Hine, 1943; Knoefel and Lehman, 1942).

PREPARATIONS—**Diphenylhydantoin Sodium,** U.S.P., **phenytoin,** N.N.R.; epanutin, B.P.; *dilantin.* White odorless powder, freely soluble in water, giving a somewhat turbid alkaline solution. *Average dose,* 0.1 Gm. *Capsules,* U.S.P., of 30 and 100 mg.

Phenylethyl-hydantoin (*Nirvanol*), $C_6H_5.C_2H_5.C-(CONH)_2$, was originally introduced as a somnifacient sedative, and was found to produce marked improvement in some cases of chorea, but proved dangerous because it often causes febrile and exanthematous reactions, and lymphocytosis and eosinophilia, which set in when the administration has been continued for a week or two. Metabolic changes occur even in the absence of pyrexia, with temporary retention, first of water, then of Na and Cl, finally of K (Rockwell, 1935). The skin reactions are often excessive, beginning with cyanotic swelling of the face, high fever (above 40°C.), excessive macular and papular exanthemata, swelling of the eyelids, suppurative conjunctivitis and stomatitis (review, Pilcher and Gerstenberger, 1930). Its use is therefore not generally advisable. The levorotatory form is more potent than the dextro to produce nirvanol sickness (B. Schick, Sobotka and Peck, 1933).

"TRIDIONE" (TRIMETHADIONE)

This substance is 3,5,5,-trimethyl oxazolidine-2,4-dione:



It is analgetic, mildly sedative, and selectively anticonvulsant; generally controlling the petit mal, myoclonic and akinetic seizures characterized by "spike and wave" electroencephalograms. It improves 83 per cent of the patients, and suppresses the seizures in 31 per cent. It terminates status epilepticus, but is ineffective against grand mal convulsions, though it sometimes reinforces diphenylhydantoin (Lennox, 1947). Its mode of action is not known. The improvement sometimes persists after stopping the medication (W. G. Lennox, 1945; De Jong, 1946). It is not soporific, and the petit mal triad against which it is effective also responds to caffeine and amphetamine, which are not otherwise sedative.

Tridione was synthesized by M. A. Spielman, 1944. Its analgetic and anticonvulsive actions were first reported by Everett and Richard, 1944.

In animals, nondepressant doses of tridione raise the threshold of metrazol seizures more than barbiturates. It is more potent than phenytoin against electroshock convulsions. Residual effects of single doses persist for two days (L. S. Goodman, Swinyard and Toman, 1946). Intravenous injection relaxes tetanus (R. K. Richards, 1947). It is the most potent analgetic of the oxazolidine-2, 4-dione series (Everett and Richards, 1944).

Side effects are chiefly a functional mistiness of vision on going into a bright light. This occurs in nearly a third of the patients, in a few days to ten days of administration. It generally disappears a week or ten days after discontinuing. Sometimes the eyeball is painful. There are no anatomic changes, and the action is not explained. It is less frequent in children (Lennox, 1947).

Skin rashes are also fairly frequent, gastric irritation less so.

The most serious, but fortunately infrequent, side actions are *aplastic anemia* and fatal granulocytopenia. The drug should therefore be carefully supervised. It should not be used if there is a history of blood dyscrasias (R. P. Mackay and Gottstein, 1946; F. F. Harrison *et al.*, 1946).

Administration.—The usual dosage in pyknoepilepsies is 1 to 2 Gm. per day in divided doses, as 0.3 Gm. capsules. It may be advisable to decrease the amount if the photophobia is annoying. If grand mal is also present, phenytoin, phenobarbital or bromide may be added.

PREPARATIONS—**Trimethadione, Tridione,** N.N.R., is a white crystalline solid of a slight camphoraceous odor; slightly soluble in water, readily in alcohol. Evaporates rather readily. Marketed as *Tridione Capsules,* 0.3 Gm.

Benzimidazole, investigated by L. Goodman *et al.*, 1943, has a selective depressive effect on the tonus of skeletal muscle, on postural reflexes and on voluntary motion. The action is central, and mutually antagonistic with metrazol.

SYSTEMIC ACTION OF GASES

Gas may act (1) mechanically, by excluding oxygen from the lungs; this is the case with the "indifferent gases," such as nitrogen, hydrogen and methane; (2) as local irritants, as do halogens (bromine, chlorine), gaseous acids (sulfurous, nitrous) or alkalis (ammonia); (3) systemically after absorption, as do other dissolved substances, by their specific actions. The irritant and anesthetic gases are considered under these headings (see Index).

Humphry Davy was one of the first to make extensive trials of gases with the object of developing therapeutic applications. He experimented on himself with N, H, N_2O, and CO (as water gas) and nitric oxide, with more enthusiasm than discretion, and had some narrow escapes (F. C. Bing, 1933).

The systemic effects of gases depend quantitatively on their concentration in the blood; this, when equilibrium has been reached, is the simple product of the partial pressure in the alveolar air and the solubility coefficient for blood plasma. The *rate of absorption* of a given gas is directly proportional to its concentration in the air breathed, the rate of the pulmonary ventilation, and the rate of the pulmonary circulation. The last two factors are more important for the easily soluble gases. The absorption rate decreases in a logarithmic curve as the concentration in the blood approaches equilibrium. The attainment of equilibrium between alveolar air, blood and tissues depends on the duration of the inhalation, as well as on the partial pressure and the *solubility*. With low concentrations equilibrium is attained so slowly that the duration of the inhalation becomes a major factor in the blood concentration.

The partial pressure of a gas at normal barometric pressure is equal to the volume-percentage of the gas. The effect of the normal percentage of oxygen at half an atmosphere is the same as that of half the percentage at ordinary pressure; conversely, 1 per cent of a gas at 3 atmospheres produces the same effect as 3 per cent at 1 atmosphere.

The *concentration of gases in air may be expressed* either as parts by volume (per cent, per thousand, or per million, "ppm"), or as weight per volume (mg. per liter), or as partial pressure (per cent volume × 7.6 mm. Hg). "Ppm" may be transposed to "mg. per liter" by multiplying by the molecular weight × 0.0000409 (based on 22.4 liters as the volume of one gram-molecule of gases at 0° C., 760 mm.). The *solubility coefficient* is the amount of gas in solution needed to balance a given partial pressure of the gas. It varies with the nature of the fluid, decreases with rise of temperature, and is independent of the pressure of other gases. It is expressed as the amount of gas (calculated as cubic centimeters at 0° C., 760 mm.) in a liter of the solution. Gas solubility in blood plasma is slightly lower than in water (about 10 per cent), approximately by the amount of solid substances. This holds also for lipo-soluble gases. The solubility of a gas may be expressed as the *coefficient of distribution*, the relative weight of gas in equal volumes of fluid and of the gas mixture to which this is exposed (for instance, concentration in fluid = 12 mg. per liter; in air = 3 mg. per liter; distribution coefficient = 12:3 = 4).

Rapidity of Action.—The effects of gases appear promptly after beginning the inhalation, and disappear as rapidly when the animal is made to respire pure air. This is due to the large surface and large alveolar surface of the lungs, and the large quantity of blood that circulates through the alveolar capillaries; for the whole blood passes through the lungs every thirty seconds. As these factors are relatively greater in small mammals, these succumb and recover much more rapidly than man, and may indeed be used as a test of the safety of suspected air. While the recovery from the direct effects of gases is rapid, indirect after-effects may be persistent.

Equilibrium of Blood and Tissues.—The gases pass from the blood into the tissues, and in the reverse direction, according to the relative concentration and solubility coefficient, speeded or restrained by the rate of blood flow and restricted to some extent by the difficult permeability of the cell surface (particularly in adipose tissue). The *average solubility of most gases in most tissues* is about proportional to their water content, and therefore slightly lower than in the blood plasma; but the concentration at equilibrium approaches fairly closely to the product of the concentration of the gas in the air × its solubility coefficient at body temperature.

When the tissues are taking up gas from the blood, the concentration in the arterial blood is higher than in the venous. The difference decreases as equilibrium is approached. When the inhalation has been stopped, the gradient of gas concentration is reversed, so that it passes from the tissues to the venous blood, to be excreted into the alveolar air, and the concentration in the arterial blood is lower than that of the venous. In either case, the concentration of the venous blood approaches most closely that in the tissues. The increase and decrease in the tissues follow exponential curves. The half-saturation time is a convenient criterion for comparisons of the speed of absorption and elimination, as it is independent of the concentration of the gas. This time increases with the solubility of the gas. With a man at rest, it requires about two and one-half hours for ether, and only seven minutes for nitrogen. Tissues with rapid circulation (the brain, viscera and glands) reach equilibrium much sooner than those of slower circulation (the muscles, bone and fat). The spleen is also slow, as it is largely outside the active circulation (Henderson and Haggard, "Noxious Gases").

Absorption of gases from the intestines is active. When 60 cc. of various gases were injected into a ligated 25 cm. loop of small intestines of anesthetized cats, the absorption rate per hour averaged: CO_2, 160 cc.; H_2S, 69 cc.; O_2, 14 cc.; H_2, 7.5 cc.; CH_4, 4.3 cc.; N_2, 1 cc. Similar results were obtained from the colon. The low absorption of nitrogen is due partly to its slight solubility, partly to the fact that the blood and tissues are already four-fifths saturated with nitrogen. If atmospheric air is injected into the intestines, the volume diminishes rapidly until the oxygen has been absorbed, then slowly. Parallel with the absorption of the injected gases, there is also *diffusion of other gases into the lumen;* for instance, after intestinal injection of 100 per cent oxygen, the gas remaining after an hour contained 73.5 per cent of O_2, 5 per cent of CO_2 and 21.5 per cent of N_2. In two hours, the percentage of nitrogen had risen to 33 per cent. Two hours after an injection of hydrogen, the gas contained 45 per cent of H_2, 10 per cent of O_2, 5 per cent of CO_2 and 40 per cent of N_2 (McIver, Redfield and Benedict, 1926). *Postoperative gas distention is* due largely to the faulty propulsion of swallowed air. McIver, Benedict and Cline, 1926, found the percentile composition of the rectal gases similar in postoperative surgical distention and in medical cases, as follows: nitrogen, 49 to 92, indicating the important share of swallowed air; hydrogen, 0 to 34 (median about 3); carbon dioxide, 3.8 to 14 (about as in venous blood); methane, 0 to 19 (median about 3); oxygen, 0 to 9.4 (median about 1.5); hydrogen sulfide, present in only one patient of the thirteen.

CARBON DIOXIDE (CARBONIC ACID)

This acts as a weak acid, producing locally rather mild irritation; and after absorption, strong medullary stimulation; in higher concentrations, narcosis. These actions play the principal role in ordinary asphyxia. Deficiency of CO_2 (acapnia) leads to corresponding depressant phenomena. The carbonic acid therefore acts as a hormone (Bayliss and Starling, 1906) which regulates the activities of various functions, especially of the respiration. In this way the CO_2 tension of the blood and tissues is normally kept automatically at a practically constant level.

Its function in neutrality regulation will be considered under that heading (see Index).

Local Actions.—CO_2 as gas or solution produces a prickling sensation and reddening of the skin and mucous membrane, followed by numbness and local anesthesia. The sensory irritation leads to reflex stimulations (Quincke, 1877). The cutaneous stimulation is utilized in the form of carbonated baths (Nauheim baths), especially in cardiac diseases. Frozen CO_2 (carbon dioxide snow) is employed as a superficial cauterizant. In the stomach, carbonated water ("soda water") hastens absorption, increases the secretion of acid gastric juice (Chiari, 1915), and acts as a carminative. It is useful against nausea, and valuable for disguising the taste of medicines. Experimentally, it produces marked augmentation of the gastric contractions and of the pyloric discharge. This is apparently due to parasympathetic stimulation, for it can be prevented by atropine (Carnot and Koskowski, 1922).

Normal CO_2 Exchange.—Inspired air contains normally physiologically insignificant amounts of CO_2 (0.04 vol. per cent). In the alveoli it enters into equilibrium with the gases of the blood (by purely physical diffusion, *not* by active secretion), losing part of its oxygen and gaining carbon dioxide, which is constantly formed by the combustion of the body. The concentration of CO_2 in the expired air is about two-thirds that of the alveolar air, as about one-third of the tidal air does not reach the alveoli because of the "dead space."

Normal CO_2 percentages and tensions are approximately as follows, per cent as volume, tension as mm. Hg: expired air, 4 per cent, 30 mm.; alveolar air, 4.6 to 6.2, average 5.5 per cent, 42 mm.; arterial blood, 36 to 40 per cent, 30 to 42 mm.; venous blood, 45 to 50 per cent, 30 to 50 mm.; tissue, 51 to 58 per cent, 40 to 70 mm.

Condition of the CO_2 in the Blood.—Blood contains 3 to 4 volumes per cent of CO_2 in physical solution; the remainder, yielding about 50 volumes per cent, ocurs in the plasma and corpuscles in combination. In the plasma it exists as bicarbonates, chiefly as $NaHCO_3$, partly as protein bicarbonate, and H_2CO_3. The greater part is in the red blood corpuscles as $KHCO_3$ and chiefly as hemoglobin bicarbonate or carbamate (Roughton, 1935, review), chloride diffusing out into the plasma in exchange (Van Slyke, Wu and McLean, 1923), so that considerable CO_2 may be added to the blood with little change in the *p*H of the plasma (L. J. Henderson, 1920). The corpuscles contain a catalase, *carbonic anhydrase,* which accelerates the reaction between CO_2 and water in both directions ($CO_2 + H_2O \rightleftarrows H_2CO_3 \rightleftarrows H.HCO_3$) (Meldrum and Roughton, 1933). It contains about ⅓ per cent of zinc as an essential constituent (Keilin and Mann, 1940). The epithelium of the parietal cells of the *gastric mucosa* is especially rich in carbonic anhydrase, which is probably instrumental in the secretion of hydrochloric acid (H. W. Davenport and Fisher, 1940; W. Ashby, 1944).

Carbonic anhydrase also plays an essential role in the urinary tubules, and in the shell-forming organ of birds (H. W. Davenport, 1946, review).

Oxygen on CO_2 of Blood.—Oxygen (and carbon monoxide) tends to expel CO_2 from the blood; for when exposed to a given CO_2 tension, blood that has been deprived of oxygen takes up considerably more CO_2 than oxygenated blood (Christiansen *et al.*, 1913). CO_2 or lowering of *p*H decreases the oxygen-binding power of hemoglobin. It is disputed whether CO_2 combines with hemoglobin like oxygen.

Carbon dioxide *diffuses rapidly into cells* from alkaline solutions, and turns their reaction toward acid (Jacobs).

Diffusion Through Skin.—The uptake and output of CO_2 into the water of baths follows the gas diffusion laws. Hyperemia increases the exchange by 4 or 5 times (Kramer and Sarre, 1936). The ratio of diffusion $CO_2:O_2$ through *various animal membranes* differs widely: At 100 mm. Hg pressure difference it averages 8.2 for eggshell membrane, 25 for frog lung, 35 for rabbit peritoneum (Lin and Tsai, 1939).

Effects of CO_2 Inhalation in Man.—If oxygen deficiency is excluded by inhaling gas mixtures containing 20 per cent of oxygen, no effects occur until the concentration approaches 2 per cent of CO_2 by volume, when the breathing becomes deeper, and the tidal volume is increased 30 per cent, the minute volume 5 per cent (Haldane and Priestley 1905). With 4 per cent of CO_2, the depth of the respiration is greatly increased and the rate slightly quickened, with considerable discomfort. With 4.5 to 5 per cent the breathing becomes extremely labored, almost unbearable for many individuals. The tidal air rises to about 10 liters per minute, with 2 mm. rise of the alveolar and arterial CO_2 tension (Douglas and Havard). Nausea may occur. With 8½ per cent of CO_2 there is distinct dyspnea, rise of blood pressure and congestion, which become insupportable in fifteen or twenty minutes, but disappear promptly in fresh air. The limit of tolerance is 7 to 9 per cent. The respiratory stimulation culminates about 10.4 per cent (E. W. Brown, 1930); about 15 per cent in animals (Zuntz, 1897). Above 10 to 11 per cent, ataxia develops, followed by unconsciousness, in about ten minutes. The symptoms increase to 15 per cent; but even 20 per cent is not dangerous in an hour to animals, and probably not to man; but depressed patients may be much more easily injured. With 25 to 30 per cent, the stimulant phenomena pass into depression, with diminished respiration, fall of blood pressure, coma (generally without convulsions), loss of reflexes, anesthesia, and gradual death after some hours by pulmonary edema and hemorrhage. The heart outlasts the respiration. With higher concentrations, the stimulation is still briefer. With pure CO_2, death may occur in a few minutes as a mixed effect of carbon dioxide and anoxemia. *Daily exposure* of an hour to 8 per cent CO_2 did not have marked deleterious effects (Tomaszewski *et al.*, 1937).

Rats always survive abrupt exposure to 10 per cent; a few die at 15 per cent; few survive 20 per cent; at 25 per cent half die within six hours, none survive thirty-six hours (M. H. Seevers, 1944). Much higher concentrations are tolerated if the concentration is gradually increased than with sudden exposure; the acclimatization is attributed to diminished oxygen consumption. If the external temperature is low, 5 per cent of CO_2 produces reversible narcosis (J. H. Barbour and Seevers, 1943).

Share of CO_2 in Ordinary Asphyxia.—When asphyxia occurs by respiratory obstruction or by breathing in a confined space, the accumulation of carbon dioxide is solely responsible for the early symptoms, the dyspnea and distress; the fatality is due solely to the oxygen deprivation.

Respiration.—The CO_2 content of the blood is the chief regulating factor in ordinary respiration (Zuntz, 1897; Douglas and Havard), the respiratory center being stimulated (mainly the rate) even by very slight increase of the CO_2 tension. A rise of 0.2 per cent of CO_2 (1.6 mm.) above the normal percentage of the alveolar air (5.6 per cent) doubles the respiration, and a slight reduction (0.2 per cent) of the CO_2 produces apnea. The sensitiveness to oxygen is much less, the respiration being unaffected by variations of the oxygen in the air between 13 and 100 per cent (Haldane and Priestley, 1905; Fitzgerald and Haldane, 1905). The effective increase of CO_2 also produces a slight but measurable change in the hydrogen ion concentration of the blood (Campbell and co-workers, 1913). Other acids are similarly stimulant (Winterstein, 1911; Laqueur and Verzár, 1911), although not quite so much (Hooker *et al.*, 1917), because they penetrate cells less readily (Douglas and Havard). The hyperpnea of muscular exercise is due to CO_2 rather than *p*H changes (review, J. H. Comroe, 1944). Loevenhart, 1913, referred the effects ultimately to interference with oxygenation. The response to CO_2 is used experimentally as a test of the excitability of the respiratory center (A. Loewy, 1890). Concentrations above 15 per cent depress the respiration (Lowry and Zuntz, 1897). *Bronchial muscle* (*excised*) is constricted by moderate, relaxed by high, concentrations (Trendelenburg, 1912).

Medullary Centers in Asphyxia.—The effects are alike whether they result from CO_2, acidosis or oxygen deprivation. The stimulation occurs in the order of respiratory, then vasomotor and then vagus centers. It is followed by depression of these centers. The relative preponderance of stimulation and depression depend on the degree and suddenness of the asphyxia, and on the prevailing condition of the centers (Loevenhart, 1915). The stimulating effects are due largely to reflexes from the carotid body, but the medullary depression is direct.

Asphyxial Reflexes from the Carotid Sinus and Cardiac-Aortic Regions.—Increase of CO_2 or increased hydrogen ion concentration of the blood and decreased oxygen concentration stimulate the respiration and vasomotor center through these reflexes. Heymans *et al.* report that these are sensitive to smaller changes than are required for direct stimulation of the centers. The opposite changes in the concentration produce the opposite reflexes. Comroe and Schmidt, 1937, concluded that the hyperpneic response to CO_2 and acid is much more central than reflex, but that oxygen deficiency acts mainly or entirely by reflex.

The respiratory ventilation of insects is materially increased by 15 per cent of CO_2.

CO_2 on Circulation.—Increase of carbon dioxide from 3 to 25 volumes per cent in the inspired air causes a marked rise of blood pressure, mainly by stimulation of the vasomotor center. Moderate increase of CO_2 tension perhaps also increases the output of the heart. The central constrictor stimulation is exerted chiefly on the splanchnic vessels. The vessels of the skin are passively dilated. The peripheral action on blood vessels results in their dilatation. Concentrations above 25 per cent lower the blood pressure by depression and finally paralysis of the vasomotor center and heart (Hill and Flack, 1908; van Esveld, 1930).

Vasomotor Center.—Violent stimulation was proved by Sollmann and Pilcher, 1911, and by Mathison, 1911. The latter demonstrated that identical effects are produced by other acids and by lack of oxygen, and that all these act probably by increasing the hydrogen-ion concentration of the blood. The spinal vasomotor centers are much less sensitive than the medullary (Mathison, 1910). The stimulation of the vasomotor center by increase of carbon dioxide or acidity or by deficiency of oxygen is chiefly reflex from the carotid sinus (C. Heymans, Bouckaert *et al.*, 1932). The vasoconstriction involves mainly the splanchnic vessels.

Direct Action on Vessels.—Perfused or excised vessels are dilated by physiologic concentrations of CO_2, such as stimulate the respiratory center (Bayliss, 1901; Hooker, 1912). Very high concentrations may constrict (Fleisch *et al.*, 1932). A similar dilatation is produced by other weak acids (Schwarz and Lemberger, 1911). Barcroft, 1914, considered this an important factor for the increase of local circulation in active organs, especially with the rise in blood pressure resulting from the sinus reflex. Bernthal and Shoemaker, 1937, however, claimed that CO_2 is purely constricting to blood-perfused dog legs, and that decrease below the normal CO_2 level (43 mm.) causes dilatation.

Pulmonary Circulation.—The pressure in the pulmonary arteries rises in asphyxia, even if the rise of the systemic blood pressure is prevented by destroying the medulla (Wood, Jr., 1911). The pulmonary circulation time is slowed (Langlois and Desbouis, 1912), indicating pulmonary vasoconstriction.

Venous Pressure.—Increase of carbon dioxide causes a large rise of venous pressure, even when the arterial pressure is but little affected. Henderson and Harvey, 1918, interpreted this as due to direct dilatation of the capillaries and venules.

Efficiency of the Heart.—In intact animals, the cardiac effects are complicated by the other actions. In dogs whose heart rate, venous return and arterial tension were kept constant, Wiggers, 1929, found that changes of alveolar CO_2 between 15 and 60 mm. had no effect on the ventricular contractions, so that the changes ordinarily observed would be indirect. The *heart rate* is ordinarily slowed by stimulation of the vagus center; but if the vagi are divided, it is quickened by stimulation of the accelerator center (Dastre and Morat, 1885). Ketcham, King and Hooker, 1912, found that the *isolated heart* is depressed by all concentrations. Jerusalem and Starling, 1910, claimed that increase of CO_2 in the coronary blood lessens the tonus both in systole and diastole. The coronary vessels are also dilated (Markwalder and Starling, 1913). With higher concentrations, the systolic tonus is lowered more, so that the excursions are diminished; with moderate concentrations, the diastolic tone is more relaxed and the output increased. A certain concentration would therefore be necessary for the optimum efficiency of the heart; this is insufficient in acapnia. Perfusion of the coronary vessels of a mammalian heart with CO_2 gas causes prompt fibrillation and arrest, whereas the heart continues to beat for a considerable time if the perfusion is made with oxygen, or even hydrogen (Magnus, 1902).

The *blood viscosity* is somewhat increased by CO_2, but not to an important degree (Burton-Opitz, 1911). The *erythrocyte volume* is increased by CO_2 in passing from the arteries to the veins, and decreased when CO_2 is lost in the lungs. Under the influence of CO_2 the *erythrocytes* take up chloride from the serum, and increase its alkalinity. Similar changes occur in hemolysis (Rohonyi and Lorant, 1916). Increased acidity diminishes the *affinity of hemoglobin* for oxygen (or carbon monoxide); with a carbon dioxide tension of 40 mm., the oxygen percentage must be doubled to secure the same degree of saturation (Barcroft, 1914).

Protoplasm Consistency.—The fluidity is first increased by CO_2, then decreased. Accordingly, the protrusion of *pseudopodia* is first favored, then arrested (M. H. Jacobs, 1922).

Peristalsis.—In intact animals this is stimulated by asphyxia. Excised intestine is started to rhythmic contraction if it was quiescent; but is relaxed if it was already rhythmically active (Hooker, 1912). Inhalation of 50 per cent carbon dioxide inhibits cecal peristalsis induced in rabbits by physostigmine or pilocarpine (J. Auer and Krueger, 1942).

Oculomotor Center.—The pupils are ordinarily widely dilated by asphyxia, after primary constriction (Guthrie and Ryan, 1910). The mydriasis occurs after division of the cervical sympathetic (Braunstein, 1894). It must therefore be ascribed to inhibition of the oculomotor center. Peripherally, CO_2 constricts frogs' pupils (Auer, 1909).

Convulsants.—Strychnine convulsions may be suppressed by CO_2 inhalation (Ryan and Guthrie, 1908). On the other hand moderate asphyxia increases the convulsant effect (Pilcher). Concentrations above 20 per cent also heighten the susceptibility to acid fuchsin convulsions (Joseph, 1915). Conversely, picrotoxin, lobeline and camphor appear to make animals more subject to CO_2 convulsions (Wieland and Mayer, 1922).

Temperature.—CO_2 dyspnea lowers the temperature in health, and especially in fever. It also reduces metabolism (v. Magyary-Kossa, 1910).

Hyperglycemia.—Inhalation of carbon dioxide increases the blood sugar, even when given with oxygen. The effect may be partly directly on the splanchnic innervation of the liver, partly indirectly through augmented epinephrine output, and probably also directly on the liver cells (Cordier, 1934).

Deficiency of CO_2 (Acapnia).—The carbon dioxide tension regulates the heart rate, vascular tone, peristalsis, mental condition and a number of other functions. A decrease of this tension in the blood and tissues causes depressant effects.

The *phenomena of acapnia* were emphasized especially by Y. Henderson, 1908 to 1910. Even a slight reduction of the CO_2 causes marked increase of the heart rate and slowing of respiration. Further reduction produces tachycardia, venous stasis, arrest of peristalsis, failure of many reflexes, coma and stoppage of respiration. Extreme reduction causes an almost tetanic condition of the heart, abolishing its output, lowering blood pressure and resulting in death. In the lighter grades, recovery occurs promptly if the CO_2 tension is increased, as by breathing through a long tube.

Acapnia resulting from *pulmonary hyperventilation* promptly produces dizziness, blurred vision, numbness of the extremities. If long continued, it causes muscular spasms of the face, hands and feet, sometimes opisthotonos, generalized convulsions and unconsciousness. Physical and nervous fatigue may persist for some days (E. C. Schneider, 1930; R. Harwood, 1938).

Acapnia and Respiration.—The respiratory center is readily depressed by deficiency of CO_2 in the blood. This is the main factor in the apnea following hyperpnea, and one factor in Cheyne-Stokes respiration (Haldane, 1905, 1909). The increased oxygen content, to which it was formerly attributed, seems to be unessential, although excessive oxygen concentration is also depressant (Loevenhart, 1913). The direct depressant effect of CO_2 deficiency on the respiratory center was demonstrated by Winterstein's (1911) *perfusion experiments.* The respiration was not restored by oxygen, but by carbonic or other acids, and is therefore a hydrogen ion effect. In intact animals a persistently low oxygen tension leads to the accumulation of lactic and other acids, and hence to stimulation of the respiration.

Apnea.—Suspension of the respiratory movements is usually due to depression of the respiratory center by excessively low CO_2 content of the blood (acapnia); for instance, as a consequence of hyperpnea. Fredericq showed that apnea can be produced by the transfusion of the blood of an apneic animal. Acapnia is not essential, however, for excessive distention of the lungs may produce apnea even when the air contains 5 per cent of CO_2. This phenomenon does not occur if the vagi were divided (Githens and Meltzer, 1914). In fowls, CO_2 deficiency also stops the respiratory movements, but the effect consists in tonic spasm of the respiratory muscles, and not in heightened threshold. The function of CO_2 would therefore consist in the maintenance of the respiratory rhythm (Meyer and Meltzer, 1915).

Therapeutic Use of Carbon Dioxide and Oxygen Inhalation.—The stimulant actions of carbon dioxide on respiration and on the vasomotor centers may be utilized in acute respiratory depression by the inhalation of oxygen containing 5 per cent of CO_2. Stronger concentrations, 7 to 10 per cent, become detrimental if inhaled longer than a few minutes. A well fitting mask with appropriate valves is indispensable. This has been used especially in the treatment of *carbon monoxide poisoning.* The deeper and more rapid respiration raises the percentage of oxygen in the alveolar air, so that it may displace the CO more promptly, which is also fanned out of the lung more effectively. Brief inhalation may be useful to ventilate excess of *volatile anesthetics* from the lung (Henderson, 1924; Waters, 1933), but continued administration, as by rebreathing, tends to postanesthetic pneumonia (Waters, 1938). It improves respiration in *poisoning by alcohol, methyl alcohol or morphine* (Henderson, 1924), but it cannot be continued sufficiently to be of much benefit. It is undesirable in pneumonia and *pulmonary and cardiac disease,* because of the discomfort and exertion (Boothby, 1932; D. J. Cohn *et al.*, 1939).

Inhalation of 10 per cent CO_2 with 90 per cent oxygen may be used to dislodge adherent bronchial mucus (A. L. Benyai and Cadden, 1943). Y. Henderson, 1932, advocated inhalation for carbon dioxide in the paroxysmal stage of *pertussis,* 6 or 7 per cent in air or oxygen, for ten or fifteen minutes once or twice daily for eight days, to cause deep breathing, distend the lungs and clear the air passage, thus diminishing the incidence of pneumonia.

Psychiatric Conditions.—Very short inhalation of 30 per cent carbon dioxide in oxygen, resulting in anesthesia, may produce a remarkable, but only temporary, clearing of the psyche in paralytic *dementia* (Loevenhart). Similar temporary improvement is obtained in schizophrenia. Inhalation of 5 per cent carbon dioxide has been tried against *catatonia,* but without success (de Jong, 1934).

PREPARATION—***Carbon Dioxide,** **U.S.P.** (*Carbonei Dioxidum*), is 99 per cent by vol. of CO_2. Usually supplied in metallic cylinders.

OXYGEN

The oxygen inhaled as air replaces that which is used up in the combustion of the tissues. It is carried by the hemoglobin, and restores venous to arterial blood. It constitutes about one-fifth (20.94 per cent), by volume, of ordinary air. An increase of this proportion, and even the inhalation of undiluted oxygen, produces no noticeable effect under ordinary conditions. The rate of *oxidation* or the consumption of oxygen is not increased (Pflueger); indeed, the output of CO_2 is rather lessened. Evidently the proportion of oxygen in air suffices for all ordinary needs (or, rather, it is greater than necessary); additional oxygen acts as an indifferent gas. In other conditions, however, namely, when the supply of oxygen is deficient from any cause, its inhalation removes the asphyxial symptoms with striking promptness and efficiency.

Historical.—Oxygen was discovered by Priestley in 1744. Its function in respiration was shown by Lavoisier in 1777. The history of its first therapeutic use, also that of nitrous oxide, by Beddoes, 1798, is reviewed by A. H. Miller, 1931.

Condition of the Oxygen in the Blood.—The effects of most gases are directly proportional to their partial pressure in the respired air. Oxygen departs from this rule, for there are practically no further effects when its percentage is raised above 10 per cent. This is explained by the fact that only a small part of the oxygen is carried in physical solution in the blood plasma. By far the greater part is in loose chemic combinations with hemoglobin, 1 molecule of hemoglobin combining with 1 molecule of O_2 (Butterfield, 1913). When respiring ordinary air without obstruction, the hemoglobin of the arterial blood is already over nine-tenths saturated with oxygen, and the amount taken up can be but little increased by raising the oxygen tension (Buckmaster and Gardner, 1913). The oxygen of the plasma increases directly with the oxygen percentage of the alveolar air, but the amount thus carried is small, 0.6 per cent (Haldane, 1917).

The *dissociation curve of oxyhemoglobin* follows the law of mass action, showing that the reaction is chemic, and not adsorptive. The curve is identical for pure solutions of hemoglobin, whatever their origin, but it is affected by electrolytes, and therefore differs in the blood of different animals or even individuals. Increased acidity diminishes the affinity, and therefore the effective concentration of oxygen. The same holds for CO-hemoglobin (Barcroft, 1914). Hemoglobin dissolved in plasma combines with oxygen ten times faster than when it is enclosed in the corpuscles (Jacobs), but it is less effective as an oxygen carrier.

Oxygen Concentrations of Air and Blood.—The following represent the usual values:

	Volume of O_2 Per 100 Cc.	Pressure of O_2, mm. Hg	Per cent Saturation of Hemoglobin
Inspired air.......	20.9	158	
Alveolar air.......	14.5	110	
Expired air.......	16.4	125	
Arterial blood.....	19.5–20.6	100–105	92–98
Venous blood (right heart)....	14	35–40	64–81
Tissues (approximate)...	....	20–40	

The *absorption of oxygen in the lungs* is simply physical under ordinary conditions; but if so much CO is inhaled that the supply of oxygen to the tissues becomes inadequate, there is an active (secretory) absorption, so that the partial pressure of oxygen in the arterial blood becomes higher than in the alveolar air. This occurs also when the demand for oxygen is increased by muscular work. It is not known how this correlation is brought about (Douglas and Haldane, 1910).

Excessive Oxygen Concentrations.—The inhalation of pure oxygen produces no immediate effects, even with pressure of 4 atmospheres; but injuries develop gradually and progressively if the partial pressure exceeds 60 per cent of an atmosphere; the speed and severity depend on the concentration of the oxygen, and on the age of the individual, young subjects being less susceptible. It is inadvisable to inhale undiluted oxygen for more than a few hours at a time, or to use concentrations higher than 65 per cent if the administration is to be prolonged indefinitely. Continuous sojourn in 80 to 100 per cent oxygen is innocuous for twenty-four to forty-eight hours, but longer exposure may result in pulmonary irritation, edema and pneumonia (J. Lorrain Smith, 1899). Higher pressures, 3 or 4 atmospheres, may be tolerated for a time, but after about three hours serious symptoms appear, including peripheral vasoconstriction, visual changes, rise of blood pressure, convulsive seizures terminating in death by paralysis of the respiratory and cardiovascular centers. If the subject is restored to ordinary air before death, recovery occurs immediately or within an hour.

Minor Effects of Oxygen Inhalation.—Cl. Bernard claimed that birds placed in pure oxygen are greatly excited, and that the urine of rabbits becomes acid.The *efficiency* of athletes is increased, and forced respiration can be maintained longer (Hill and Flack, 1909, 1910). Christiansen and co-workers, 1913, attributed this to the smaller solvent power of blood for CO_2 in the presence of excess of oxygen. Lavoisier and Seguin, 1789, reported that pure oxygen has no effect on *metabolism.* This has been confirmed by modern investigators.

Toxic Effects of 67 to 100 Per Cent of Oxygen.—Results differ somewhat quantitatively with animal species, age and other conditions, even when complicating impurities are excluded. Partial pressures *below 60 per cent* appear to be tolerated indefinitely (53 per cent for three and a half days; Karsner and Ash, 1917). Normal men show no symptoms when exposed to 50 per cent for twenty-four hours (J. R. Comroe *et al.*, 1945). Most animals are not affected by 60 per cent, but some developed severe pulmonary injury, although they did not die in a week of exposure (J. A. Campbell, 1927). Rabbits remained well for three months, except for a decrease of about 15 per cent in hemoglobin and in red cell count (Barach, 1926). Between *67 to 80 per cent* most animals develop pulmonary congestion and inflammatory changes, usually not fatal. Rabbits exposed to 67 per cent for eleven days showed slight pulmonary irritation; 80 per cent usually produced no change in twenty-four hours, but definite damage in forty-eight hours (Karsner, 1915), and pulmonary edema in two or three weeks (Barach, 1926). About half of normal men inhaling 75 per cent oxygen for twenty-four hours show some symptoms (J. R. Comroe *et al.*, 1945). Dogs exposed to 80 per cent for a week became ill, but not fatally. Exposure to 90 per cent killed by pulmonary edema within five days (J. R. Paine *et al.*, 1941).

Undiluted (100 per cent) oxygen is probably safe for all patients for brief administration, but not beyond twelve hours. Inhalation for twenty-four hours by a large number of normal men produced substernal distress, significant decrease of vital capacity, often with nose and throat irritation. Intermitting the administration for fifteen minutes every three hours did not diminish these effects (J. R. Comroe *et al.*, 1945). Dogs exposed to 100 per cent oxygen developed respiratory distress within forty-eight hours and died in about sixty hours, the lungs showing extreme congestion, interstitial edema and polymorphonuclear infiltration (J. R. Paine, 1941). *Guinea pigs* in 80 to 100 per cent oxygen develop marked dyspnea and die with gasping respiration. Their bronchioles to and excluding the alveoli show tumefaction and necrosis, resembling phosgene poisoning (J. Pichotka, 1941). *Humidity and heat* both increase the toxicity of oxygen (H. R. Hulpieu and Cole, 1944). Considerable resistance to oxygen intoxication may be induced by *habituation*, either by gradual increase from 60 to 100 per cent, or by intermittent exposure to 100 per cent for fifteen minutes four times daily (A. L. Barach *et al.*, 1944). *Differences in the threshold of injury concentration* are due at least partly to the much greater resistance of *young individuals* (Smith, Thompson and Drinker, 1932). This applies also to *compressed air.* Young rats tolerated indefinitely sojourn in air at 4 atmospheres (equivalent to 86 per cent of oxygen at ordinary pressure). In older rats, symptoms of acute pulmonary hyperemia began on the fourth day. A few died, generally in about a week, at most in two weeks. If this period is survived, adaptation occurs and the animals recover, although remaining in the compressed air, and tolerate further exposure indefinitely (two hundred and seventy-two days). If rested and again exposed, there is no recurrence of the acute symptoms. The difference in age susceptibility is connected with age differences in the structure of the normal lung (Smith, Thompson and Granville).

Compressed air injury, more properly decompression injury (*caisson disease*), is due to the mechanical injury of the central nervous system by the liberation of nitrogen bubbles during rapid decompression. The damage is especially marked in nervous structures because fats and lipoids dissolve more nitrogen than does water.

Compressed Oxygen.—Paul Bert found 3 to 4 atmospheres very toxic to animals. The symptoms resemble those of asphyxia (review, J. W. Bean *et al.*, 1945). *Healthy men* can breathe *oxygen at 3 atmospheres* for three hours without distress. During the fourth hour visual symptoms appear, progressive contraction of the visual field, mydriasis and some impairment of central vision. These are associated with signs of peripheral vasoconstriction, culminating in the fourth hour in abrupt rise of systolic and diastolic pressure, increase of the pulse rate, extreme pallor of the face, dizziness, sensation of impending collapse, and partial stupor. Prompt and complete recovery occurs on restoration to normal air (Behnke, Forbes and Motley, 1936). *Anesthetized dogs exposed to oxygen at 4 atmospheres* for three hours show blood pressure changes, convulsive seizures of the head and neck, death by paralysis of the respiration, with depression of the cardiovascular centers. *Increase of CO_2* accentuates and hastens oxygen poisoning, even with CO_2 concentrations innocuous at atmospheric pressure (Shaw, Behnke and Messer, 1934). *Rats* exposed to 5 or 6 atmospheres of oxygen for fifteen to twenty minutes may have convulsive seizures, followed by spastic paralysis which is sometimes permanent. Repeated exposures spaced to permit symptomatic recovery produce additive effects, increased acute central nervous response and persistent motor dysfunction, attributed to tissue damage (J. W. Bean and Siegfried, 1945). Anesthetized rats die by apnea in a little over an hour when exposed to 6 atmospheres of oxygen; somewhat later if hyperventilated (J. W. Bean, 1945). These effects are not due to pressure as such, for they are not produced by compressed air until the partial pressure of oxygen reaches these figures. The high pressure of oxygen interferes with the reduction of blood hemoglobin by the tissues, entailing inadequate liberation of base to carry away carbon dioxide, and so resulting in acidosis (J. W. Bean, 1931). It also poisons the respiratory enzymes of the cells directly (J. W. Bean and Bohr, 1938). Paul Bert, 1878, also showed that oxygen above 3 or 4 atmospheres pressure is fatal to *tissues.* It is toxic to *unicellular organisms,* beginning at about 1½ atmospheres, probably by interfering with respiratory enzyme processes (J. W. Bean, 1941). Excised *frog heart* responds to 5 or 6 atmospheres of oxygen by initial increase in the force of ventricular contractions, followed in a few hours by slight weakening and slowing, then cessation of automatic contractions. It remains excitable to electric stimulation much longer (Bohr and Bean, 1939). *Carbon dioxide production by skeletal muscle* is first increased, then decreased, and is reversible by decompression; the effects are not produced if the pressure is increased by addition of nitrogen (R. E. Cass, 1945). *Excised intestine* of rabbits is also depressed and paralyzed, reversibly, by oxygen at 5 atmospheres, apparently by direct action on the muscle (Bean and Bohr, 1940).

OXYGEN DEFICIENCY

The most important phenomena connected with oxygen arise from its deficiency, *anoxia*, through inadequate access to the lungs (asphyxia), unsaturation of the hemoglobin (anoxemia), deficiency of the hemoglobin (anemia), inadequate circulation (ischemia), or incapacity of the tissue cells to utilize oxygen (histologic anoxia, as in cyanide poisoning).

Etiology.—Asphyxia by obstruction of the air passages or by breathing in a confined space involves hypercapnia as well as anoxia. Pure anoxia without carbon dioxide accumulation results from breathing rarefied air or air diluted with indifferent gases, nitrogen, hydrogen, methane, and so forth; by carbon monoxide, which displaces oxygen from hemoglobin; or by agents that convert hemoglobin into methemoglobin. Anoxemia without carbon dioxide accumulation may also exist in pneumonia and cardiac decompensation when obstruction of a part of the lungs is compensated by overventilation of other parts; this washes out the excessive carbon dioxide, but does not materially increase the oxygen saturation of the mixed blood (R. G. Pearce, 1917).

The symptoms of anoxia develop so insidiously that the subject may be unaware of them. They arise chiefly from stimulation and depression of the central nervous system, since this is most susceptible to oxygen deficiency. The course depends upon the duration as well as the degree of the deficiency. Ordinary air may be diluted until it contains about 15 per cent of oxygen (or may be rarefied to the same degree), without producing any immediate effect (Bernstein, 1882). A candle is extinguished when the oxygen has fallen to about 17.5 per cent, and is therefore a test for the safety of the air, as far as oxygen is concerned. At about 10 per cent slight symptoms are noticeable, especially on exertion, but they are not alarming—dizziness, shortness of breath, deeper and more frequent respiration, quickened pulse, slight cyanosis. With 7 per cent, these symptoms become serious, and stupor sets in. With a slightly lesser percentage, unconsciousness occurs; 5 per cent is the minimal concentration compatible with life. With 2 to 3 per cent death occurs within forty-five seconds. Different persons vary in sensitiveness to oxygen deficiency or to mountain sickness (N. E. Baxter *et al.*, 1944). Patients with cardiac and pulmonary disease are more susceptible because their compensation is impaired; thyrotoxic patients develop anoxia more easily because of their greater oxygen consumption. Conversely, hypothyroid subjects are more tolerant. This has been confirmed experimentally on animals (Asher and Durand; Asher and Streuli).

Minor grades of oxygen deficiency have been studied by the Air Service Medical Research Board, because of their importance in aviation. It was found that even slight lowering of the oxygen tension produces reactions to compensate for the diminished oxygen supply of the tissues (Y. Henderson and Seibert, 1918). The chief reactions are increased ventilation of the lungs and more rapid blood flow. In a few men there is also concentration of the blood. The *differences in tolerance* depend upon the completeness of these reactions. Some tolerate 6 per cent of oxygen for brief periods; others are incapacitated by much smaller changes. The degree of tolerance and the reactions is an objective test of general "fitness," and is diminished by any indisposition, colds, worry, and so on (Schneider, 1918). The relation of *age and sex* was investigated by R. F. Kline and Britton, 1945, on various mammals. Fetal and newborn animals are very resistant to reduction of barometric pressure. Adult females resist a fourth to a half longer than males, especially in the cold. *Estrous* conditions and *castration* do not appear related to the difference. Petit mal loss of consciousness occurs in epileptic patients when the inspired air contains 8 to 12 per cent of oxygen; high oxygen pressures induce convulsions (W. G. Lennox and Behnke, 1936). Full narcotic doses of *alcohol* reduce the lethal effects of acute anoxia in mice; amytal and pentobarbital do not produce much effect. Some *cholinergic* and *sympathicolytic agents* have a limited prophylactic value. Adrenergic and para-sympathicolytic agents tend to increase the fatality rate (G. A. Emerson and Van Liere, 1943; standardized technic for testing). Polycythemia produced by *transfusion* does not increase resistance to reduced barometric pressure (P. Wetzig and D'Amour, 1943).

Henderson and Haggard group the phenomena of anoxia into *four stages*, best marked when they develop slowly. The *first stage* starts when the oxygen of the inspired air is reduced to 16–12 per cent. It begins with increased volume of respiration, which lowers the CO_2 concentration of the blood. The pulse quickens. Attention and clear thinking require more effort. Muscular coordination for skilled movements is somewhat diminished. The *second stage*, with oxygen reduced to 14–9 per cent affects the higher brain centers, resembling alcoholic inebriation. Some subjects become exhilarated, talkative or quarrelsome; with emotional outbursts or fixed ideas. Some complain of headache or numbness. Voluntary coordination and attention are impaired, but perception, memory and discriminative judgment may remain good. Burns and bruises are not noticed. Muscular efforts fatigue readily, the subject may faint. The respiration is often of Cheyne-Stokes type (which always denotes anoxemia; Douglas and Haldane). The *third stage*, with oxygen range of 10 to 6 per cent, exaggerates the earlier symptoms. Nausea and vomiting may set in. Vigorous movements become impossible. There is ascending paralysis of motion, then of sensation. The patient is bewildered and does not realize that anything is seriously wrong until his "legs give way" and it is too late to escape. He may then realize that he is dying, but is indifferent. Consciousness is lost, with amnesia on revival. In the *fourth stage*, with oxygen below 6 per cent, the respiration stops, convulsive movements occur and the heart is arrested six to eight minutes after the respiration.

Abrupt anoxia results in immediate loss of consciousness. The symptoms are seen clinically *when nitrogen is administered* for three or four minutes in *treating schizophrenia* where the arterial oxygen is reduced to about 2 per cent (volume). They begin with progressive stimulation of the respiration; then progressive tachycardia, to about 160 per minute, with various types of arrhythmia. The systolic blood pressure rises progressively. Muscular twitching starts about the face, followed by generalized clonic contractions, tetanic opisthotonos, or extensor torsion. Consciousness is lost about the time when the twitching appears. Urinary incontinence is exceptional. Cyanosis is relatively late and never intense. One or two inflations with oxygen produce prompt and complete recovery from this acute anoxia (F. A. D. Alexander and Himwitch, 1939). *With somewhat slower anoxia*, the recovery is also slower, and is likely to leave sequels, hallucinations, excitement, headache, often with nausea, depression and apathy, which may increase for several hours and last till next day. These phenomena are attributed to pressure from cerebral edema. They may be temporarily relieved by intravenous injection of hypertonic sugar or salt solution. If the anoxia is more severe or prolonged, *organic degenerative changes* occur in the nervous system, especially in the cerebral cortex and basal ganglia (Steegmann, 1939). These result in persistent paralyses, amnesia, and so forth. These are especially common after carbon monoxide poisoning, since its anoxia is more persistent. Pulmonary congestion is frequent, probably owing to circulatory changes. Pneumonia is also a frequent and indirect sequel. Degenerative lesions may be produced in the myocardium, aorta, testes and bone marrow. Anoxic changes occur also under various conditions which interfere with the oxygen supply to the tissues; in shock of all varieties, and in poisoning by carbon monoxide or dioxide, convulsants, digitalis, epinephrine, histamine, nitrites. *Mountain sickness* corresponds to the second and third stages of anoxia as described above. *Airplane nausea* is also partly anoxic, and patients with cardiac or pulmonary disease or thyrotoxicosis should be cautioned against high flying.

Injury to the nervous centers by anoxia has been studied in dogs and cats by occlusion of the cephalic circulation. Consciousness, corneal reflex and respiration are arrested within forty seconds; in six to eight seconds if the oxygen supply of the brain is suddenly reduced, so that the oxygen saturation of the blood of the internal jugular vein, which is normally 60 per cent, falls to 24 per cent (Lennox, Gibbs and Gibbs, 1933). If the occlusion lasts not longer than two minutes, recovery is complete within a few hours, without histologic changes. If it lasts ten minutes or longer, the animal does not come out of coma; if the anoxia lasts eight minutes or less, consciousness returns within forty-eight hours; but permanent sequels follow if the anoxia lasts three and one-quarter to five minutes. They are due to degenerations of the nervous structures, necrosis and softening of the cortex, especially of the motor and visual areas. Laminae 3 and 4 are the most vulnerable. Purkinje cells of the cerebellum rank next to the cortex. The geniculate are the most vulnerable of the basal ganglia. The brain stem and spinal cord are not injured (L. M. Weinberger *et al.*, 1940; C. Dennis and Kabat, 1939).

C. Heymans and Bouckaert, 1938, report that the respiratory, vagus and vasomotor centers of the dog can be revived after thirty minutes of total suspension of their circulation. The pupillary and corneal reflex centers are revivable after ten to fifteen minutes; some other centers only to five minutes, with later death following muscular rigidity, coma and hyperthermia.

The *vulnerability of the nervous centers* may be explained by the *high oxygen consumption* of the brain, amounting to about 13 cc. of oxygen per 100 Gm. of wet brain weight per minute (Himwich and Nahum, 1932), or about 8 per cent of the total oxygen consumption of the body (C. A. Handly *et al.*, 1943). The oxygen consumption of brain tissue suspensions is not affected by reducing the oxygen tension to 4 mm. Hg (K. A. C. Elliott and Henry, 1946). *Monoiodoacetate* inhibits the oxidation of glucose by the brain *in vitro*, but has little effect on the oxidation of lactate, pyruvate, glutamate or succinate (Quastel and Wheatly, 1934).

Medullary Centers in Anoxia.—These are stimulated by moderate deficiency of oxygen, and paralyzed by extreme oxygen deficiency. The respiratory center is the most sensitive, then the vasomotor, and least the vagus center. The stimulation is partly direct, but chiefly reflex from the carotid sinus (Heymans *et al.*, entirely so, A. G. H. Bjurstedt, 1946; the depression is direct. The intensity of the reaction is determined by the rapidity and degree of the change and by the state of the centers. Excessive oxygen is depressant.

The *resiratory response* generally starts at about 16 to 14 per cent of oxygen and becomes marked with 12.5 to 9 per cent. It usually affects the depth more than the rate; indeed, the rate may stay unchanged, especially if the reaction is good (Schneider, 1918). It begins with hyperpnea, followed by decreased amplitude when the overventilation has lowered the CO_2 tension. The decrease of CO_2 may be useful, as it increases the oxygen capacity of hemoglobin.

Haldane, 1919, stated that the first response of anoxemia is *periodicity of the respiration*. With further reduction, the type becomes rapid and shallow. Patients with "irritable heart" are especially likely to react in this way to exertion. Oxygen inhalation gives relief. *Cheyne-Stokes respiration* is also referable to oxygen deficiency (Douglas and Haldane, 1909); the apnea lowers the oxygen and leads to accumulation of lactic acid. This increases the excitability of the respiratory center, so that a low CO_2 tension suffices to produce hyperpnea. This lowers the CO_2 and increases the oxygen, so that the lactic acid is oxidized, apnea reappears and the whole process is repeated.

The *blood pressure* shows several types of response. *If the reaction is good,* it may be unchanged; if the heart quickens, the systolic pressure may rise and the diastolic fall gradually. *If the reaction is poor,* the systolic pressure falls suddenly, soon followed by fall of diastolic pressure and then slowing of the heart. These phenomena are often accompanied by fainting (Schneider, 1918).

Heart.—Reduction of the partial pressure of oxygen to 14 per cent increases the rate and diastolic volume of the heart, with increased minute output. These effects increase to 11.5 per cent of oxygen, and the rate increases further to 7 per cent oxygen (Hilton and Eichholtz, 1925). The *coronary vessels* are markedly dilated in asphyxia, anoxia and myocardial anemia, increasing the diastolic and especially the systolic coronary flow (H. D. Green and Wégria, 1942). The response to electric stimulation of the peripheral stump of the divided vagus is increased (Danilewsky and Wyalkowa, 1931). *When the capacity of response is exceeded,* the heart may either slow or quicken by 50 to 90 beats (Schneider, 1918). *Temporary heart failure* is not uncommon. It is shown by dilatation, also followed by collapse and fainting, unless the oxygen is increased (Whitney, 1918). The *terminal cardiorespiratory crisis* starts with great vagal slowing, preventable by atropine. This is followed by irregularities due to functional changes in the conducting system. Cardiac decompensation then causes abrupt fall of the arterial and rise of the venous pressure, accompanied by severe depression and final arrest of the respiration.

The blood vessels (including the coronaries) are dilated by anoxemia, on direct perfusion (Richards, 1914). Oxygen deficiency also lowers the tone of excised arteries (Roncato and Oselladore, 1923). *Capillaries* likewise are dilated by deficiency, and constricted by excess tension of oxygen (Krogh). Carbon dioxide dilates the capillaries and arteries, but low concentrations of CO_2 may be somewhat stimulant (Roncato and Oselladore).

Digestive Tract.—Reduction of partial oxygen pressure to 43 mm. depresses the hunger contractions and the digestive peristalsis of the stomach. It has no effect on the motility of the small intestines; the colon is somewhat more sensitive. There is little effect on gastric or intestinal secretion, or on intestinal absorption (E. J. Van Liere *et .,al* 1944).

The *oxygen consumption of smooth muscle* is rather slow. It is increased by rhythmic contractions, and by temperature rise within physiological limits. It is not increased, but rather is diminished when the tonus is raised by drugs. It is depressed but not abolished by cyanide (C. L. Evans, 1923). *Excised smooth muscle organs* suspended in Locke's solution require continuous aeration in order to function. The stirring of the solution by the air bubbles helps to remove carbon dioxide and to bring oxygen to the surface of the tissue, so that even nitrogen or hydrogen is effective for a time (Evans and Underhill, 1923; Simonart, 1926), but they soon become harmful (Gross and Clark, 1923).

The pupillary dilatation in anoxia is due chiefly to diminished tonus of the oculomotor centers. Epinephrine and sympathetic stimulation play no part (Gellhorn and Levin, 1945).

Disturbances of Vision.—These are among the minor manifestations of oxygen deficiency (Wilmer and Berens, 1918) and are probably due to the disturbed circulation. Rats exposed to severe anoxia develop lens opacities (J. G. Bellows and Nelson, 1943).

Cyanosis.—The reduced hemoglobin of oxygen deficiency gives a cyanotic tint to the skin and mucous membranes. (A similar but more intense blue is conferred by methemoglobin and sulfhemoglobin.) The unsaturation may occur through incomplete aeration in the lungs, through slowed peripheral circulation, or through excessive oxygen consumption in the tissues. In ordinary asphyxia involving increase of carbon dioxide, superficial vessels are dilated, giving a *blue cyanosis;* an ashen-gray cyanosis is characteristic of anoxemia without hypercapnia, as in mountain sickness, shallow breathing, acute pulmonary edema of "gassing" and pneumonia (Haldane, Meakins and Priestley, 1918). Ischemia, as in surgical shock and in anemia, gives a pallid blue tint.

Ordinarily, cyanosis is just detectable in the finger nails and lips when 10 per cent of the hemoglobin of the arterial blood (or 30 per cent capillary blood) is unsaturated; it is definite with 15 per cent, and marked with 20 per cent of unsaturation (Stadie). The intensity and depth are also materially influenced by the amount of blood in the capillaries and veins of the area (Lundsgaard, 1918, 1919).

The cyanosis of reduced hemoglobin is distinguished from that of methemoglobin in that it may be caused to disappear by increasing the local blood flow, as by placing an arm in a bath at 45° C. (Meakins and Davies, 1920). The color of the venous blood coming from an organ depends upon the flow. That from the submaxillary gland is black when the gland is resting, red when it is functioning. The blood of the renal vein is normally always red (Cl. Bernard).

Asphyxial Glycosuria.—All forms of asphyxia, whether from CO_2 or deficiency of oxygen, lead to hyperglycemia and glycosuria. This does not occur if the liver is excluded, or in poorly nourished animals (W. Auel, 1914). It requires the cooperation of the adrenals, for it does not occur if these have been excised (Macleod, 1913). *Basal metabolism* is first increased by the greater respiratory exercise of oxygen deficiency. It decreases with the depression.

Oxygen Deprivation in Treatment of Schizophrenia.—The measures used therapeutically to impress schizophrenic patients involve decrease of cerebral oxidation: insulin by diminishing the fuel dextrose; metrazol and other convulsants by producing anoxemia; cyanide (Loevenhart) by poisoning the oxidative function of the cells. This does not appear to be the chief mechanism, however. Himwich *et al.*, 1939, reported encouraging results by pure anoxia produced by inhaling nitrogen; but others have failed to obtain a therapeutic response (L. R. Sillman and Terrence, 1943).

Accommodation to Acute Oxygen Deficiency.—Brouardel claimed that an animal asphyxiated slowly revives much more readily than one asphyxiated abruptly. Similar observations have been made clinically. *Newborn infants* and animals also resist asphyxia (by drowning or strychnine) much longer than adults. Newborn babies have been revived after ten to fifteen minutes of immersion ("Les Asphyxies," p. 13).

Chronic oxygen deficiency, as seen in anemias, and the like, causes increased tissue destruction, fatty degeneration, acidosis and general paralysis of all organ functions. Exposure to slightly rarefied air, as on mountains, causes "*mountain sickness*"—nausea, headache, insomnia, and so forth. This generally disappears after a few days. Henderson and Haggard attribute these symptoms to hyperventilation, resulting in alkalosis. A curious phenomenon is a prompt and persistent increase in the corpuscles and hemoglobin content of the blood (by 25 to 40 per cent). This is at first due to diminution of the plasma, the total quantity of hemoglobin being unaltered. After a time the absolute hemoglobin is also increased by stimulation of the formation of corpuscles by the bone marrow (G. H. Martin *et al.*, 1916). The respiratory metabolism is increased. These effects are attributed to oxygen deficiency (Douglas; Haldane, Henderson and Schneider, 1913). *The accommodation is limited:* Mice and rabbits, which are highly resistant to oxgyen deficiency, remain healthy indefinitely and continue to grow normally in 12 per cent oxygen; but in 10 per cent oxygen (equivalent to 20,000 feet altitude) growth ceases promptly, the weight decreases, the animals are sickly, and many die in four or five weeks, with chronic cardiac hypertrophy. Some show tetany, with normal or high serum calcium (J. A. Campbell, 1935). In rabbits, exposure to this altitude for sixteen hours daily, for five days a week, promptly induces polycythemia (J. Goodman, 1947).

Acute clinical asphyxia, such as is produced by obstruction, by breathing in a confined space, or by arrest of the heart, involves both accumulation of carbon dioxide and deficiency of oxygen; the hypercapnia is responsible for the air hunger and other early symptoms, and the anoxia for the final fatality. *When asphyxia occurs rapidly,* three typical stages may be distinguished: During the *first stage,* the respirations (particularly the inspirations) are increased. In the *second stage,* the respirations are irregular and convulsive, the inspirations shallow and weak, the expirations powerful and prolonged. Consciousness is lost. The skin, especially the face, becomes cyanotic. The *third stage* is characterized by collapse and convulsions. The respiratory centers are depressed. The respiratory movements are shallow and infrequent. The convulsive, vagus, vasomotor and pupillo-dilator centers are stimulated. The extremities and the muscles of the face and neck twitch convulsively; there are gasping movements; the body is rigid and arched backward. Urine and feces are expelled. The pulse is slow and soft, at first strong, then progressively weaker. The pupils are at first constricted, then widely dilated until death. The heart continues to beat weakly for several minutes after the respiration has stopped. Artificial respiration during this interval generally results in recovery. *Death* occurs within six or eight minutes, if the trachea is tied. The *autopsy* shows the veins of the upper part of the body and the right heart greatly distended with very dark blood. *If the asphyxia is produced slowly,* the first symptoms are cyanosis and dyspnea on exertion. The individual becomes stupefied, but so gradually that he may not be aware of his condition. The stupor passes into unconsciousness and this into collapse. The motor symptoms may be entirely absent.

The **effects of stale air** are not due to oxygen deficiency or even to carbon dioxide excess. "Pure" air contains 0.03 per cent of CO_2; in badly ventilated rooms it may reach 0.3 per cent, which is far below the effective concentration. Human expired air contains small amounts of toxic substances, presumably volatile bases, which depress the frog heart (Gramenitzky and Siwerzew, 1935); but it is questionable whether their quantity is significant. The acute discomfort and the suffocating sensation experienced in these places is largely psychic, attributable to the heat, humidity, odors, noise, and so on. Whether this accounts also for the severely detrimental effect on health and resistance, the increased tendency to tuberculosis, and so forth, which are associated with habitually deficient ventilation, is an open question. Continued or repeated exposure to gases—particularly those acting upon the blood, and indeed to any poison which alters the blood, such as acetanilidid—does not generally cause tolerance, but increase of susceptibility.

Indifferent gases, nitrogen, hydrogen; the "rare gases," helium, argon, and the like, act merely as diluents of oxygen and produce quantitatively the effects described under oxygen deficiency. One volume of such gases may be added to two volumes of air (reducing the oxygen percentage to 14) before any symptoms set in. Equal volumes are dangerous. They interfere with efforts to escape. Three volumes to one of air is quickly fatal. The *rare gases* are not essential to life: continuous sojourn of mice in an artificial air of pure oxygen and nitrogen for over forty days produced no symptoms or lesions whatsoever (Barach, 1934).

Helium as Therapeutic Diluent of Oxygen.—Because of its low density, a mixture of 21 vol. of oxygen and 79 vol. of helium can be moved through small orifices with half the effort required for air. This is practically unimportant with the normal airway, but is effective for relieving obstructive dyspnea, especially in prolonged asthmatic attacks when epinephrine has failed (A. L. Barach, 1936); and in postoperative tracheal edema, hemorrhage and laryngospasm (Eversole, 1938). Its actual value in bronchiolar obstruction is not great.

Helium, U.S.P., is a colorless and odorless gas, very slightly soluble in water.

The **treatment of asphyxia** should be directed primarily to the oxygen deficiency. The patient should be removed to fresh air, but protected against cold, as the temperature control is impaired. He should be laid flat and prone, with the face turned to one side. Oxygen should be administered, preferably with 5 per cent of carbon dioxide (Y. Henderson), to increase the pulmonary ventilation. This also helps to restore the circulation and to offset the cerebral depression (Gellhorn, 1936). If the patient has stopped breathing, artificial respiration should be started at once and kept up for fifteen to thirty minutes. This is not likely to be injurious; even positive and negative pressure resuscitating machines, used on anesthetized and curarized dogs for one to three hours, gave no evidence of lung damage (H. Schwerma and Ivy, 1945). After recovering, the patient should be kept warm, to prevent pneumonia. Alcohol is contraindicated (Henderson and Haggard). The treatment must be started promptly. Success cannot be expected if the respiration has stopped for fifteen minutes (B. D. Ross, 1945). The heart beats at most ten minutes, more often only six minutes, after the respiration stops, and death occurs in ninety to 120 seconds after complete arrest of the heart. Resuscitation is unsuccessful or incomplete after seven to ten minutes of complete cerebral anemia (G. N. Stewart and Pike).

The heart has been restored clinically by direct cardiac massage after it has been arrested ten or eleven minutes. The brain stem resumed function, but the patient remained in coma for twenty-six days, when death occurred from pneumonia and urinary imfection. Autopsy showed degeneration of the cerebral and basal ganglia and cerebral cortex (Howkins *et al.*, 1946).

OXYGEN THERAPY

The administration of oxygen is useful only in those forms of asphyxia in which the access of oxygen to the blood is hindered, as by *vitiated air* (anesthesia, mines, wells, and the like); by *mechanical interference with respiration* (suffocation, drowning, croup, and so on); by *depressed respiration* (anesthesia, collapse); or by a *diminished absorbing surface of the lung* (pulmonary edema, pneumonia); and in carbon monoxide poisoning. Higher concentrations, up to 100 per cent, give prompter relief, and are safe for some hours, but should be reduced to 60 per cent if this gives sufficient saturation of the blood, as it is of little benefit unless its concentration in the air actually inhaled is at least 60 per cent, three times that of ordinary air. Concentrations above this may become injurious if inhaled longer than twelve hours. Its benefits cease within a few minutes after its inhalation is discontinued, so that it must be administered continuously as long as the need for it exists. At high altitudes, undiluted oxygen may be inhaled indefinitely since its pressure is lowered.

Pneumonia responds to continuous oxygen inhalation with marked symptomatic improvement, especially postoperative cases in which the virulence of the infection is generally less. In the oxygen chamber, the patients often show a crisis-like drop of 2° to 5° F. in the febrile temperature, with corresponding decrease of the rate of the heart and respiration. The administration must be continued as long as needed, and must be resumed if its discontinuance is followed by a temperature rise of more than 1° F.

In *pulmonary edema from irritant gases*, the gas exchange in the lung is hindered by the alveolar and bronchial foam. The inhalation of oxygen converts this into an oxygen foam and relieves the cyanosis (Haldane, 1918). It does not, however, help to remove the accumulation of carbon dioxide, so that the air hunger persists (C. F. Hoover, 1918).

According to Haldane, 1918, oxygen inhalation is of considerable benefit in *emphysema* and gives temporary relief in *asthma*, but has little effect on the dyspnea of *cardiac disease* or of nephritis. *Coronary thrombosis* has been reported benefited by oxygen therapy (Barach and Levy, 1934), but animal experiments indicate that it is useless (Wiggers). In *anemia* (whether from hemorrhage or any other cause, such as chlorosis or leukemia) asphyxial conditions result, not from deficient supply of oxygen, but from a deficiency of hemoglobin. The inhalation of oxygen, in these cases, does not increase the quantity of oxygen carried by the hemoglobin, but that carried in solution by the plasma. The practical benefits are not great. Indeed, *in chronic cyanosis generally, oxygen administration is not advisable*, as it tends to interfere with compensation. *In epilepsy*, the number of seizures is reported to be decreased by oxygen administration and to be increased by oxygen deficiency (W. G. Lennox and Behnke, 1936).

Inflammation.—Mustard conjunctivitis is checked by the intravenous injection of substances containing chemically active oxygen, such as iodosobenzoic acid. Conversely, inflammation is intensified by cyanides, which heck oxidation (Amberg *et al.*, 1917).

Administration.—In acute anoxemia the oxygen may be administered undiluted, through a valved mask or pharyngeal or tracheal catheter, after passing the compressed gas from the tank through warm water. Continuous administration is necessary because the oxygen is used immediately and not stored, and temporary anoxemia on withdrawal produces sharper reactions than when the functions have adjusted themselves as well as may be to a given level of oxygen content. This close and continuous control of the oxygen content is practical only in an oxygen chamber or tent. The amount must be controlled by air analysis three or four times daily. The carbon dioxide is kept between 1 and 1.5 per cent, by circulation through alkali, for the respiratory stimulation of higher concentrations fatigues the patient without improving the oxygenation (D. J. Cohn *et al.*, 1939). The fire and explosion danger of oxygen must be remembered. Oil must not be used in the valves.

Intravenous injection of oxygen was described by Tunnicliffe and Stebbing, 1916. It gives rapid relief to the cyanosis and dyspnea. In man, the gas can be injected into a vein at the rate of 600 to 1200 cc. per hour, usually beginning with the rate of 500. The heart must be watched, and the injection stopped if any irregularity appears. Unless great care is used, intravenous injection of oxygen is more likely to accentuate anoxemia, presumably by producing pulmonary gas emboli and cardiac insufficiency (Bourne and Smith, 1927).

Subcutaneous injection of oxygen was introduced by Derose, 1912. McCrae, 1914, believed that it has a limited field as substitute for inhalation. Y. Henderson, 1918, stated that life may be maintained by *intraperitoneal* injection of oxygen. *Oxygen absorption from the skin* occurs to some extent (Shaw, Messer and Weiss, 1929), sufficiently to prevent local cyanosis between two ligatures of the arm, if this is immersed in oxygen (Goldschmidt and McGlone, 1932).

Oxygen, U.S.P. (*Oxygenium*), 99 per cent by vol.

CARBON MONOXIDE

Carbon monoxide (carbonic oxide, CO) has great toxicologic importance, through its occurrence in artificial illuminating gas, especially "water gas" (not in "natural gas") and as a product of incomplete combustion. It is a colorless, odorless and nonirritant gas, so that there is no warning of its presence. It forms a relatively firm compound with hemoglobin, thereby preventing it from carrying oxygen, and thus produces asphyxia. This agrees with ordinary asphyxia, except that the skin and mucous membranes are usually not cyanotic, but are often bright red, owing to the color of CO-hemoglobin. High concentrations depress various vital activities directly, but this depression does not play a significant role in ordinary poisoning.

Historical.—Claude Bernard made an important study of carbon monoxide poisoning (Leçons sur les Anesthétiques et sur l'Asphyxie, 1875) and showed that it does not act directly, but by combining with hemoglobin. He advised treatment with artificial respiration, preferably with oxygen, and transfusion. Good reviews of carbon monoxide poisoning are given in Henderson and Haggard's "Noxious Gases," and by E.M.Killick, 1940.

The **frequent incidence of carbon monoxide poisoning** is partly suicidal, partly accidental. *Accidental* deaths occur chiefly through defective ventilation of rooms where the gas is formed by incomplete combustion, in stoves, damped furnaces, automobile motors, in conflagrations and in mine explosions. These also furnish occasion for chronic poisoning. Carbon monoxide does not occur spontaneously in nature, aside from these conditions. The easy accessibility of the gas, in illuminating gas and automobile exhaust gas, and the easy exitus, explains why it is used in over half of all *suicides* by poisons. The recorded suicides by carbon monoxide in the United States number over 5000 annually, and the actual number is doubtless higher. In New York City, carbon monoxide is responsible for three-fourths of the cases of suicidal poisoning, two-thirds of the accidental and four-fifths of the homicidal (Helpern, 1939).

Occurrence in Artificial Illuminating Gas.—Carbonic oxide constitutes 4 to 10 per cent of ordinary *coal gas* and 30 to 40 per cent of *water gas*. Blast furnace gas contains 24 to 30 per cent, producer gas 22 to 26 per cent. It is the principal toxic ingredient of these gases, but does not account fully for the toxicity of coal gas (A. H. Huebner, 1916). The difference is due to coal tar products (which may be removed by passing the gas through oil). The disagreeable odor of gas is due to sulfur compounds. These are not toxic, but serve as warning of the escape of gas. They are removed by filtration through soil, so that underground breaks in gas mains are especially dangerous. *Automobile exhaust gases* contain an average of 6 per cent of CO, roughly 1.4 liters per minute per horsepower. The engine of a small automobile when running in a small closed garage would contaminate the air to a dangerous degree in about three minutes and be fatal within five minutes (U.S.P.H.S.).

Manner of Action.—In the concentrations reached in intact animals, carbon monoxide acts only by displacing oxygen and has no direct action of any kind; for if an animal is made to breathe oxygen under 2 atmospheres pressure (which renders it independent of the hemoglobin), the addition of carbonic oxide in any amount produces no symptoms.

Action on Hemoglobin.—Carbon monoxide forms a firm compound, carbonic oxide hemoglobin, with the blood pigment. Its spectrum differs but slightly from that of oxyhemoglobin, but it is not reduced by ammonium sulfide (Hoppe-Seyler, 1864, 1865). It has a cherry red color (Piorry, 1826), quite different from that of oxyhemoglobin, especially when it is diluted. This forms one of the best tests for its presence. The ochre tint can also be distinguished microscopically in the corpuscles after poisoning (Bernard).

The scarlet color of the blood is observable at *necropsy*, and the CO bands have been demonstrated six weeks after death (Wachholz and Lemberger, 1905). With survival, they have been present for ninety-six hours. In some parts of the body the blood may appear black, presumably when death occurred before the CO was uniformly distributed; but even the black blood gives the CO-hemoglobin spectrum. The cadaveric ecchymoses have a rose color (Brouardel, Les Asphyxies; he suggested its use to preserve the red color in anatomical specimens).

The CO behaves toward hemoglobin essentially as if it were an isotope of oxygen (E. T. Adams, 1934), but with a relative affinity about three hundred times greater. The reaction with hemoglobin may be represented as $HbO_2+CO \rightleftarrows HbCO+O_2$. With the CO in the atmosphere of $\frac{1}{300}$ that of oxygen, *i. e.*, at 0.07 per cent by volume, half of the hemoglobin would be transformed to carbon monoxide hemoglobin.

In the absence of oxygen, the combination of hemoglobin with CO_2, and the dissociation of carboxyhemoglobin, follow the same laws as those of oxyhemoglobin, but the reaction with carbonic oxide is much slower than with oxygen, in combining but especially in releasing; under body conditions about a tenth as fast in combining, about a sixtieth as fast in dissociation (Roughton, 1934). This slow release accounts largely for the greater "affinity" of carbonic oxide hemoglobin. Light, temperature and *p*H affect the combination and dissociation in different degrees; light lowers the equilibrium content, (*K*) by accelerating the dissociation of HbCO; increase of temperature also lowers (*K*) (Hartridge, 1912). It is not altered by barometric pressure (J. L. Lilienthal, Riley *et al.*, 1946). The (*K*) is practically independent of salt content, laking or purification of the hemoglobin (F. J. W. Roughton, 1934), but it varies considerably for different animals. At 15° C., it is 570 for dogs' hemoglobin, 120 for rabbits'. The affinity of *myohemoglobin* for carbon monoxide is much less than that of blood hemoglobin (review, E. M. Killick, 1940). Increase of the CO_2 in the blood decreases the affinity of hemoglobin for CO relative to O_2, so that hypercapnia tends to more rapid elimination of carbon monoxide (Stadie and Martin, 1925).

Fate.—The *absorption* and excretion of carbon monoxide occur exclusively through the lungs, as it is but little soluble in water (0.0178 per cent by volume at 40° C.). It is not absorbed through the human skin (Schütze, 1927) and does not penetrate through the skin of rabbits, while CO_2 and NH_3 do so readily (E. Burgi, 1936). The *CO is excreted* (*unchanged*); practically none is oxidized to CO_2. It may penetrate post mortem into a cadaver, but so slowly that it cannot be demonstrated in the internal organs (Stoll, 1909). Claude Bernard observed that CO delays the postmortem degeneration of blood corpuscles, the serum separating very clear. Oxidation of CO in tissues is less than 0.1 per cent (Gregersen, 1945; isotope). *In vitro*, skeletal and heart muscle may consume up to three times as much oxygen, in a mixture of 79 per cent CO and 21 per cent oxygen, as in ordinary air; but other tissues show little increase (Carleton and Fenn, 1938). The oxidation of CO in frog skeletal muscle is accomplished by a distinct enzyme system, which is inhibited by cyanide, azide and hydroxylamine. The *cytochrome oxidase* system is inhibited by CO in many cases (J. N. Stannard, 1940). With yeast and germinating seedlings the effects on oxygen consumption and CO_2 production appear more complex (Tang, 1932).

After mild CO poisoning in man, about 90 per cent of the inhaled CO is eliminated by the lungs in the first four hours; but during the first hour the expired air contains only 60 to 70 per cent of the CO that leaves the blood. The remainder is probably held temporarily by the hemoglobin pigments outside the blood stream (Roughton and Root, 1945).

Course of Carbon Monoxide Poisoning.—The phenomena agree with those of ordinary asphyxia, except that cyanosis may be absent; the skin is pink or pale, and the lips are bright red, the color of CO hemoglobin. This is of diagnostic importance. The effects are insidious, the person becoming unconscious often with no premonitory symptoms, "the patient gliding imperceptibly from waking to sleep and from sleep to death." The clinical cases may be classified as acute, relapsing and chronic (McConnell and Spiller, 1912). The *symptoms of acute illuminating gas poisoning* generally begin with a feeling of discomfort, throbbing blood vessels; dizziness, headache, weakness and sometimes nausea and vomiting; sometimes pain in the extremities and muscular twitching. The temperature is normal, the pulse full and bounding, the blood pressure elevated; feeling of constricted thorax; pupils widely dilated; gradual drowsiness, stupor and *unconsciousness*. After this has set in, the respiration becomes accelerated and stertorous; the skin dusky, often with a diffuse reddish coloration, or pink patches, sometimes with blisters. Reflexes are lost; involuntary evacuations of urine and feces are exceptional. Tetaniform convulsions may occur and be followed by marked muscular rigidity, especially in the jaws. The convulsions are produced only in very rapid poisoning, however, and are therefore rare clinically. The pulse and respiration gradually weaken, ending in apnea, and finally arrest of the heart. Death sometimes occurs acutely through aspiration of vomited matter during unconsciousness. *Recovery* is often slow, but it may occur even when the coma has lasted two or three days. Convalescence is also often tardy, with pulmonary and nervous sequels. Patients who recover consciousness under treatment suffer for several days from headache and dizziness, perhaps with some gastric distress, due to cerebral edema (H. S. Forbes *et al.*, 1924). *Different sources of CO* may introduce impurities which modify the effects. The coma is longer and more severe in illuminating gas poisoning than with pure CO (Y. Henderson and Haggard, 1918, 1922). In automoblie gas, the benzene vapors play a minor part.

Individual Functions in Acute Poisoning.—Carbon monoxide produces progressive fall of *blood pressure*, and marked slowing of the *heart*, apparently not affected by section of the vagi. The *respiration* is at first slow and shallow, then slower and deep (D. E. Jackson and Chance, 1925). If the carbon monoxide is diluted with nitrogen instead of oxygen, the blood pressure rises (Brewer, 1937). *Heat regulation* is disturbed and the temperature may either fall or rise. *Protein metabolism* is markedly increased, even in relatively mild poisoning, probably by a central action. The nitrogen excretion may reach three to four times the normal level and remain high for one or two weeks. *Glycosuria* by mobilization of hepatic glycogen occurs in one-twelfth to one-third of the patients. It is relatively mild and short, generally not longer than a day (H. Jacoby, 1930). *Albuminuria* indicative of nephrosis occurs in about the same ratio; as also urobilinogen, showing some hepatic insufficiency. The *necropsy findings* in sixty-three deaths from garage poisoning, reviewed by McNally, 1928, revealed small hemorrhages in many organs, including the brain. The brains of animals killed acutely with carbon monoxide are edematous and markedly congested with severe perivascular perineuronal edema, most marked in the corpus striatum, cortex and dorsal motor nucleus of the vagus. The vessels throughout are dilated and packed with red cells, with a few petechial hemorrhages. The lesions in slow poisoning, with eight to fifteen hours' exposure to 0.2 per cent, differ only in degree (Sayers *et al.*, 1934). Bilateral softening of the globus pallidus occurs in almost every case of acute asphyxia in which coma has lasted longer than twenty-four hours (Helpern, 1939).

Direct Actions on Isolated Organs and on Lower Organisms.—Tadpoles are not injured by saturating the water with CO. Intact *frogs* lose their *reflexes* in pure CO after about two hours, about the same as in hydrogen (Kochmann, 1920). If the vessels were perfused with saline to remove all hemoglobin, exposure to CO abolishes the remaining reflexes, indicating direct depression of the central nervous system (Fallori, 1932). It also depresses the exposed cerebrospinal axis (Baglioni preparation) of the toad (Mitolo, 1929, 1931). The isolated heart (Straub preparation) is not materially injured by pure CO (Kochmann). The conductivity and excitability of *nerve trunks* is depressed reversibly, as in nitrogen. The direct excitability of skeletal *muscle* is greatly diminished by dilute CO, and recovery requires long aeration (F. Krause, 1930). It may be assumed that the CO binds the myohemoglobin. *Infusoria* and *ciliated epithelium* are checked, but not killed. The growth of *bacterial* cultures is slightly retarded. The germination of the seeds of higher plants is not affected. The gas kills plants when applied to the leaves, but not when applied to the roots (Heider, 1914). Oxidation in insects and plants is retarded (Haldane, 1927).

Relation of CO Concentration and Effects.—The effects of carbon monoxide depend upon the amount of hemoglobin which it binds and withdraws as oxygen carrier. This can be calculated from the carbon monoxide tension of the air; but the element of time also enters, to allow for the dead space of the air passages and for absorption of adequate quantities, especially with dilute mixtures (Gréhant).

Air containing 0.07 volume per cent of CO (7:10,000) is capable of converting 50 per cent of hemoglobin into carbon monoxide hemoglobin. *In vitro*, this is accomplished instantly; but several hours of inhalation would be necessary to approach this result for a man, for only 210 cc. of CO would be inhaled in an hour. If this were all absorbed and bound by hemoglobin, it would suffice to saturate only a fifth of the hemoglobin, instead of a half. In fact, however, only about half of the carbon monoxide is absorbed during the early stages of exposure. Anything which increases respiration, such as severe muscular work, increases the rapidity with which equilibrium is attained. In man at rest, half of the final saturation is reached in about forty-seven minutes; twice as rapidly if walking; three times, with fairly hard work. Small individuals approach saturation more rapidly, because the volume of the respiration varies with the body surface (in rest), while the volume of the blood varies with the weight. For a given concentration the time till unconsciousness is about twenty times as long for man as for a mouse or canary. The *elimination* varies in the reverse direction. About a third of the absorbed gas is eliminated in two hours after the exposure has been discontinued; the remainder much more slowly (Killick).

For ordinary conditions, Henderson and Haggard propose a *toxicity factor* obtained by multiplying the concentration of CO in the air (volume per 10,000 or cubic centimeter in 10 liters) by the time in hours. If this factor is below 5, there are no acute symptoms. The effects begin to be perceptible with 6, as slight headache and inertia. With 9, the headache is severe, with nausea. With 15 to 20, there is serious danger; 40 or more per 10,000 is fatal in less than an hour.

The following tabulation, chiefly from data of Sayers *et al.*, gives the *actual ranges of the degree of hemoglobin saturation in man* at rest:

CO in Air, Parts per 10,000	Hours of Exposure	Percent of Hemoglobin Bound by CO	
		Under These Conditions	At Complete Equilibrium
1 to 2	5 to 6	1 to 20	13 to 23
3	4 to 5	22 to 27	33
4	1	15 to 19	38
4	2	21 to 23	
	With Exercise		
2.5	1	14 to 16	
3.3 to 3.6	1	17	
4	1	23	

The *correspondence of the effects with the percentage of hemoglobin saturation* is as follows (McNally, 1928; Dreser, 1891; Balthazard and Nicloux, 1911): 0 to 10 per cent: no symptoms. 10 to 20 per cent: tightness across forehead, possibly some headache; flushed skin; yawning. 20 to 30 per cent: headache, throbbing temples; dizziness and palpitation on exertion. 30 to 40 per cent: severe headache, weakness; dizziness, dim vision, nausea, emesis. 40 to 50 per cent; as above, plus increased respiration and pulse rate, coma; intermittent convulsions; Cheyne-Stokes respiration. 60 to 70 per cent: as above, plus weakened heart and respiration; possibly death. 70 to 80 per cent: weak pulse, slow respiration; respiratory failure; death. 90 per cent: prompt cardiac arrest. The limit of safety is 18 to 20 per cent (Dreesen and Sievers, 1946).

Toxic Concentrations in the Air.—Gruber, 1881, found that 0.024 per cent is harmless even after several hours. The toxicity begins with about 0.05 per cent, is severe with 0.07 per cent, and dangerous with 0.16 per cent; 0.2 to 0.4 per cent is generally fatal. A man at rest would collapse within an hour when exposed to 0.2 per cent (Burrell and Gauger, 1919). Several persons in the same room may be affected in different degrees, owing partly to air currents (the gas is slightly lighter than air: sp. g., 0.967), partly to differences in the absorption velocity.

Newborn rats and rabbits have relatively high resistance, which declines by successive steps for two or three weeks, when it becomes stable. Newborn guinea pigs do not show this resistance, presumably because they are more mature (J. A. Cameron, 1941). *Fetal blood* may contain so much less CO than that of the mother (Quinquaud and Gréhant) that cesarean section may be indicated to save a fetus near term.

Sequels.—The severe and prolonged anoxia which is liable to occur in carbon monoxide poisoning may cause cellular disorganization, functional and organic, the latter persistent or permanent. The direct anoxic damage is complicated by the effects of capillary injury, especially in the lungs, skin and central nervous system, with edema and small hemorrhages, followed by perivascular infiltration and focal necrosis.

The principal sequels are: aspiration pneumonia, often fatal; palpitation, localized hyperemias, gastro-intestinal disturbances, transient asphyxial glycosuria (review, S. Weber, 1904), cutaneous eruptions, herpes and vesication, localized edemas, gangrene (J. E. Briggs, 1919). Nervous symptoms of central and peripheral origin may develop some weeks after apparent complete recovery ("*relapsing type*"). The *pneumonia* may set in after one or two days, or more quickly in serious cases by the confluence of localized bronchopneumonic patches and lead to death in a few days. The temperature may rise excessively high, presumably because the heat centers are injured. *Myocardial damage* may develop slowly, with the same pathologic foundation as in the brain and other organs. These have also been produced in animals. Coronary thrombosis is frequent (H. G. Beck and Suter, 1938). *Polycythemia* may occur promptly or progress slowly through several months and last for years. It has been attributed to damage of the basal ganglia.

Nervous and mental changes are serious and persistent only in severe cases of profound and lasting anoxemia, when resuscitation was difficult and coma prolonged. They do not occur from chronic exposure to low concentrations.

In a study of forty-three patients with persistent mental nervous sequels, Shillito *et al.*, 1936, found that in two-thirds the symptoms had started immediately after the poisoning; in the other third a clear period of seven to twenty days had intervened. About half of the patients eventually recovered. The *mental sequels* were chiefly confusion psychosis with disorientation, lack of judgment, and amnesia. Aphasia was much less common. Hallucinations, delusions and convulsions were not conspicuous. Nervous symptoms ranged from slightly increased deep reflexes to well advanced Parkinsonian syndrome, attributed to degeneration of ischemic areas in the thalamic region and basal ganglia. Some patients develop sensory disturbances (violent headache, lancinating pains in the extremities) and peripheral motor neuritis. Rutenburg, 1939, reported *nystagmus* and *deafness* from injury of the eighth nerve, appearing in twenty-four to forty-eight hours in actute poisoning, and also in chronic poisoning.

Chronic exposure to carbon monoxide occurs industrially and in the daily life of cities. The effects are those of anoxemia. Some acclimatization occurs by habitual exposure to low concentrations (Killick, 1937), chiefly through polycythemia, and by adaptation of the circulation; but the general health is likely to suffer (H. G. Beck, 1936).

The *clinical symptoms* are headache, naüsea, vertigo, weakness, anemia, slowed intellect and failure of memory, and all the phenomena of the acute type more slowly developed. The memory for recent events is impaired much more than for those of older standing (S. Brown, 1906). The nervous phenomena have been referred to serous leptomeningitis ((Zieler, 1897). Slow CO poisoning shows marked histological disintegration of tissues, extreme hepatic congestion and atrophy of the liver cells, attributed to cardiac failure (J. A. Campbell, 1929). The symptoms of chronic poisoning occur with 4 per cent saturation of the blood, and continued exposure to 1:20,000 air may therefore be considered injurious (E. Kohn-Abrest, 1927). Exposure of dogs to 0.01 per cent for five and one quarter hours daily produces electrocardiogram changes, degeneration of cardiac muscle, and damage in the cerebral and cortex and basal ganglia (F. H. Lewey and Drabkin, 1944).

Acclimatization.—Men exposed repeatedly to low concentrations develop considerable tolerance as regards symptoms, but without change in the hemoglobin content or cell count. Somewhat higher concentrations, 0.01 to 0.05 per cent for several hours daily for several months, gradually induce hypersusceptibility and neurasthenic symptoms (Killick). *Guinea pigs* can be accustomed to live for months in an atmosphere by which 25 per cent of their hemoglobin is saturated with CO. This tolerance is attained by an increase of the corpuscles and hemoglobin, so that the oxygen capacity becomes almost normal. *Rats* exposed to ⅓ per cent CO for an hour daily for 150 consecutive days lost weight and became unkempt. The hemoglobin percentage and the cell:plasma ratio rose and remained high, with considerably increased tolerance (acclimatization). Both sexes, however, became sterile, the males much earlier than the females (I. R. Williams and Smith, 1935). Mice exposed to the same concentration also developed infertility and cardiac hypertrophy (J. A. Campbell, 1934). Dogs and guinea pigs react with falling of hair, salivation, temporary fall of temperature. The hemoglobin rises slightly in dogs (H. Fetzer and Weiland, 1934).

Incidental CO concentration in city air arises chiefly from automobile traffic. The air in half of the cars examined at random on highways contained measurable traces, and 7 per cent of the cars had "dangerous concentrations" (L. T. White, 1934). R. F. Sievers *et al.*, 1942, found that the air in the Hudson Tunnels averages 0.007 per cent. Traffic officers on duty there for thirteen years showed no ill effects. Their CO hemoglobin ranged from 0.5 to 13 per cent. Gettler and Mattice, 1933, found the hemoglobin bound by CO in the blood of persons living in rural localities less than 1 per cent; in persons living in New York City under conditions of minimal exposure, it was 1 to 1.5 per cent; in street cleaners it rose to 3 per cent; and in two taxicab drivers it was 8 and 19 per cent. Tobacco smoking may also increase the CO of the blood somewhat (to 3 or 10 per cent, Dreesen and Sievers, 1946), but none of the smokers in the rural group had over 0.64 per cent. CO is alone concerned in the chronic effects of automobile exhaust gas (Supfle and May, 1934).

Treatment of CO and illuminating-gas poisoning is usually successful if begun while the heart is beating. In the presence of a large excess of oxygen, the carbonic oxide hemoglobin is again decomposed, and the CO eliminated (not burned). The treatment therefore consists in artificial respiration or, better, the inhalation of oxygen containing 5 or 10 per cent of CO_2, the latter being more efficient (D. C. Walton *et al.*, 1926). Epinephrine may be injected (½ to 1 cc. of 1:1000) to contract the spleen and so mobilize its unpoisoned corpuscles. Bleeding with transfusion of healthy blood is effective (Claude Bernard; Worm-Mueller; Crile and Lenhart, 1907). Patients should not be exposed to cold. With respiration, natural or artificial, of ordinary air, the CO-hemoglobin is decomposed below the danger limit within an hour, the CO being practically eliminated in two or three hours. It is therefore superfluous to use oxygen or transfusion after an hour. If the coma continues longer than an hour, it is due to persisting injury of the nerve centers by the early asphyxia. Once this injury has occurred it would not be helped by oxygen. The existence of acidosis indicates alkalis; otherwise the late treatment would be expectant (J. E. Nadler *et al.*, 1934). The *prognosis* varies with the duration of the exposure and of the coma. It is bad if the coma has lasted more than forty-eight hours, of if edema or cutaneous blebs have developed (G. I. Jones, 1909). Even in favorable cases, recovery is rather more slow than with most gases; but the acute effects have generally disappeared within three hours.

The displacement of CO by oxygen is rather slow. (In a case of industrial poisoning with 40 per cent COHb saturation, this was reduced to 25 per cent after an hour of oxygen administration; to 8 per cent in four hours; and traces were still present after twenty-four hours; Nicloux and Herson.)

Methylene blue injection as an antidote to carbon monoxide poisoning has been advocated especially by M. M. Brooks, 1933 (50 cc. of 1 per cent, intravenously), with the expectation that it would supply oxygen to the tissues directly. She also reported that it changes CO-hemoglobin into oxyhemoglobin; but others claim that it forms methemoglobin and would do more harm than good (Haggard and Greenberg, 1933). Mack and Smith, 1933, found that it had no effect on the survival of CO poisoned cats, in either direction.

OXYGEN CONVEYANCE BY HEMOGLOBIN

The ability to combine loosely with oxygen, so that this is readily released, is a peculiar and most essential property of hemoglobin, although this has other important functions in neutrality regulation, as an amphoteric protein, acting as a weak acid buffer and as a base for the transport of carbon dioxide, with which it forms an alkaline bicarbonate. It does not bind CO_2 directly in the sense that it binds oxygen or carbon monoxide.

Chemical Structure.—Hemoglobin consists of a characteristic colored iron compound, *hemin*, and a colorless protein, globin. These can be separated and may recombine under certain conditions (Robert Hill). The globin may be replaced by much simpler bases, such as pyridine or nicotine, yielding *hemopyridine* or *hemo-*

nicotine. They react with oxygen similarly to hemoglobin. *Hemin* (Teichmann, 1853) is a relatively simple tetrapyrrole compound containing four atoms of ferrous iron bound to the pyrrole nitrogen. The iron is its active nucleus, and the biologically important reactions of hemin are reactions of complex iron compounds (O. Warburg, review, 1928).

Reaction with Oxygen.—The iron of the hemoglobin reacts reversibly with molecular oxygen, one molecule of oxygen for each atom of iron, to form oxyhemoglobin: $Hb + O_2 \rightleftarrows HbO_2$. It is not known whether the O_2 links directly to the Fe^{++}, but the ferrous is not oxidized to ferric iron. Oxyhemoglobin is a true stoichiometric chemical compound, but the union is loose and can be dissociated by relatively simple conditions, such as change ofp artial pressure of oxygen or of *p*H. Oxyhemoglobin is more acid than hemoglobin (Haldane), so that the saturation curve is not in simple or exponential proportion of the oxygen pressure, but sigmoid. This aids in expelling CO_2 in the lungs. Fetal hemoglobin is reported to have a greater affinity for oxygen than that of adults (Barcroft, 1936), attributed to differences in the globin fraction. Normally, saturated oxyhemoglobin carries about 1.36 cc. of O_2 per Gm. This may be replaced by the same volume of CO (D. B. Morrison and Hisey, 1935). Normal blood at complete (100 per cent) saturation carries 18 to 20 cc. of oxygen per 100 cc. of blood. The saturation is practically complete (ca. 97 per cent) in arterial blood in the body, or *in vitro* with 15 per cent of oxygen in the air. Reducing the oxygen of the air to 9 per cent reduces the hemoglobin saturation to 90 per cent. Mixed venous blood has about 75 per cent saturation; with vigorous work this may fall to 40 per cent or even less. Carbon dioxide or lowered *p*H decreases the oxygen-combining power of hemoglobin.

The **reaction of hemoglobin with carbon monoxide** appears analogous to that with oxygen, the distribution being determined by the partial gas pressure: $\frac{Hb.O_2}{Hb.CO} \times \frac{CO}{O_2} = K$.

Other Molecular Hemoglobin Compounds.—The nature of these is less understood. There is a nitric oxide hemoglobin, HbNO, of a cherry-red color (also a NO methemoglobin), and a sulfhemoglobin, possibly HbH_2S, but the mode of combining may be quite different. It is doubtful whether these can be formed in the body under normal conditions.

Methemoglobin is formed quite differently, by the oxidation of the bivalent (ferrous) iron of hemoglobin into the trivalent (ferric) iron, which cannot carry molecular oxygen: $HbFe_2''O_2 \rightarrow HbFe'''OH$. This may again be reduced to oxyhemoglobin, but only slowly. The oxidation to methemoglobin can be accomplished *in vitro* by oxidizing agents, such as ozone, peroxides, chlorates, quinone, ferricyanide. Of these, only chlorate is effective in living animals, but methemoglobin is formed in life by various agents that are not directly oxidizing; for instance, by *aniline* and nitrobenzene (von Issekutz, 1939). Both form *phenylhydroxylamine*,

$C_6H_5.N\begin{smallmatrix}H\\OH\end{smallmatrix}$, which oxidizes to azoxybenzene,

$C_6H_5.N\underset{O}{—}N.C_6H_5$. Oxygen is liberated in this reaction and forms methemoglobin. *Paraminophenol* is also formed from aniline and nitrobenzene, and part of this undergoes transformations, probably by way of *quinonimine,* which liberate active oxygen and therefore form methemoglobin. As this restores the reagent, it acts as a catalyzer, so that a small quantity may form a large amount of methemoglobin. *Nitrites* also form methemoglobin in the living animal. In rabbits, 0.15 Gm. of $NaNO_2$ per Kg. converts 15 per cent of the hemoglobin into methemoglobin. *Dextrose* injection (1 to 2 cc. of 1 per cent per Kg.) is reported to convert this back into hemoglobin, within five minutes. It acts similarly *in vitro* (M. M. Brooks, 1934). However, W. W. Cox and Wendel, 1941, report that variations in the dextrose concentration from 50 to 250 mg. per 100 cc. have no effect on the rate of methemoglobin formation, in animals or *in vitro*. *Methylene blue* acts in both directions, forming methemoglobin from oxyhemoglobin, and oxyhemoglobin from methemoglobin. It speeds greatly the reduction of methemoglobin by ascorbic acid (C. S. Vestling, 1942).

Methemoglobin tends to revert to hemoglobin at the rate of about 12 per cent per hour *in vivo* or *vitro* (Cox and Wendel, 1941). Many substances that form methemoglobin also form disintegration products, "*verdohemochromogens,*" intermediate to bilirubin. These have been mistaken for sulfhemoglobin, which often accompanies them (F. Jung, 1939).

The *physiologic significance of methemoglobin formation* rests on inability to carry out the functions of oxyhemoglobin. This produces asphyxia of the tissues. Its presence also interferes with the release of oxygen by oxyhemoglobin (R. C. Darling and Roughton, 1942). Normal blood, however, contains a small amount of methemoglobin, 0.01 to 0.5 Gm. per cent (W. D. Paul and Kemp, 1944); and pure methemoglobin solutions may be injected into the blood, without causing any symptoms in normal dogs. In acidotic dogs it produces renal injury, hydropic degeneration in the proximal and necrosis in the distal convoluted tubules (Bing, 1944). The half-life of methemoglobin in the circulating plasma is about eight hours, and practically all has disappeared in three days. Much is converted into oxyhemoglobin, about a third is excreted as such or as oxyhemoglobin into the urine (Van Slyke, 1945), part is secreted by the bile; the remainder goes to the hematopoietic organs. The restoration of oxyhemoglobin from methemoglobin is considerably slower than from carbonic oxide hemoglobin, and the effects are correspondingly more lasting. They are considerably less dangerous, however, than those of carbon monoxide. Dogs injected with sodium nitrate became unconscious when 80 per cent of the hemoglobin is changed to methemoglobin; cats exposed to carbon monoxide became unconscious when the CO hemoglobin reached 60 per cent, and died at 71 per cent (D. Lester and Greenberg, 1944). The conversion of a third of the hemoglobin into methemoglobin causes only slight symptoms; life is still possible when three-fifths of the hemoglobin has been replaced. Life becomes extinct when the hemoglobin has sunk to one-third. The condition becomes dangerous only if the methemoglobin former continues its action. This does not occur with therapeutic doses of any of these drugs, but may contribute to the fatal ending in poisoning. The *symptoms* are those of asphyxia. There is a peculiar blue tint about the lips and finger nails. In severe cases the blood is chocolate-colored and thick, the urine discolored, the respiration increased in rate and volume, the pulse rapid.

Muscular weakness develops, followed by collapse, unconsciousness and death by respiratory failure, sometimes preceded by convulsions. The methemoglobin gradually returns to oxy- or reduced hemoglobin after death, so that an examination after several days may fail to reveal its presence.

Most of these drugs transform the hemoglobin inside the corpuscles, without injuring the vitality of the latter; but some cause, in addition, a *breaking up of the corpuscles*, and the proteins and other substances liberated produce injury to the kidney—albuminuria, glycosuria, methemoglobinuria, and the like. It is also claimed that it causes the sudden formation of fibrin ferment, which may then cause extensive intravascular clotting. The debris is credited with causing emboli. A small destruction, such as may be caused by the subcutaneous injection of glycerin, has no permanent injurious effect. The destruction of the corpuscles produces anemia, which in turn stimulates the bone marrow, so that with chronic exposure the blood count may be increased, with decreased color index, and imperfect cells in the blood stream.

The specific action of the drug is joined to these methemoglobin effects, and may entirely overshadow them. Thus, rabbits die of potassium chlorate before it comes to any methemoglobin formation. Herbivorous animals are, as a rule, much less subject to the formation of methemoglobin during life, although their shed blood does not differ in this respect from that of carniverous animals (Hanzlik and Richardson, 1934).

Hemin compounds occur as "*cytochrome*" in all cells, including plants, bacteria and yeasts (Keilin, 1925). Hans Fischer showed that yeast can synthesize hemin from porphyrine and iron. **Hematoporphyrin** is hematin with the FeOH group replaced by H_2, but retaining the four-linked pyrrole group. **Hemocyanin,** the copper-containing oxygen-conveying pigment of crustacean blood (which is blue when oxygenated, colorless when reduced) can also yield oxygen to mammalian tissue. It does not pass into the urine (R. Bing, 1938).

Intracellular Oxidations.—The food materials in the tissues are not readily oxidized by molecular oxygen, at body temperature. Oxidative metabolism is accomplished for the most part by various "chains" of oxidation-reduction of graded potentials, activated by special enzymes, which transfer hydrogen atoms from the substrate through a series of chemical "carrier" compounds until it finally unites with oxygen. The cellular oxidizing ferments are generally made up of two components, a specific protein component and one or more nonprotein substances, "co-enzymes," often related to the B-complex vitamins; thiamine, nicotinic acid, riboflavin and ascorbic acid are especially important for the intermediate metabolism of carbohydrates. The co-enzymes are not merely accelerators, but essential links in the chain, uniting with hydrogen and passing it on to the next compound. Neither enzyme nor co-enzyme of these systems can act without the other (review, C. A. Elvehjem, Wilson *et al.*, 1942; E. S. G. Barron, 1939; A. Szent Györgyi, 1938).

The oxidation systems involve chiefly three types of enzymes: (1) *Dehydrogenases*, which cause the "donation" of hydrogen to a suitable "acceptor," eventually combining with oxygen to form hydrogen peroxide or water. One group, the "aerobic," use molecular oxygen directly; the "anaerobic" require the cooperation of some other system, such as cytochrome, "yellow enzyme," methylene blue and other redox dyes of similar potential. (2) *Oxidases, which activate oxygen without the intervention of peroxide*, appear to be metallo-proteins. The most important is *cytochrome*, or indophenol oxidase, which occurs probably in all cells, plant as well as animal. It has been estimated that about two-thirds of the normal respiration of most animal tissues occurs through cytochrome. It is an iron compound, a heme derivative, a mixture of three hemochromogens, A, B and C, originally described as myohematin by MacMunn, 1886, and rediscovered by D. Keilin, 1925. It is especially abundant in the rapidly contrasting muscles of insects. Its oxidizing action is inhibited by reagents that stabilize metal groups, especially by cyanide, hydrogen sulfide, sodium azide, carbon monoxide. The CO inhibition is reversed by light of definite wave length (F. J. Ogston and Green, 1935). Formaldehyde and aliphatic narcotics inhibit its oxidation, but not its reduction. Warburg's theory (1928) attributes cellular oxidation to the catalysis by the heme iron of the "respiratory enzyme" (indophenol oxidase). (3) *Catalase*, which decomposes hydrogen peroxide into water and ordinary oxygen, and *peroxidase*, which decomposes peroxide and activates the liberated oxygen toward readily oxidizable substances, are also hematic derivatives, but they are probably not important in cellular oxidation (G. Bancroft and Elliot, 1934).

◆

HYDROCYANIC ACID AND CYANIDES

Hydrocyanic (prussic) acid is perhaps the most rapidly acting poison. It produces death with asphyxial symptoms, by hindering the oxidative processes of the tissues. It also interferes with most catalytic reactions and is therefore a general protoplasmic poison. Compounds containing the CN radical are toxic only if they can liberate HCN. Ferro-, ferri- and sulfocyanides (thiocyanates) are stable and therefore do not show these effects.

Occurrence.—Hydrocyanic acid exists in glycosidal form as *amygdalin* in many plants, especially in the seeds and leaves of the cherry, almond, peach, and so on. This amygdalin, when pure, is almost entirely harmless, except as it is decomposed in the body. But in most plants it coexists with the ferment emulsin, by which it is split up in the presence of water into hydrocyanic acid, glucose and benzaldehyde. One Gm. of cherry kernels yields 1.7

mg. of hydrocyanic acid; 1 Gm. of bitter almond pulp yields 2.5 mg. of hydrocyanic acid. The ancient Egyptians are said to have prepared it as a poisonous extract from peach and other plants, and the Romans used these as a suicide poison (Blythe).

The most important cyanogen (CN) compounds are the acid (prussic acid, official as the dilute, 2 per cent solution) and cyanide of potassium. Mercury cyanide has mainly a mercury action. The cyanide action is also shared by the organic esters (*nitriles*); these differ from potassium cyanide only in the rapidity with which the cyanogen is liberated (Lang, 1894; Heymans and Masoin, 1897, 1901; R. Hunt, 1904).

Etiology of Acute Cyanide Poisoning.—Hydrocyanic acid is rarely used in criminal poisoning (0.5 per cent of the recorded cases), because its quick action leads to the detection of the crime; but cyanides are often employed in suicide. Death is prompt and practically certain in spite of any treatment, if enough has been taken. Potassium cyanide can be easily obtained through its technical uses in photography, electroplating, cleaning of metals. Many fatal accidents have occurred from fumigations with the gaseous acid.

Pure hydrocyanic acid is very volatile and toxic. Scheele, who discovered hydrocyanic acid, was killed by the vapors set free in the breaking of a flask of this fluid.

Hydrocyanic acid gas fumigation is effective against all forms of vermin, "from rats to roaches" (McClintock et al., 1911). It is also used extensively for fumigating food, as well as other goods, and houses. It is safe if it is properly applied and followed by thorough airing (A. Cousineau and Legg, 1935). It is available as liquefied gas in steel cylinders, or it may be produced by the reaction of sodium cyanide with 50 per cent sulfuric acid, or with sodium chlorate and 50 per cent hydrochloric acid; or it may be solidified by adsorption on fullers' earth or on unsized paper disks. It is not injurious to most goods; it is not corrosive, and a concentration that kills rats does not injure the flavor of tea or tobacco; but fumigated eggs usually do not hatch. It penetrates readily, so that weevils in the center of a car of flour are killed by six hours' exposure. Aeration removes it completely and rapidly, so that an hour's airing renders a mattress safe for sleeping; but water holds it tenaciously, especially if cold. The objectionable feature is the *liability to accidental poisoning*. This depends partly on the facilities for diffusion: In the open air it dissipates so rapidly that it is difficult to reach fatal concentration. It effuses through brick walls, although rarely in the time of a fumigation, unless there are cracks. Careful technic is necessary to render it safe. Good protection is furnished by masks charged with a mixture of charcoal, sodium hydroxide and pumice; but toxic quantities may be absorbed by the skin on prolonged exposure. Detoxification of the air should be tested by benzidine acetate: copper acetate paper. Fire usually burns HCN to innocuous gases (C. L. Williams, 1931). It is said that about 5 to 10 per cent of people are unable to detect the characteristic odor. Lacrimator gases have been added as a warning, but are not reliable, as their diffusion is different.

The *minimum lethal concentration* for cats is about 0.35 mg. of HCN per liter of air; severe but not fatal symptoms may arise with five or ten minutes' inhalation of 0.1 mg. per liter; 0.05 is tolerated for hours (Flury and Wolfgang, 1919). The toxicity of HCN in air is reviewed critically by Barcroft, 1931. Calcium cyanide solution is a convenient means of exposing animals to constant HCN gas concentrations (Robbie and Leinfelder, 1945). The *absorption of HCN and other gases by the skin* was tested on the arm, by Schultze, 1927. It may reach dangerous proportions in twenty-seven minutes. It has been studied on animals by Flury and Walther, 1942. *Hydrogen sulfide* proved dangerous in sixty minutes, if high concentrations were used. *Carbon monoxide* and *aniline* vapor were practically not absorbed. Guinea pigs and rabbits are readily killed by absorption of HCN gas through the skin. *Spilling of cyanide solution on the skin* is not likely to be toxic, in view of the high volatility.

The fatal dosage of absorbed HCN for man is calculated as 0.7 to 3.5 mg. per Kg. (Halstrøm and Møller, 1945).

Clinical Phenomena of Acute Poisoning by Swallowing Solutions of Hydrocyanic Acid or Cyanides.—In the so-called *apoplectic form, i. e.*, when very large doses are taken, the patient may fall unconscious, often with a loud cry, within ten seconds, and die within two to five minutes, after some convulsions. Ordinarily several minutes may elapse after taking the poison before any effect is noticed; death occurs between fifteen minutes to an hour. The *symptoms* are vertigo, mental dimness, headache, palpitation; then dyspnea, which may be great; the patient then becomes totally unconscious and undergoes violent convulsions. During this stage the heart may be greatly quickened. The respiration becomes difficult and then ceases. The heart at this time is much weakened, but still continues to beat for a short time and then stops. The *mortality* is high: 95 per cent. If the patient survives an hour, *recovery* is the rule. It is often followed by persistent headache, tremors, and so forth. The prompt *diagnosis* of cyanide poisoning is important in view of the treatment. The odor is characteristic, as is also the rapid onset of the symptoms.

At the *autopsy*, the *odor* is noticeable on opening the body. There are no peculiar *lesions*, except with potassium cyanide, which acts as an alkaline caustic. The *blood* is generally liquid and remains so after removal from the body (by interference with the fibrin ferment). Its color is stated to be very dark, but this is not true of all cases: it may be of a bright arterial color. Bright red *ecchymotic* spots, due to cyan-hemoglobin, occur during putrefaction. The final *proof* of cyanide poisoning rests on chemic tests. The poison disappears within two weeks during putrefaction; but remains for a long time if the latter is prevented and if there is no evaporation. *Tests* and the quantitative determination in human tissues are described by Gettler and Baine, 1938. The *strength* of the official (dilute) acid should be 2 per cent, but many samples are much weakened by decomposition. Potassium cyanide is also variable. The pharmacopeia requires a strength of 90 per cent, but the commercial article sometimes contains only 30 to 40 per cent. This accounts in part for the variability in the severity of the symptoms. Another variable factor is the *rate of absorption*. If the stomach is full there is much better chance of saving the patient. Application to raw surfaces or to cuts has given rise to poisoning. The *fatal dose* of absolute HCN is about 0.05 Gm. (1 grain); that of KCN is 0.2 to 0.3 Gm. (3 to 5 grains); that of dilute hydrocyanic acid would be about 2.5 Gm.; 50 to 60 bitter almond seeds would be fatal. Correspondingly larger doses are needed if the drugs are impure or decomposed. The impression prevails widely that prussic acid is one of the most powerful poisons. This reputation is based on its *extremely rapid action*, rather than on its toxic dose.

Chronic Poisoning.—Repeated administration of sublethal doses of cyanides was said to lead to chronic cachexia, without altering the susceptibility to the poison (Schlegel, 1892). Peripheral neuritis has been reported (Collins and Martland, 1908). However, C. J. Reed, 1920, found neither chronic symptoms nor increased susceptibility in dogs exposed daily to sublethal doses of cyanide vapor. Chronic poisoning may be produced by *foods* containing cyanic substances, such as cassavas in Africa, and fermented maize. A. Clark, 1939, found visceral and nervous degenerations in such cases. The glutathione level of the blood had fallen to half the normal level.

Symptoms of Poisoning by Cyanide Gas.—Concentrations of 2 or 3 oz. per 1000 cubic feet produce no noticeable effects within half an hour. Concentrations used to kill rats, 6 to 10 oz. per 1000 cubic feet, cause immediate and progressive *sensation of warmth* over the entire body, due to vasodilatation, with visible rubefaction in five minutes. This is a danger signal. If the exposure is continued, it is followed by prostration, then nausea and vomiting, often with headache; then by difficult respiration, with sensation of tight bands around the chest. This is the final warning. It is soon followed by loss of consciousness, then within ten minutes by paralysis of the respiration and prompt death. Exposure to convulsive concentrations for fifteen minutes is almost always fatal, even if the animal is then removed from the poisoned atmosphere; if convulsions have started, treatment is ineffective. If the unconscious patient is brought into the open air before breathing stops, he usually *recovers* unaided. Nausea, vomiting, fast pulse and headache may last for a time, but he is able to walk home, and is practically well in two or three days, without any serious sequels. If the respiration is stopped, but the heart is still beating, artificial respiration generally leads to recovery, but the after-effects are more severe. A "weak heart" may persist for months. If the heart has stopped beating, there is no hope of recovery.

If lower concentrations of cyanide gas are breathed over longer periods, one-half to several hours, the course is somewhat different, and may take two directions: (1) The patient may lose consciousness, but continue breathing, and finally die in convulsions; or he may recover after several hours of coma, usually followed by extreme weakness and headache, and a slow convalescence of half a year to a year, before the normal is restored. Asphyxial cerebral degenerations may be assumed. (2) Other patients retain consciousness, but fall dead of heart failure on making some extra exertion. Subconvulsive concentrations of cyanide can be prolonged indefinitely, as the natural detoxifying mechanisms are practically inexhaustible, although slow (C. L. Williams, 1931, clinical; E. Heldorf, 1939, dogs). *Cyanide dermatitis* has been described (ref., J.A.M.A., *95:*1690).

Effects on higher animals consist in *fleeting stimulation of certain parts of the central nervous system, followed by depression and paralysis.* The action *begins in the medulla.* The vomiting, respiratory, vagus, pupil-dilator and vasomotor centers are all stimulated, in part reflexly from the carotid sinus. Then comes *unconsciousness,* and after this *convulsions.* In man these are probably mainly medullary in origin. They are followed by paralysis of the whole central nervous system. Involuntary evacuations of feces, urine and semen are frequent.

The **respiration** is at first greatly increased, especially in depth; it then becomes slow, shallow and irregular (Cheyne-Stokes type). It stops considerably before the heart, paralysis of the respiratory center being the immediate *cause of death.*

Respiration is more sensitive to cyanides than the vasomotor center, and this again is more sensitive than the vagus center. Larger doses slow the rate, but greatly increase the depths of respiration. Toxic doses depress and paralyze the center. Boehm and Knie, 1874, showed that the hyperpnea is not due to a reflex arising in the lungs, for it is not affected by section of the vagi (nor by atropine). It was attributed to direct stimulation of the respiratory center, until Heymans showed that the hyperpnea and bradycardia result almost altogether from stimulation of the chemoreceptors of the carotid glomus and aortic body (Heymans, Bouckaert *et al.*, 1932; Winder *et al.*, 1933; Comroe and Schmidt, 1937). *Direct action on the respiratory center* is subordinate; but painting the floor of the fourth ventricle with sodium cyanide produces stimulation (Owen and Gesell, 1931). In *frogs,* the respiratory center is also stimulated by small and depressed by large doses.

Pyruvic acid cyanohydrin, injected into dogs and cats causes prolonged stimulation of respiration and counteracts respiratory depression by barbiturates and morphine. It is effective when CO_2, metrazol and lobeline fail. It also acts mainly through the sinoaortic reflex (E. K. Marshall and Rosenfeld, 1937).

Clinical Use for Respiratory Stimulation.—The intravenous injection of sodium cyanide is the most potent available measure for stimulating the respiratory center. The effective dosage (0.05 mg. per Kg. for animals) is about 1/20 of the minimal fatal dose, so that there is an ample margin of safety; and the cyanide is so rapidly detoxicated by conversion into thiocyanate that cumulation can be easily avoided. The effects of a single injection are not lasting (rarely longer than ten seconds), but they can be repeated as desired, or they may be maintained by continuous injection. The usefulness is limited by the fact that the presence of cyanide prevents the tissues from utilizing the oxygen; but this becomes available when the cyanide is destroyed. It therefore seems advisable to make the injections intermittently. In drowning and in anaesthetic poisoning, the increased respiratory movements help to clear the air passages of obstruction or poison.

For this purpose, the starting dose should be 5 cc. of a 0.1 per cent solution, for man. The ordinary dosage is 1 cc. for this solution. This may be repeated indefinitely, at a rate not faster than every fifteen to thirty seconds. It should be discontinued on the appearance of marked pallor, nausea, marked increase of pulse rate, or depression of respiration. The solution must be freshly made by dissolving 100 mg. of sodium cyanide in 100 cc. of normal saline, without the use of heat. Hypodermic or intramuscular injection is not feasible, as the dose and effect cannot be adjusted with sufficient accuracy (Loevenhart *et al.*, 1918).

Convulsions.—Rabbits deprived of their hemispheres exhibit the usual type of convulsions, but the course is more rapid (Morita, 1915). In frogs, doses of cyanide which are ineffective alone evoke convulsions with subconvulsive doses of brucine, hydrastine and coramine (Bergstermann and Krauskopf, 1938).

The effects on the circulation are those of anoxia. As in the latter, the heart may again execute a few movements after it has stopped for a time, but these do not suffice to maintain the circulation. The *bradycardia* is due practically entirely to carotid and aortic reflex. However, the response to electric stimulation of the peripheral stump of the divided vagus is also increased (Danilewsky and Wjalkowa, 1931). The *vasomotor center* shows intense stimulation, with corresponding rise of blood pressure, as in asphyxia (Pilcher and Sollmann, 1915). The rise is chiefly reflex from the carotid sinus and aortic arch, but the vasomotor center plays a larger part than with the respiratory stimulation (Heymans *et al.*, 1932). The share of the aortic body is larger than that of the carotid body (Comroe, 1938). In *excised kidneys* perfused with saline solution, the addition of hydrocyanic acid causes marked dilatation of the renal vessels. The effect is apparently due to a paralysis of the arterial muscle. It disappears promptly on removing the cyanide (Sollmann, 1908). In heart-lung-kidney preparations it abolishes selective reabsorption by the tubular epithelium. In intact animals small doses of cyanide produce spasm of the glomerular vessels and decreased output of urine (Richards *et al.*, 1938). The *coronary vessels* are also dilated (Loevenhart and Eyster, 1931; G. T. Kent *et al.*, 1939). Applied directly to the *frog's heart*, cyanides cause standstill which is not removed by atropine; the heart responds strongly, however, to electric or mechanical stimulation. There is no evidence of this action on blood pressure tracings from mammals. *In limulus*, weak concentrations stimulate the heart muscle and ganglia (Carlson, 1907).

Excised Intestines.—Potassium cyanide interferes with the contractions, especially of the higher portions, in which metabolism is probably more active (Alvarez, 1918).

Local Anesthesia.—Direct application of HCN to the intact skin produces local anesthesia. It has been used as an anodyne in pruritus, and against cough and vomiting; but it is not very effective and the danger of fatal mistakes renders its use inadvisable.

Metabolism.—Severe cyanide poisoning increases the total N excretion, mainly as urea, both in starving and in fed animals. Injection of cyanide into anesthetized rabbits results in immediate increase of *oxygen consumption*, followed by a severe drop (K. O. Möller, 1935). The *glutathione* and *lactic acid* of rabbit *muscle* are reported increased after subconvulsive and convulsive doses of cyanide (Handovsky, 1928). The lactic acid content of the *brain* rises materially (W. E. Stone, 1938).

Growth and Tumor Development.—Long-continued inhalations of HCN gas arrest body growth in young rats and retard the growth of Jensen rat sarcoma transplants, often with regression of the tumor and lessened takes of retransplants. The effective dose is close to the lethal (L. Karczog, 1927; I. H. Perry, 1935).

Phagocytosis is stimulated *in vitro* by traces of KCN, the effect being analogous to oxygen deprivation (H. J. Hamburger, 1915). Intravenous injections of cyanide intensify *mustard conjunctivitis* (Amberg *et al.*, 1917).

Lower Organisms.—Cyanide is a *violent protoplasmic poison*, presumably through its interference with enzymes which play a most important role in life processes. All forms of life, all tissues and organs, are affected. Infusoria are killed in a concentration of 0.1 per cent. The growth of yeast and of higher plants, the germination of seeds, the contractility of animal cells, the conductivity of nerves, and so forth, are inhibited. If the action is sufficiently continued, all vitality is destroyed; but if the cyanide is promptly removed, complete recovery occurs. Its effects agree with those of deprivation of oxygen. Amphibian eggs can develop in cyanide up to the beginning of gastrulation, and are then arrested. *Sodium azide* arrests development in all stages, from fertilization on (Spiegelmann and Moog, 1945). In certain fish ova, cyanides suspend the autolytic processes accompanying death, so that the cells remain in a condition between life and death for several days (Sollmann, 1906). Sodium cyanide inhibits putrefactive *bacteria* in the diultion of 1:25,000, but it is not a potent bactericide. Green *plants* are killed when the air contains 0.02 to 0.2 per cent of HCN; the germination of *seeds* is stimulated by these concentrations (C. Wehmer, 1918). The *site of the toxic action on cells* appears to be the cell membrane, for concentrations which kill amebae promptly on immersion, fail to kill them if injected into the cell, in one-half of the volume of the cell (Brinley, 1928). Presumably the cyanide forms reversible compounds with oxidases on the cell surface, that are necessary for oxygen uptake into the cell (A. J. Clark, 1937). Even very dilute cyanide solutions increase the *permeability* of Tradescantia cells. This effect is enhanced by low concentrations of chloroform or alcohol; diminished by higher concentrations (Krehan, 1914).

The cyanide inhibition of yeast growth is antagonized by yeast extract, but not by any isolated constituent (M. A. Eppright and Williams, 1947).

Cyanide Action as Tissue Asphyxia.—The phenomena of the action of hydrocyanic acid on the central nervous system—the stimulation of the medullary centers, the convulsions, the vascular paralysis, and the like—bear a close resemblance to those of asphyxia and it can be shown that oxidation is enormously diminished. There is, however, one marked difference from ordinary asphyxia, for the blood remains of a bright arterial color; indeed, the oxygen content of the venous blood in typical cyanide poisoning approaches that of ordinary arterial blood (Cl. Bernard); the red color of the venous blood is partly due to more rapid circulation from vasodilatation and cardiac stimulation (Chio, 1911). The oxygen is in the ordinary combination with hemoglobin, and can be removed as readily as normally *in vitro;* for instance, by a vacuum (C. L. Evans, 1919). It is therefore evident that the oxygen supply to the tissues is not lessened. The cause of the asphyxia, of the lessened oxidation, must lie in the protoplasm of the tissues. This undergoes "*internal asphyxia,*" in sight of abundant oxygen (Geppert, 1889). Cyanide asphyxia is more promptly fatal than is complete exclusion of oxygen, for in the latter event the cells can use the oxygen as long as any is left in the blood. The interference with oxidation has also been demonstrated with "salted frogs"; excised kidneys (Vernon, 1906); many lower animals; and with ferments. *In vitro,* cyanide inhibits all but 2.5 per cent of the oxidation of brain tissue, indicating that brain respiration is effected through the *cytochrome* system (review, J. H. Quastel, 1939).

Action on Hemoglobin.—It is doubtful whether HCN combines directly with hemoglobin under the conditions of the body (v. Zeynek, 1901). When added to methemoglobin, however, it causes the formation of *cyanhemoglobin* (Kobert, 1891) with a characteristic spectrum band. This is responsible for the bright red ecchymotic spots seen after hydrocyanic poisoning. Methemoglobin can be used as a test for hydrocyanic acid. The cyanhemoglobin formed by treating washed erythrocytes of dogs with nitrite and then with cyanide, is not toxic on intravenous injection, even in quantities equivalent to six fatal doses of free cyanide. It is gradually reconverted into functional hemoglobin at the same rate as methemoglobin, suggesting that the cyan is gradually liberated and detoxified (Etteldorg and Morrison, 1940). M. M. Brooks, 1935, denies the existence of cyanhemoglobin.

Oxidation in Invertebrates.—Oxygen consumption in *sponges* is first increased, then diminished. High concentrations produce practically pure depression (Hyman, 1916). In *planaria,* G. Allen, 1919, found the oxidation reduced by 30 per cent through minute doses of cyanide. Larger doses caused a further reduction to 20 per cent, beyond which there was no other reduction, even with larger doses. The action is reversible, *i. e.,* rapid and complete recovery occurs after removal of the cyanide. The respiration of *paramecium* is partially inhibited by cyanide, the extent depending on the supply of carbohydrate food. Starved and aged organisms are relatively insusceptible (D. M. Pace, 1945).

Action on Enzymes.—Schoenbein, 1867, first showed that hydrocyanic acid inhibits oxidizing ferments, preventing the catalytic action of shed blood on H_2O_2. The *catalase* is not destroyed, but only inhibited. (In acute cyanide poisoning, the inhibitory concentration is not reached; Duncker and Jodlbauer, 1911.) The *cytochrome* (indophenol) oxidase system is highly sensitive to cyanide (also to *azide*); if oxidation is not inhibited by these, it is not effected by cytochrome. The converse does not hold. It increases the adenosine triphosphate activity of myosin and nullifies the inhibiting effect of copper (F. Binkley *et al.,* 1944). It has a similar inhibitory effect on many other organic ferments and inorganic catalyzers (spongy platinum). The effect on metals is probably produced by a minute film of cyanide, and its mechanism is therefore probably not analogous to that on organic ferments.

The maintenance of the high energy phosphorus compound appears to be mediated largely through the cytochrome oxidase system which is inactivated by cyanide (H. G. Albaum *et al.,* 1946).

Fate.—Hydrocyanic acid changes readily by exposure to light and air and undergoes rapid decomposition in the body. Part of it combines with sulfur-containing molecules to form thiocyanate, part is excreted unchanged by the lungs. The fate of the remainder is unknown. Post mortem, Waller, 1910, found the largest quantity in the heart and brain; but it disappears in a few days by transformation into thiocyanate (Chelle, 1919; Kohn, Abrest and Lupis, 1928). Cyanide disappears when incubated with *serum,* the loss being proportional to the dextrose content.

The *limited detoxicating efficiency of thiocyanate formation* is illustrated by the fact that the toxicity of 0.001 per cent of NaCN solution, perfused through the toad heart, is not antagonized by the addition of $NaHSO_3$; nor does perfusion with the latter hasten recovery (Combes, 1927). *Thiocyanate formation from nitriles* can be demonstrated on pigeons, whose blood does not normally contain SCN, but does so if cyanide, propionitrile or phenylacetonitrile are administered (Tsurw, 1933).

Treatment of cyanide poisoning is of limited efficiency, because of the rapid course and by the inherent gravity of any degree of tissue asphyxia. Attempts have been made to evacuate and to destroy the cyanide in the stomach, especially by oxidation, and after absorption to convert it into firm compounds, especially by methemoglobin, thiosulfate, colloidal sulfur or certain sugars.

Routine Clinical Management of Cyanide Poisoning (based chiefly on Hanzlik and Richardson, 1934).—One of the oral antidotes should be given as promptly as possible—animal charcoal, hydrogen peroxide (1:5), permanganate (1:1000) or sodium thiosulfate, 5 per cent; followed as promptly as possible by gastric lavage with one of these solutions, diluted 1:10. Brisk respiration should be maintained, mechanically or by 5 per cent CO_2 in oxygen. As promptly as possible 1 per cent sodium nitrite should be injected into a vein, slowly, in 10 cc. doses, to a total of 50 cc. in an hour. Epinephrine should be in readiness against excessive fall of blood pressure. Between nitrite injections, 20 cc. of 5 per cent sodium thiosulfate should be injected intravenously and if necessary continued to a total of 500 cc. In place of the nitrite, methylene blue may be injected intravenously, 50 cc. of 1 per cent in isotonic (1.8 per cent) sodium sulfate, repeated as needed to a total of 200 cc. If the patient becomes too much cyanosed from the methemoglobin, blood transfusion may be used. The fatal dose of hydrocyanic acid for man is about 0.05 Gm.; for potassium cyanide, about 0.25 Gm.; but the latter varies with the acidity of the stomach. The tabulated efficiency of treatment in dogs (see below) indicates the maximal doses that might be survived under treatment.

Hydrogen peroxide forms oxamide: $2HCN + H_2O_2 = (CO)_2(NH_2)_2$. *Cyan-metal compounds* are formed too slowly to be of much practical value. *Alkaline ferrous sulfate* forms the nontoxic ferrocyanide, but is too slow to be reliable. It was advocated by Smith, 1884, and again endorsed by Sandwick, 1906. It is prepared by mixing ferrous sulfate solution with milk of magnesia, or with sodium bicarbonate solution. Similarly, cobaltous nitrate (administered as 0.5 per cent solution) forms cobaltocyanide. It has not come into clinical use.

Brisk respiration favors the excretion of the cyanide by the lungs—it is not generally needed to supply oxygen. It is useless in collapse, when the circulation is slow. It should therefore be begun early, and continued until the circulation fails. Counterirritation and general stimulants such as caffeine, atropine and metrazol are probably of no value.

Thiosulfate ("Hypo"), $Na_2S_2O_3$; tetrathiosulfate, $Na_2S_4O_4$; and other sulfur compounds and colloidal sulfur simulate the natural detoxication of cyanide, by forming thiocyanate, SCN, which lacks the cyanide action and is practically nontoxic. The slowness of the reaction greatly limits its usefulness in acute poisoning. Thiosulfate is of little use in the stomach, and is but slowly absorbed. It is best administered intravenously (A. Buzzo, 1932).

In animal experiments, using generally rather larger doses than would be safe clinically, it is successful as a prophylactic, especially in the slowly developing nitrile poisoning (Heymans and Masoin, 1897), but is not brilliant in the developed poisoning. It is most useful in combination with the methemoglobin-forming antidotes, which secure more time for the thiocyanate formation. This occurs but slowly with thiosulfate, in life and in the test tube.

Thiocyanate Formation.—Intravenous injection of NaCN, 1 mg. per Kg., into dogs doubles the thiocyanate content of the serum within half an hour, and this continues to rise to a maximum of two to eight times the normal, in two to five hours (R. G. Smith and Mukerji, 1939).

Sulfur on Thiocyanate Formation.—Colloidal sulfur forms thiocyanate slowly in acid solution, but practically at once in alkaline solution (E. Milanesi, 1926). This led to the suggestion to administer colloidal sulfur as such, suspended in sodium bicarbonate solution (A. W. Forts, 1928). In life tests, however, the antidotal superiority of colloidal sulfur over thiosulfate is not striking.

Tetrathiosulfate was introduced by A. Chistoni and Foresti, 1932, with the claim that it is speedily effective and superior to thiosulfate and colloidal sulfur, but others found no material difference from thiosulfate.

Methemoglobin Formation.—Methemoglobin binds cyanide promptly and firmly to form cyanhemoglobin, which is nontoxic, perhaps because it does not penetrate into the cells. All methemoglobin formers therefore antidote cyanide; but cyanhemoglobin and methemoglobin are not oxygen carriers. Since at least a third of the hemoglobin must be kept in function, this sets a quantitative limit to the antagonism, which lies practically at 3 to 4 fatal doses. It may be extended somewhat by transfusion; in any event, it acts immediately and provides an opportunity to supplement it by the more slowly acting thiosulfate. Any agent would be suitable which forms methemoglobin promptly *in vivo*, without destroying the corpuscles or being otherwise toxic. Practically, the two most available agents are sodium nitrite and methylene blue.

Sodium nitrite (introduced by E. Hug, 1932) is the more effective, but the optimal dosage for animals (10 to 20 mg. per Kg.) might be dangerous clinically (fall of blood pressure). However, the doses advised above appear safe. Amyl nitrite may be used, but it has no advantage and the patient is probably more liable to collapse.

Methylene blue has been used perhaps more extensively in the clinic, although in animal experiments it is somewhat less effective than nitrite; it does not potentiate as well with thiosulfate and probably has more toxic side actions.

Quantitative Comparison of Cyanide Antidotes.—Rabbits are not suitable for methemoglobin-forming antidotes, nitrites and methylene blue (W. Heubner, 1927). With dogs, which are probably fairly comparable with man in this respect, Chen, Rose and Clowes, 1934, found the treatments to protect against the following number of hypodermic fatal doses of sodium cyanide (6 mg. per Kg.) (in ascending order): methylene blue = 2; sodium thiosulfate and tetrathiosulfate = 3; sodium nitrite and amyl nitrite = 4; methylene blue plus tetrathiosulfate = 6; amyl nitrite plus thiosulfate = 10; sodium nitrite plus thiosulfate = 20.

The *efficiency of methylene blue* in cyanide poisoning was first shown by Sahlin, 1926, and established by Eddy, 1930 and 1931. Its first clinical use was by Geiger, 1932, at the suggestion of Hanzlik. The question is still open as to what extent the methylene blue acts through methemoglobin formation, and to what extent through other actions. The peculiar oxidation-reduction action of methylene blue suggested a direct antagonism, the methylene blue acting as a substitute for the normal cellular oxidation catalysts inactivated by the cyanide; this explanation was developed especially by Sahlin, by Eddy and by M. M. Brooks, 1932, 1939; but Hug, 1932, suggested that it acts chiefly by forming methemoglobin; this was supported by Wendel, 1933, and is probably most generally accepted as the main factor, chiefly because with rabbits, which do not readily form methemoglobin, methylene blue is not an effective cyanide antidote. Ethylene blue, which does not form methemoglobin, is also ineffective as a cyanide antidote (Hanzlik and Richardson, 1934). Haggard and Greenberg, 1933, found that methylene blue converts 8 to 12 per cent of the hemoglobin of blood into methemoglobin, in the test tube. The excess of dextrose interferes, however, with the formation of methemoglobin by methylene blue (but not by nitrite; Warburg, Kubowitz and Christian, 1930), and Brooks, 1934, denies that methylene blue forms methemoglobin in living dogs. Methylene blue has marked pharmacologic actions (hyperpyrexia, and so forth), and when Sahlin discovered the antidotal value of methylene blue he considered it as probably too toxic to encourage its practical employment. This limits the dosage, but it appears safe in the quantities which have been employed clinically. Its clinical efficiency, however, is dubious, notwithstanding the earlier glowing reports, as it is not certain that the outcome would have been fatal even without treatment. Trautman, 1933, found it of no value under practical conditions and against inhalation of cyanide vapors in lethal or near lethal doses, for rabbits, rats and guinea pigs; but these are probably not suitable est animals.

Other methemoglobin formers, pyrogallol, pyrocatechiol, phenylhydrazine and dinitrophenol, are too toxic for practical use. Potassium ferricyanide would be ineffective with intact blood, since it does not penetrate the corpuscles sufficiently readily; but if added to laked blood and injected, it is fairly effective (Hug, 1932). However, the renal excretion of methemoglobin when dissolved in the plasma reduced its efficiency.

Sugars, Aldehydes and Ketones as Cyanide Antidotes.—Of various sugars that have been tried, triose (glycerinic aldehyde) has been the most successful (A. W. Forst, 1932), but not so good as nitrites. It acts by the formation of the nontoxic cyanhydrin (H. Casser, 1930), possibly assisted by central actions. Zanda and Atzori, 1938, found that detoxication of cyanide by glucose *in vitro* requires two hours, which would be too slow for a clinical antidote. The chemical reaction involves an equilibrium constant, which was determined for various aldehydes and ketones by E. K. Marshall and Rosenfeld, 1934. Dihydroxyacetone (oxantin) acts briefly and thus secures time for thiosulfate (Forst, 1928; B. B. Turner and Hulpieu, 1933), but by itself is less effective than triose. Forst claimed some benefit from glucose, about the same with and without insulin, but Turner and Hulpieu found it ineffective. They point out that cyanide itself tends to raise the blood sugar markedly, proportional to the severity of the symptoms.

Acrylonitrile (vinyl cyanide) is used in the manufacture of synthetic rubber. Exposure to the vapor produces typical nitrile effects, *i.e.* somewhat slowed cyanide poisoning, with respiratory stimulation and convulsions; death may not occur till many hours after the exposure. Thiocyanate is increased in the blood and urine. Sodium nitrite antagonizes the effects. Susceptibility varies considerably in different species. The minimal fatal concentration for dogs, which are relatively susceptible, is 0.25 mg. per liter of air, equivalent to 110 ppm. Daily exposure to sublethal concentrations produces irritation of the eyes and nose, gastro-intestinal disturbances and weakness of the hind legs, with relatively rapid recovery. Autopsy shows renal irritation in most of the animals, subacute bronchopneumonia in most except cats, liver damage only in cats (H. C. Dudley *et al.*, 1942).

Complex CN Compounds.—*Sodium ferricyanide*, $Na_3Fe(CN)_6$, and *ferrocyanide*, $Na_4Fe(CN)_6$, are not toxic as such, since the CN is bound. Dogs tolerate intravenously 35 cc. of a 7.5 per cent solution of the crystalline ferrocyanide, per Kg. of body weight, and excrete it rapidly by the urine. Poisoning is said to have occurred with oral administration from the liberation of HCN by the gastric acidity, but this has been questioned. The oral dose has been stated as 0.2 to 1 Gm. Ferrocyanide is not excreted by the aglomerular kidneys of Lophine fish (E. K. Marshall, 1930). It has been introduced as a clinical test of *glomerular function*, by intravenous injection of 0.5 Gm. of the hydrated sodium ferrocyanide (0.25 Gm. of the anhydrous) in 10 cc. of freshly distilled water. The results are fairly parallel to those of the urea clearance, phenolsulfonphthalein and urine concentration tests (E. J. Stieglitz, 1939).

Nitroprusside (sodium nitroferricyanide) is decomposed completely in the blood and tissues at body temperatures, liberating cyanide (H. E. Hill, 1942), and its toxicity is practically the same. The symptoms develop more slowly (L. W. Mahaffey, 1942). See also under *Nitrites.*

Calcium cyanamide, $CaCN_2$, is used extensively as a synthetic agricultural fertilizer. It does not contain free cyanide, but acts as cyanamide, dilating the blood vessels. The action is not cholinergic, for it is not antagonized by atropine. Slight cases of poisoning have transitory redness of the face and headache. In severe cases, the skin and mucosae show marked congestive hyperemia (especially head, thorax and lungs, if the poison is inhaled as dust), respiration is accelerated and deeper, the heart beat is irregular, blood pressure is lowered and vertigo occurs. The attack usually lasts one-half to two hours, generally with complete recovery. Large doses produce profound shock (R. D. Barnard, 1943). The fatal dose is about 40 to 50 Gm.

Cyanogen chloride, CNCl, produces cachexia on long-continued exposure (C. I. Reed, 1920). Its acute effects closely resemble those of HCN. If the vapor is inhaled it also acts locally on the respiratory passages, producing bronchial constriction and irritation. Blood corpuscles rapidly convert about 30 per cent of the CNCl into HCN; serum quickly destroys it without producing HCN (W. N. Aldridge and Evans, 1946).

PREPARATIONS.—*Diluted Hydrocyanic Acid*, N.F., contains about 2 per cent of HCN. On standing, it loses strength rapidly, decomposing into ammonium formate, CO_2, cyanic acid, and a brown precipitate of paracyanogen (L. A. Brown, 1910). The decomposition is retarded by acid, alcohol and acetanilid (Coblentz and May, 1908). *Potassium Cyanide*, KCN, occurs usually as white, opaque masses, with cyanide odor. Dose, 5 mg., $\frac{1}{12}$ grain. Commercial samples are often impure. *Sodium Cyanide*, NaCN, white, opaque pieces, or granular powder; deliquescent in the air and exhaling the odor of hydrocyanic acid. Freely soluble in cold water. *Oil of Bitter Almond*, U.S.P. (Ol. Amygdalae Amare), a volatile oil distilled from Amygdalus communis or other sources. Yields not less than 95 per cent of benzaldehyde, and not less than 2 per cent or more than 4 per cent of hydrocyanic acid. *Not to be used or sold for flavoring foods.* Dose, 0.03 cc., $\frac{1}{2}$ minim. *Wild Cherry Bark*, U.S.P. (Prunus Virginiana), the stem-bark of Prunus serotina; contains tannin, amygdalin and bitter glucoside. The *Syrup* represents 15 per cent of the bark. Dose, to 10 cc., $2\frac{1}{2}$ drachms; mainly as flavor for cough-mixtures.

PHYSICAL FACTORS OF "SALT ACTIONS"

Besides the properties ordinarily designated as chemical, substances in solution or suspension also have certain *physical* properties, depending on their molecular state, and independent of their chemic composition. Both the drugs and the cells have these properties.

Molecules in solution have qualitatively and quantitatively identical effects on the boiling and freezing point, on vapor pressure and on osmotic tension. Through osmosis they may alter the water and salt content of the cell, its internal pressure, the surface tension, and the electric surface potential, and consequently the functions. This may occur even though the substance itself does not enter into the cells. These effects are produced by all substances in solution, but since the results are proportional to the number of molecules dissolved in the unit volume of the solvent, their importance varies with the quantity of the drug that can be introduced without producing serious chemic changes. They are practically important mainly for the neutral salts of alkalis, and are therefore commonly called "*salt actions*." In *colloid solutions*, the solute occurs in smaller or larger groups or "aggregates" of molecules, which approach more or less in their properties to mere suspensions of solids or liquids, and exert less of the physical qualities of true solutions. On the other hand, the suspensions exhibit the electric and surface phenomena of particles. Because of the relatively high state of subdivision, the "*surface phenomena*"—surface tension, adsorption, catalytic properties, and so forth—are conspicuous and play an important part in the functionation of protoplasm. The consistency of the protoplasm, fluid or gelatinous, and the quantity of water imbibed, also depend on the colloids. These properties are influenced by the physical, electrical and chemical conditions of the medium in which the colloid is suspended.

COLLOIDAL SOLUTIONS

Relation of Colloids and Crystalloids.—Graham, 1861, divided soluble substances into crystalloids and colloids, according to whether they diffuse through parchment and similar membranes. This criterion has been supplemented by others, but the division is important and has been retained. Any substance assumes the colloidal state when it is suspended in sufficiently fine comminution, in a liquid that does not dissolve it materially in the molecular state. A "solution" may therefore be colloidal in one solvent (tannin in water), molecular in another (tannin in alcohol). As the size of the aggregates of molecules which constitute the colloid state varies, the transition between the physical properties of the two kinds of solutions is not abrupt, but gradual.

Properties of Colloids.—Each aggregate behaves like a single molecule, so that the molecular concentrations of colloid solutions are relatively low. Colloids therefore have relatively little influence on the *osmotic pressure*. One of the most distinctive properties of colloid solutions is their *turbidity*, which may be perceived directly, or only by the Tyndall phenomenon (*viz.*, a beam of light becomes visible when passed through a colloid solution). Colloids *do not dialyze* through parchment or similar membranes. *Diffusion* through the solvent is slow or practically absent. The *electric properties* are characteristic: colloids are usually electrically charged, the quantity and sign of the charge being variable at will. The important *surface actions* will be discussed later. The colloids easily undergo further aggregation to larger particles, *i.e.*, *coagulation*. Colloid solutions are often permanently changed by temporary physical conditions, such as boiling, freezing or keeping (*hysteresis*).

Suspension and Emulsion Colloids.—Colloid solutions fall into two classes: the suspension colloids, in which the particles behave as solids; and the emulsion colloids, in which they generally behave as fluid. The difference is probably one of affinity for the solvent. The emulsion colloids are *hydrophilic*, or lyophilic; they seem to attract the solvent into the aggregates which are thereby more or less liquefied. The suspension aggregates are *hydrophobic;* they do not take up water, but remain discrete and solid. The emulsoids approach more nearly to true solutions, and may sometimes consist of discrete but large molecules. They are typified by soluble proteins and are therefore of a special biologic importance. The colloid metals and sulfides, congo red, and so on, are suspensoids. The *emulsoids* form viscid solutions or jellies, lower the surface tension, and are coagulated only by large quantities of electrolytes. The *suspensoids* are not viscid, have little effect on surface tension, and are easily precipitated by traces of electrolytes.

Permanance of Suspensions.—Small particles suspended in a liquid tend to coalesce by surface attraction, to form larger particles. The molecular particles in colloid solutions have the same tendency; but since all the particles in a solution are charged with the same sign (negative electricity in most protoplasm), they repel each other. Any increase of the charge (negative in the example) increases this repulsion, and consequently diminishes the size of the aggregates. If electricity of the opposite sign (positive) is introduced, some of the charges are neutralized and the particles tend to coalesce. If this (positive) electricity is increased beyond the point when all the original (negative) charges are neutralized, the particles become charged with positive electricity, and again fly apart. These modifications may be produced by the passage of an electric current, or by the electric charges of the ions of electrolytes. Suspensions of hydrophobic colloids (such as colloidal gold) contain an infinite gradation of sizes of aggregates in the same solution; while the size of a hydrophilic colloid (such as a protein) is uniform in a given solution (Svedberg, 1938).

Precipitation of Suspension Colloids by Electrolytes.—Since suspensoids have no affinity for the solvent, they are readily precipitated when their electric charges are removed. This occurs most easily when their electric charge is already small, *i. e.*, when they approach the "isoelectric point." Minute traces of electrolytes are then sufficient. The precipitation of positively charged colloids depends mainly on the anions, that of the negative on the cations (Hardy's Law). The precipitant power of the ions is a function of their valence (Schulze, 1882, 1884), since this determines their electric activity. However, ions of the same valence are not equally active.

Fate of Intravenously Injected Colloids.—Finely divided powders or true colloids appear to be taken from the blood stream primarily by the Kupffer and other reticulo-endothelial cells. For instance, an hour after intravenous injection of finely divided MnO_2, Drinker and Shaw, 1921, found 38 per cent in the liver, 47 per cent in the lungs, 4.3 per cent in the spleen, leaving only 11 per cent for the remainder of the body; but after twenty-four hours most of the material was in the liver. Gye and Purdy, 1922 and 1924, reported that repeated intravenous injection of silicic acid produces enlargement of the fixed histologic cells of the liver, spleen and bone marrow, and their detachment into the circulation. Injections of colloidal suspensions are used experimentally to "fill up" the reticular endothelium and thus to render it functionally inactive.

Red blood corpuscles constitute a coarser suspension, but are governed by similar laws. They bear negative charges and therefore tend to be agglutinated, sedimented and precipitated by positively charged ions (acids). The rapidity with which *sedimentation of red corpuscles* occurs in shed blood varies with conditions. It is accelerated, for instance, when albumoses are injected; in the "hemoclastic crises" of colloidal and immunity reactions (Widal); in the cachexia and anemia of malignant disease (Gragert, 1923); in pregnancy (Fahraeus, 1918); and in various pathologic conditions, especially those associated with fever and inflammation (Fiedler, 1923).

Emulsions are fine and permanent suspensions of one liquid in another immiscible liquid; *f. i.*, oil in water, or vice versa. Surface tension tends to separate immiscible liquids. This tendency may be counteracted by lowering the surface tension of the dispersing medium (as by saponin or soap) or by increasing its viscosity, and by adsorbing the water by hydrophilic colloids (as by gums and proteins). The essential feature of permanent emulsion is the adsorption of a colloid on the surface of the oil droplets, coating these with a resistant membrane. Saponin, which has relatively little effect on surface tension, acts mainly in this manner (Howard and Sollmann, 1924).

The water-soluble alkali soaps secure the suspension of lipoids in water, while the oil-soluble calcium soaps change the phases so as to suspend the water in the oil. The addition of sodium or calcium ions therefore changes the phase of an emulsion, and thereby influences the permeability; the sodium soap system is freely permeable to water, the calcium system being impermeable (Clowes, 1914 to 1916).

Precipitation of Hydrophilic Colloids by Electrolytes.—These, like the suspensoids, are precipitated only by electrolytes, not by nonelectrolyzed crystalloids (the precipitation of proteins by alcohol is attributed simply to insolubility). The process, however, is probably quite different. With the emulsoids, much higher concentrations of the salts are required; the precipitation is generally reversible; electrolytes may also have solvent actions, the end result being the algebraic sum of the actions of the cation and anion (Pauli, 1905, 1908).

The ions form a regular series (*"lyotropic series"*), which is reproduced in many different phenomena. The anion series run SCN, I$<$ClO$_3$$<NO_3$, Br$<Cl<CH_3$.COO$<$-SO$_4$, PO$_4$$<$tartrate$<$citrate. With (negative) proteins, lecithin, and so forth, the left side of this series is solvent, the right side precipitant. They have a similar influence on heat-coagulation temperature; on the solubility of globulins; the solubility of gases, alcohols, and the like; on the viscidity and surface tension of water; on the saponification of esters, and so on. It has been suggested that all these phenomena can be explained by the progressive affinity of these salts for water, thus competing with the emulsion colloids.

The *alkali cations* are much less important. Their series runs rather irregularly; generally Mg $<$ NH$_4$ $<$ K $<$ Na $<$ Li (Li being most precipitant). If the electric charge of the colloid is reversed, *f. i.*, by acids, then the anion and cation series are also reversed. The *earthy metals* (Ca, and so forth), form irreversible precipitates. They also reverse the charge and therefore the effects of the anion series (Mg acts like the alkali metals). The tendency to irreversible precipitation is much greater with *metallic salts*.

Imbibition.—Plates of gelatin (glue) or other hydrophilic colloids, when laid in wate, or watery solutions, imbibe water and dissolved substance, and thus swell. Polypeptides are oriented as a lattice which enables them to enmesh large quantities of water (M. Irwin, 1925). The water is attracted and retained with considerable force, according to the affinity of the emulsoid for water. This mechanism is important in the regulation of the fluid content of the cells and tissues. The colloid must compete for the water with the other dissolved substances. The imbibition is therefore influenced by the anion series, in the usual order, iodide to chloride increasing, acetate to sulfate decreasing, the imbibition (Hofmeister, 1891). The cations have relatively little effect. OH and, still more, H ions greatly increase imbibition (Spiro, 1904; Ostwald, 1905). In agar jellies, the phenomena are exactly reversed.

Ostwald (1916) noted that the results differ according to whether dry or moist gelatin is used. Lenk (1916) found that for the salts of most monobasic anions (chlorides, and so forth) the swelling increases with the concentration; whereas with dibasic and tribasic anions (sulfates, citrates, and so on) the maximal swelling occurs with medium concentrations. According to Ehrenberg, 1913, the lyotropic series is reversed for gelatin when the concentration of the salts is low ($\Delta < 0.5$). The swelling of gelatin is also influenced by *nonelectrolytes*, decreased by sugars and glycerin, and increased by alcohol and especially urea (Pauli and Rona, 1902). The coagulability of gelatin solutions is increased by the substances which lessen swelling, and *vice versa* (Pauli, 1907).

Distribution of Salts in Imbibition.—The gelatin also takes up the solutes. Hofmeister found that the quantity taken up increases with the concentration of the solution, to a certain limit, which is reached late with the iodide end of the series, and early with the sulfate group.

SURFACE PHENOMENA

Surfaces, the planes of separation of two phases, give rise to the important phenomena of surface tension and adsorption. These are especially prominent in colloids and therefore in protoplasm, the particles of which give rise to very extensive surfaces (A. B. Macallum, 1912, 1913). They are concerned in the shape and size of the cells; in the consumption or liberation of energy (for any change in surface tension implies a corresponding change in energy); and in the distribution of solutes. Dissolved substances generally modify the molecular attraction and therefore the surface tension. In watery solutions, organic substances generally diminish, inorganic sometimes increase, the surface tension; but there is no simple general law, and the effect is not simply proportional to the concentration. *"Surface tension"* properly applies to the system of liquid:air; *"interfacial tension"* to liquid:water. They are usually, but not necessarily, parallel.

Solution-Affinity.—A substance that lowers surface tension passes more readily out of the solution and into the surface; it has a low solution-affinity or "Haft-druck" (Traube). The concentration at the interface favors the penetration of the substance through membranes and into cells, and solution-affinity is therefore an important factor in osmosis, narcosis and other pharmacologic phenomena. The concentration of solutes on surfaces is illustrated by the *adsorption of dissolved substances by powders; f. i.*, by the decolorization of potassium permanganate by filtering through sand; the adsorption of colors or alkaloids by charcoal, and so forth. Sugars are not adsorbed because they have relatively little effect on surface tension. These adsorptions are reversible; *i.e.*, the adsorbed substance may be removed by the addition of another solute which lowers surface tension more powerfully.

Adsorption is a matter of the relative affinity of the solute for the two solvents. This may be determined by the cohesive or adhesive forces that constitute surface tension, but in other instances other physical forces, such as the electric equilibrium, may come into play; others are more strictly chemical. The causes are often difficult to analyze (A. P. Mathews, 1921). The firmness of the adsorption varies greatly.

Adsorption on Chemic Reactions; Catalysis.—The surface condensation facilitates chemic reactions in accordance with the law of mass action by bringing the dissolved molecules into closer contact. Accordingly, suspension colloids, with their large surfaces, generally function as catalysts; and enzymes in general probably act largely through surface action.

OSMOSIS

Osmotic phenomena belong to the more important effects of the biochemically inactive salts and other crystalloids and of water. They occur whenever solutions of different (molecular) concentration are separated by a "*semipermeable*" membrane that permits the passage of the solvent, but which interposes an obstacle to the free diffusion of the solute. Dissolved molecules tend to distribute themselves equally throughout a solvent. If their passage is hindered by a membrane, the equality can only be obtained by the passage of the solvent from the more dilute to the more concentrated solution. The more concentrated solution therefore tends to increase in volume. If this increase is prevented (*e. g.*, if the solution is inclosed by rigid walls), a certain "*osmotic pressure*" is developed. The phenomenon is illustrated by the swelling of red blood and other cells in water; and conversely, by the shrinking of plant cells and crenation of red corpuscles in strong salt solution.

The pressure is due to the kinetic energy of the molecules that can not pass the membrane. In this, each dissociated ion acts as a molecule. Colloidal aggregates, lyophilic and lyophobic, and indeed the particles of suspended powders, such as clay, also have the same kinetic energy and exert the same osmotic pressure, per aggregate or particle (Svedberg, 1934); but as the units are larger, their number cannot be so high as that of molecules in true solutions, and their "oncotic" pressure is correspondingly smaller.

The envelopes of certain *vegetable and animal cells*, such as the *red blood corpuscles*, approach fairly closely to the definition of "semipermeable." Most cells, however, and dialyzing membranes in general, are not *absolutely* impermeable to the solutes, but offer only a partial obstacle, so that the solutes pass the membranes, but more slowly than does the solvent. Nondialyzable solutes are therefore hypertonic to those which are easily dialyzable. If a membrane separates two solutions of electrolytes, one diffusible, the other nondiffusible, differences of electric potential are created by the unequal distribution of the ions, according to *Donnan's membrane equilibrium*, that the products of the concentration of each pair of oppositely charged diffusible ions are the same on the opposite sides of the membrane.

Cell membranes of vertebrate tissues are generally freely permeable to water, H ions, and probably to NH_3; more or less to urea and dextrose, and to but few other solutes (review, J. P. Peters, 1944).

Unilateral Preferential Permeability.—Living membranes and some dead membranes may be more permeable in one direction than in the other. This is important for absorption from the intestines or through frog skin (Wertheimer). In the latter it is not conditioned on life, or on electric potential, but on different colloidal structure of the two sides of the skin membrane, so that these behave differently toward the solute (Leuthardt and Zeller, 1934). The permeability to water, however, is identical in both directions, even in intact frogs (van Hevesy *et al.*, 1935). Analogous differences are observed in collodion membranes; much less protein diffuses from the side which was away from the glass when the membrane was formed (Gaebler, 1931), owing probably to differences in the retention of solvent and speed of drying (review, R. Höber, 1936).

Calculation of Molecular Concentration and Osmotic Pressure.—Since the osmotic pressure has a definite relation to the molecular concentration, the determination of the one quantity permits the calculation of the other. The molecular concentration of a watery solution can be calculated by dividing the *depression of freezing point* of water (Δ) by 1.85; the latter is the amount of depression produced by a gram-molecule dissolved in 1 liter of water (Raoult's law). The maximal *osmotic pressure* is obtained by multiplying the molecular concentration by 22.34 atmospheres. Raoult's law holds strictly for concentrated solutions of all substances, and for dilute solutions of *nonelectrolytes*, such as the sugars, urea, glycerol, alcohol, and so forth. However, dilute solutions of *electrolytes*—salts, acids or bases—behave as if each ion acted as a molecule and show a correspondingly greater concentration than would be deduced from Raoult's law.

◆

OSMOTIC ACTIONS ON CELLS AND TISSUES

These consist primarily in *changes of composition*, the transfer of water and of solutes into or out of the cells. This leads to secondary effects: *Changes of water content* alter the volume and pressure, as is seen in the crenation and hemolysis of red blood cells. They may disorganize the protoplasm, as by the precipitation of globulins; and changes in *electrolyte concentration* change the electric potential. This, and the water content, alter the state of the colloids. Hypertonic and hypotonic solutions act in opposite directions as concerns volume and pressure; but the final functional results are often similar.

Molecular Concentration of the Blood and Tissues.—The total molecular concentration of living cells is probably somewhat higher than that of the body fluids. The plasma, lymph, and all other body fluids (except urine, saliva and gastric juice) of all mammals, depress the freezing point by about 0.56° C., corresponding to 0.33 mol per liter. Relatively slight departures from this are promptly injurious, and the organism resists any attempts to alter its osmotic concentration. The fluids of lower animals have a somewhat different concentration, adapted to their environment.

Human Blood.—The extreme variations of the freezing point in health are between 0.49° to 0.59° C. The molecular concentration of the blood is not altered by the quantity of fluid or salt in the food; nor by hydremia produced by hemorrhage; nor by thickening the blood by profuse diaphoresis. The intravenous injection of anisotonic solutions alters it but temporarily. About the only method of raising it permanently consists in interfering with the regulating mechanism, by seriously injuring the kidneys; then it proves fatal when the Δ approaches 0.8° C. The limits between which cells of mammals can functionate at all are comprised between Δ0.35 and 0.6 or somewhat higher. The *molecular concentration of the saliva* averages lowest of all secretions, its freezing point being normally −0.11° to −0.27° C., but if the rate of its secretion is increased, it may reach that of the blood (−0.58°).

Osmotic Equilibrium of Lower Animals.—The narrow limits of mammals are considerably extended in the lower forms of life. With *marine animals*, up to the selachians, the molecular concentration of the body fluids approaches that of sea water, and becomes independent only in the teleosteans. Dogfish are intermediate (Scott, 1913). In the marine animals, a concentration equal to that of the serum of mammals would liberate the hemoglobin. This adaptation of the osmotic resistance of cells to their normal environment is curiously developed in the small fish Fundulus, which thrives equally well in sea water and in distilled water. It is due, in this case, to a high degree of impermeability to both water and salts, so that osmotic pressure can not be developed. *Sweet-water animals* have a molecular concentration approaching that of mammals, salts being probably retained by chemical or physical affinity for the colloids. The molecular concentration of *plant juices* is also considerably higher than that of water. In the large *vacuoles of plant cells* the concentration in the internal fluid may be ten times that of the external (M. Irwin, 1925). *Fungi* often have a high resistance against osmotic changes, presumably because their envelopes are relatively impermeable. Torula, *e. g.*, can develop in a saturated solution of sodium or lithium chloride, the latter having an osmotic pressure of 2760 atmospheres (Raciborski, 1906; see also L. A. Hawkins, 1916).

Osmotic Changes in Red Blood Cells.—Hypertonic solutions produce crenation; if the solutions are hypotonic beyond a certain degree, the cells swell and lose their hemoglobin and salts. In life, these changes can be produced only by intravenous injection of anisotonic solutions.

The *resistance to osmotic hemolysis* varies in different *species*, and somewhat even with individuals. With human blood cells, laking begins in 0.48 to 0.42 per cent NaCl, and is complete in 0.38 to 0.32 per cent. The NaCl percentages for beginning and complete laking with other animals are: guinea pig, 0.420 and 0.312; dog, 0.462 and 0.330; rabbit, 0.526 and 0.385; beef begins at 0.58; horse at 0.68 (Musser and Krumbhaar, 1946; and others).

These differences refer only to hemolysis; the osmotic swelling, measured by the hematocrite, is about equal in the different species. The difference to water laking is generally inverse to that for saponin laking (Rywosch, 1907). Hemoglobin is held in the corpuscles only when all the cell proteins are in the proper colloidal condition. Changes in this, as by *p*H, metallic salts, formaldehyde, and so forth, produce shrinkage and cause hemolysis. *Increase of temperature* increases the resistance to osmotic hemolysis, owing to a change of the internal osmotic pressure (Jacobs *et al.*, 1936). *Hemolysis by hypertonic solutions* was investigated by C. C. Guthrie and Lee, 1914.

Permeability of Red Blood Cells.—These are difficultly permeable to Na, Ca and Ba ions, fats and sugars, slightly permeable to amino acids, freely permeable to all anions, ammonia, urea, alcohol, aldehydes and bile salts. The permeability is influenced by the *p*H. It increases with the Na and K ion concentration of the plasma and decreases with Ca. *Ammonium salts* lake even when added to isotonic NaCl solution. This is explained by hydrolysis with formation of the NH_3, which penetrates readily, and is followed by the osmotic attraction of water (Jacobs). The permeability to solutes is increased by saponin and other hemolytic agents. In saponin laking, increased permeability of the cell membrane can be demonstrated before the salts pass out of the cell (G. N. Stewart; Woelfel, 1908).

The permeability of the corpuscles for Na and K ions was shown by H. J. Hamburger, 1916. He also found that the addition, within physiologic limits, of CO_2 to the serum drives K ions into, and Na ions out of, the corpuscles. Fluoride and monoiodoacetate cause rapid escape of potassium from rabbits' erythrocytes (H. Davson, 1941). *Human erythrocytes* are more resistant than other species to changes of cation concentration. Placed in NaCl solution, their K decreases about 5 per cent; in KCl solution, it increases 3 to 10 per cent. The permeability increases at *p*H 8.3 to 8.8 (Maizels, 1935). If radioactive chloride, bromide or iodide is added to human blood, equilibrium is established within ten minutes, the bromide or iodide of the red cells rising higher than that of the serum (P. K. Smith *et al.*, 1941). Rohonyi and Lorant, 1916, found that *carbon dioxide* causes the erythrocytes to take up chloride from the serum, with an increase of serum alkalinity. Similar changes occur in hemolysis.

Aliphatic narcotics in anesthetic concentrations decrease the volume of blood corpuscles and decrease swelling and hemolysis by hypotonic solutions (v. Knaffl-Lenz, 1918).

The selective permeability of cell membranes varies for each class of cells, some being impermeable to one substance, some to another. In general, K enters cells fairly readily. If Na^+, Mg^{++}, Br^-, Cl^-, I^-, NO_3^- or SCN^- are injected intravenously, they are distributed exclusively through the extra cellular fluids (Winckler, Smith and Schwartz, 1939). The selective permeability is subject to changes with the functional state of the cell. It is often different in the inward and outward direction.

Permeability to Different Substances.—With most living cells, lipid-soluble substances penetrate more readily than those which are only water soluble, but the membrane is not absolutely impermeable to salts; and some substances penetrate independently of their lipoid solubility. It is generally assumed that the membrane is constructed of lipid and protein colloids, and that both play a part in the penetration. Plant cells, like red blood corpuscles, are almost impermeable to most salts and sugars, but permeable to ammonium, urea and lipolytic agents (Overton, 1895, 1899). *Striped muscle* is nearly semipermeable (similarly to a colloidin membrane in which $CaHP_2O_4$ has been deposited); *smooth muscle* is highly permeable to sugars and salts (Meigs, 1912 and 1913). Living *human skin* is permeable to cations (K > Na > Li > Ca > Mg > Al) and to anions (I > Cl > NO_3 > SO_4 > citrate > salicylate) (Poznanskaya, 1940). Excised normal *lens* behaves as an inert semipermeable membrane (review, M. C. Bourne, 1937).

Permeability for alkaloids is easily observed in plants by the precipitation of the tannin within the cells. Only the free (basic) alkaloids penetrate; the alkaloidal salts enter much more slowly, namely, in proportion as they are hydrolyzed. Their toxicity is favored by the addition of alkalis; this applies also to fish and frog larvae. Harvey, 1913, found that cell membranes are readily permeable to weakly dissociated *alkalis*, but remarkably resistant to those which are strongly dissociated.

Absorption of Dyes.—Ehrlich, 1887 and 1893, found that vital staining occurs especially with basic dyes. Overton, 1900, referred this to their lipid solubility. However, certain lipid-soluble dyes are not absorbed; while others, insoluble in fats, are nevertheless absorbable. Indeed, Asher and Gannus, 1911; Harvey, 1911; Kite, 1913; and others, found little relation. Acid dyes stain the protoplasm diffusely, while basic dyes stain mainly the cell granules.

Permeability of Internal Cytoplasm.—Kite, 1915, found that incised and punctured cells offer the same obstacles to the penetration of dyes as do intact cells. This was originally interpreted as showing that the cytoplasm itself is semipermeable; but it is now attributed to the precipitation membrane which forms rapidly when naked living protoplasm comes in contact with watery fluids. Dead protoplasm is water soluble, and therefore does not form the precipitation membrane (Seifriz, 1918). The internal protoplasm of cells is a continuous watery phase. The existence of brownian movement in living cells shows that their interior cytoplasm is liquid; but with adult cells it may become gelatinous (Chambers, 1917). With death, the protoplasm coagulates and the brownian movements are arrested. The interior of the nucleus is also chiefly liquid (R. Chambers, 1943).

Changes of Permeability in Stimulation.—The permeability of the cell membrane appears to increase suddenly at the moment of stimulation; the resulting change of surface potential is a necessary part of the stimulation phenomena.

The membranes of all animal and plant cells are *polarized*, the inner surface being negative to the external, producing the "*current of rest.*" On stimulation, the temporary increase of permeability to ions causes a wave of depolarization or negativity to pass over the external surface.

The influence of stimulation, narcotics and salts on cell permeability was pointed out by Osterhout, 1912; R. S. Lillie, 1912; J. Loeb, 1913. Stimulation decreases the electric polarization; it causes the diffusion of intracellular pigment (Lillie); the diffusion of ions from frog eggs (McClendon, 1915), and so forth. Asher observed that the vital staining of *gland cells* is greatly influenced by their functional activity, being increased by pilocarpine and diminished by atropine. *Semipermeability persists only during life.* It is lost when the cells die, so that dead cells merely imbibe solutions, like gelatin or fibrin (J. Loeb, 1913). Living tissues resist the entrance of all acids (except salicylic), while dead tissues are freely permeable to them (Harvey, 1914).

Osmotic Exchanges in the Body.—If a foreign solution is introduced—*f. i.*, into the intestines or peritoneal cavity or blood—osmosis rapidly brings its total molecular concentration to that which is normal for the tissues. This exchange could be effected either by the passage of water, or by the passage of the normal salts from the tissues into the solution. In fact, all three processes generally participate, their share varying according to the special permeability of the tissues. In general, the exchange occurs mainly in the direction which favors the *absorption*. When the molecular concentration of the blood has been reached, there remains less scope for osmotic exchanges, and further absorption occurs by other forces (filtration, imbibition, and the like), generally much more slowly. The role of osmosis in absorption is therefore important, but limited. In the *secretion* of the body fluids, *f. i.*, the urine or lymph, it is important mainly by setting limits to the real secretory forces.

The absorption of solutions from serous cavities and lymph spaces is almost entirely physical, for it occurs in dead animals, although it is more rapid when the circulation is intact, because the absorbed products are then more rapidly removed.

Frog skin transports fluid from the exterior toward the interior surface (Wertheimer). This is due partly to the different colloidal structure on the two sides (Leuthardt and Zeller, 1934), the resistance of the osmotic and electrical potential being overcome by the oxidative processes of the living cells (Adolph, 1929), probably by the combustion of pyruvic and lactic acids (Huf, 1936). Its permeability to water (or deuterium oxide) is the same in both directions (von Hevesy *et al.*, 1935).

Absorption from the alimentary canal is probably more dependent upon forces other than the osmosis than is absorption from serous cavities, but in man, for instance, hypertonic sugar solution does not leave the stomach in significant amount until its concentration has been reduced to 15 per cent; and it does not leave the duodenum until it has become isotonic (T. G. Miller, 1939).

Importance of Osmotic Exchanges in the Intestine.—Osmosis has at least a modifying influence on intestinal absorption. An isotonic condition becomes established promptly (but is not completed in the stomach; E. Otto, 1905). The changes result in corresponding alterations in the composition of the cells of the gastric and intestinal mucosa, which are therefore also subjected to osmotic salt action. This causes irritation. When the irritation is mild, it increases secretion, absorption and peristalsis. More severe grades of irritation produce emesis and inflammation. Salts not absorbable by the intestine (*cathartic salts*) are reduced to isotonic conditions by the transfer of fluid. This fluid is retained in the intestine with the salts, increasing the bulk and fluidity of the intestinal contents, and serving as a mechanical stimulus to peristalsis. This explains largely the cathartic effects of these salts.

Absorption Curve.—Hanzlik and Sollmann (1909 to 1913) found that the absorption of phenol, alcohol, iodide and presumably other substances from intestinal loops follows a similar curve, the rate being rapid for the first ten to thirty minutes, and then much slowed. Various factors seem to be concerned in this phenomenon. Brodie and Vogt, 1910, showed that the *oxygen consumption* of the intestines is increased during the absorption of normal saline, water and peptone solutions, indicating that the cells also play an active part in the process.

Absorption from Colon.—Goldschmidt *et al.*, 1919, found that diffusion occurs in both directions. With fluids below a certain threshold (about 0.16 per cent NaCl, with $\Delta 0.134$), chlorides pass from the blood into the colon. With hypertonic solutions (above $\Delta 0.786$ = NaCl 1.2 per cent), fluid at first goes into the colon. Finally, the Cl and the freezing point come into equilibrium with the blood.

Fate of Salt Solutions within the Body.—In whatever concentration and by whatever channels salts are introduced into the body, they *tend to produce hydremic plethora.* If isotonic or hypotonic solutions are introduced, they dilute the blood by their own fluid; if hypertonic solutions are injected, the blood draws fluid from the tissues until it has resumed its original concentration. *Anisotonic solutions* temporarily alter the *molecular concentration* of the plasma.

However, *the blood has a remarkable power of resuming its normal condition, its total molecular concentration, ratio of individual constituents, ratio of corpuscles to plasma, and total quantity* (*in about this order*). This process of restitution is far advanced before a quick intravenous injection can be completed; the molecular concentration returns to near normal within ten minutes; the quantity of blood and individual constituents are restored somewhat more slowly, but they are almost normal in half an hour; after two hours, the blood presents only slight abnormalities, even when large injections have been made (Magnus, 1901; Sollmann, 1901).

The *total molecular concentration* is the first factor to be restored, mainly by the passage of the dissolved molecules: if a *hypertonic solution* is injected, the injected molecules leave the blood rapidly. Other molecules leave more slowly, and water is taken up into the blood from the extracellular fluid, which becomes hypertonic and, in its turn, draws water from intracellular fluid until its volume is actually increased, the intracellular fluid becoming more hypertonic (A. W. Winkler *et al.*, 1944). When the normal molecular concentration is restored, the phenomena become identical with those following the injection of isotonic solutions. If a *hypotonic solution* is injected, the principal phenomenon at first is the passage of molecules into the blood, the injected molecules leaving the plasma slowly. The water also leaves only gradually, *i. e.*, mostly after the normal concentration has been reached; and then by the same process as with isotonic solutions. If an *isotonic solution* of a single salt (sodium chloride or sulfate) is injected, both the fluid and the injected molecules leave the circulation, the molecules somewhat more rapidly. At the same time, other molecules enter the circulation. This process continues (for about two hours), until the original quantity and composition of blood have been practically restored.

Mechanism of Restoration.—This is initiated by the rapid exchange between the blood and the extracellular and intracellular fluid, chiefly by transfer of water. It is completed by the elimination of excess fluid and solutes from the body, by the urine, sweat and, if necessary, by vomiting and diarrhea. The larger volume of the extracellular and especially of the intracellular tissue fluids enables them to take up a correspondingly larger volume of water and salts than the blood. The striated muscle cells (Wahlgren, 1909) and the liver (Sherrington and Copeman, 1893; Uschinsky, 1905) play the most important role in the rapid exchange.

Fluid Distribution in the Body.—The blood plasma amounts to about 5 per cent of the body weight; the interstitial tissue fluid to about 15 per cent; the intracellular fluid is about 50 per cent. The "*bromide space*," or "*thiocyanate space*," which corresponds approximately to the sum of the plasma and interstitial tissue fluid, amounts to about 25 per cent of the body weight in normal human subjects. The *concentration of dissolved substances* is approximately the same in the plasma and interstitial fluid (except protein); but it is quite different in the intracellular fluid. The *milliequivalents per liter of blood plasma* are: *cations*, Na, 153; K, 5; Ca, 5; Mg, 2; total, 165; *anions*, Cl, 113; HCO_3, 27; proteins, 18; others, 7; total, 165. For *intracellular fluid*, they average K, 150; Mg, 30; Na, 12; Ca, none; total, 192; protein, 80; phosphate, 70; others, 42; Cl, none; total, 192.

The quantity of material of which tissues can dispose, without visible change, is astonishingly great. In rabbits, the tissues may take up Ringer's solution amounting to four times the quantity of the blood (Bogert, Underhill and Mendel, 1916). However, very large injections give rise to ascites, effusions and diarrhea.

Conditions Delaying the Restoration of the Blood Volume.—Bogart, Underhill and Mendel, 1916, confirmed that in normal dogs and rabbits the blood volume returns to normal within half an hour after the intravenous injection of warm Ringer's fluid, equivalent to the total blood volume. This is delayed by morphine and by nephritis (uranium, chromate or tartrate), but not by ligation of the kidney vessels. The restoration is not affected by the addition of 0.4 per cent sodium carbonate, either in normal or in nephritic animals. Gelatin solutions (2 per cent) may leave the blood as rapidly as plain saline, although more commonly from 11 to 27 per cent is still present in the blood after half an hour. The gelatin leaves the blood in the same ratio as the fluid (Boycott, 1914) and is partly excreted in the urine.

Dehydration.—Reduction of the fluid of the body below the amount necessary for the normal functions may occur through deficient income or excessive loss by perspiration, diarrhea, persistent vomiting; it may be hastened experimentally by injection of hypertonic sucrose solution (Gregerson and Painter, 1939). It may also be produced by withdrawal of sodium, since there is a close relation between the volume of water and of sodium in the extracellular fluids, so that the loss of either entails decrease of the other. In the early stages of dehydration the loss of water and sodium falls chiefly on the interstitial fluid, but the plasma contributes somewhat from the start, and much more when the loss of either water or sodium exceeds a critical amount rmine, methylene blue, wyler *et al.*, 1942). merular filter holds

Lymph formation takes place chiefly by it passes egg the blood plasma through the capillary endothglomerular the tissue spaces, although other forces also play ules of (Carlson *et al.*, 1908; Boehm and Asher, 1909). This filtration depends chiefly on the balance between the hydrostatic pressure in the capillaries (35 mm. Hg toward the arterial, 13 to 14 mm. toward the venous end) and the colloidal osmotic pressure of the plasma, 25 to 35 mm., owing chiefly to the albumin. This permits normally some filtration of fluid near the arteries, especially as the plasma proteins filter to some extent, especially in the portal circulation and in inflamed capillaries (C. H. Wies and Peters, 1937). Some reabsorption would take place toward the venous side (E. M. Landis, 1934). The total normal lymph filtration in twenty-four hours has been estimated as fifty times the plasma volume. It is increased by decreasing the plasma colloids, and by increasing the plasma volume by injection of fluid, especially of hypertonic solutions. It is also increased locally by increased activity of the tissues.

Asher, 1913, pointed out that filtration can not be an important factor in the secretion of *saliva*, *sweat* and *bile*, since the secretion pressure exceeds the blood pressure. The physico-chemical conditions of salivary secretion were investigated by Japelli, 1906; those of tears and collyria by Cerrano, 1909.

Edema.—Salt action, osmosis and colloid imbibition are important factors in edema, *i. e.*, the excessive accumulation and retention of fluid and salt within and between the cells.

The edema fluid is analogous to lymph and may therefore be increased by the same agencies which increase lymph flow; hydremic plethora; lymphagogues of the "second class" (peptones, and so forth); increased blood pressure; venous obstruction; injury to the vascular endothelium, and so on. However, for the retention of fluid it is further necessary that the drainage of the lymph be obstructed, or that there be an increased affinity of the tissues (or colloids) for fluid. The cooperation of several of these factors is generally necessary for the production of noticeable edemas. Experimental edemas, resembling the clinical, require the simultaneous presence of nephritis, hydremic plethora and vascular injury (Pearce, 1909). Extensive intravenous injection of salt solutions produces ascites and edema of the internal organs, but not of the normal skin or subcutaneous tissue. To effect these, the skin must be irritated (Cohnheim and Lichtheim, 1877); or the vessels injured, as by arsenic (Magnus) or uranium.

Salts and Edema.—As intercellular fluid cannot be retained without sufficient solute to keep it isotonic, deficiency of sodium chloride tends to lessen the production of effusions, and to hasten their absorption. This is the rational basis of *the treatment of nephritic edemas by withholding salt from the food* (advocated by Widal and Javal, 1903). The treatment is not always successful (Blooker, 1909). *Edema by decrease of plasma proteins* occurs when these are reduced below 5.5 per cent (Peters and Van Slyke; Leither and McLean, 1929), as after repeated hemorrhages, and in starvation or "war edema" (Schittenhelm and Schlecht, 1919; J. B. Youmans *et al.*, 1932).

Colloids and Edema.—Martin Fischer (1908 to 1915) suggested that edema is due chiefly to changes in the affinity of the tissue colloids for water and salts, analogous to the swelling of gelatin or fibrin. This is modified to a varying degree by electrolytes, not by nonelectrolytes. It is especially increased by acids; and the production or accumulation of acid, including CO_2 in inflammation, venous stasis, and so forth, would therefore be the principal cause of edema (and the concomitant salt retention), and incidentally of nephritis. Fischer was also inclined to deny that osmosis has any part in these or other vital phenomena, and to refer to imbibition all the phenomena generally classed as osmotic; but serious objections have been raised to some of Fischer's deductions (L. J. Henderson *et al.*, 1914). *Particulate matter*, such as finely divided carbon and especially blood corpuscles and platelets, are reported to promote the flow of perfusion fluid through the finer capillaries of frogs, and thereby diminish edema (Zweifach, 1940; Danielli, 1940).

Salt Actions on Urine.—The introduction of salts or fluid into the body results in increased output of urine, *i. e.*, saline diuresis. This is largely physical, owing chiefly to the hydremic phethora which increases the renal circulation and the glomerular filtration pressure, and decreases the viscosity of the blood and the water-retaining affinity of the plasma proteins. Hypertonic solutions dehydrate and shrink the kidney cells, and thus widen the blood and urine channels. Saline dehydration also increases filtration through other colloid surfaces, *f. i.*, frog skin.

Filtration in Dead Kidneys.—Hydremic plethora and dehydration increase the ureter flow in perfused dead kidneys, in close analogy to their effects on the living kidney, except that the composition of the filtrate is that of the perfusing fluid (Sollmann, 1903 to 1905). This holds true also for heart-lung-kidney preparations when the vitality of the kidneys is suspended by cyanide (Starling and Verney, 1925). The urine flow and kidney volume of excised and *reimplanted kidneys* react the same as normal kidneys to urea, hypertonic salt solutions, and to the methylxanthines (Quinby, 1917); these, however, also change the composition of the filtrate. Such transplanted kidneys have been observed to function normally over four months (Ibreka, 1926).

Course of Saline Diuresis.—The physical element in the diuresis is especially conspicuous in the early periods of the diuresis, when the changes in the blood are relatively large, and when the rapid flow of the urine through the tubules leaves less time for the secondary, reabsorptive and secretory changes. The *degree* of diuresis (the total quantity excreted) depends largely on the quantity of solution (both of the dissolved substance and of the water) which has been introduced; but the *rate* of diuresis (the quantity excreted within a short time after injection) depends largely on the concentration of the solution, if this is given intravenously. Water, which is strongly diuretic when taken by mouth, may diminish the urine when injected by a vein. The course of the diuresis is fairly parallel to that of the changes in the renal circulation, in the case of gum saline solution; but with intravenous injection of hypertonic solutions (of sodium sulfate or urea), the diuresis considerably outlasts the circulatory changes (Cushny and Lambie, 1921); this is probably due to the persistence of slight changes in the saline composition of the blood. The *concentration of the urine* varies with the concentration of the solution which has been introduced: it may fall as low as △0.12°, or rise as high as △3.0° C. On the whole, the composition of the urine approaches the more closely to that of the blood, the faster the diuresis. In the *ordinary secretion of urine*, osmosis would be an obstacle, rather than an aid; for the molecular concentration of urine differs widely from that of the blood (△ *urine, ordinarily*, 0.9° to 2.1°; *extremes*, 0.12° to 3.0°; △ blood, 0.55° to 0.60°); and the kidney has to perform considerable labor to overcome the difference in osmotic pressure. Inability to concentrate or dilute urine is characteristic of various types of nephritis. This work does not seem to be injurious to normal kidneys, but concentration of urine may be injurious to nephritic kidneys.

The *work performed in urine formation* can not be calculated directly from the total molecular concentration, since the departure of every constituent from its concentration in the blood requires work. Barcroft and his coworkers found that the diuresis following the injection of isotonic solutions did not increase the *oxygen consumption of the kidney* and therefore presumably does not involve work; but that the oxygen consumption increases when hypertonic urines are secreted in response to sulfate injection. Caffeine diuresis also involved work. However, Hayman and Schmidt, and Fae, 1929, did not obtain increase of oxygen consumption with sulfate diuresis, unless the renal blood flow was markedly increased, so that the interpretation of the oxygen consumption is ambiguous.

Threshold and Nonthreshold Substances.—The relative concentration of the constituents of the urine differs more or less from that of the plasma. Cushny pointed out that they may be arranged into two classes: The *threshold substances*, sugar, Na^+, Cl^-, HCO_3^-, are found in the urine only if their concentration in the plasma surpasses a certain threshold level. Their urinary concentration is ordinarily not much higher than in the plasma, and may be very much lower. The *nonthreshold substances* occur in the urine whenever they are present in any quantity in the blood plasma, and their urinary concentration is much higher than in the plasma. They include urea, creatinine, ammonium, phosphate, sulfate ions, inulin and most substances not normal to the body. Uric acid and potassium are also more concentrated in the urine, but the difference is not so great. *The explanation of the classification* lies in the changes which the glomerular filtrate undergoes in passing through the tubules, where the threshold substances are reabsorbed to a large degree, the nonthreshold group little, if at all. *Diuresis* tends to increase the elimination of all the constituents, in absolute amount per unit of time. The percentage of nonthreshold substances is invariably diminished; that of the threshold substances is also often diminished, but may actually rise, according to whether they were previously above or below the concentration of the blood.

The **mechanism of urine formation,** according to the work of A. N. Richards and his associates, 1922 to 1938, consists of (1) filtration in the glomerulus of an ultrafiltrate of the plasma, containing all the nonprotein constituents of the plasma in the concentration present there. (2) Passing down the tubules, the ultrafiltrate is concentrated by the reabsorption of water, and (3) modified by the reabsorption of dextrose, NaCl and certain other salts, and (4) by the secretion of some dyes, such as phenolsulfonphthalein, and limited amounts of some other substances. Diuretic drugs may act either by increasing glomerular filtration or by decreasing tubular reabsorption. They can act on these only if there is sufficient intactness of the kidney structure, sufficient blood pressure and sufficient blood flow (J. M. Hayman, 1936).

The *evidence* of the mechanism of urine formation rests fundamentally on the application of micromethods for the direct collection and analysis of urine from individual glomeruli and tubules in frogs and necturus, by A. N. Richards and his associates, and in mammalian kidneys by A. M. Walker and Oliver, 1941.

The *glomerular fluid,* as collected from Bowman's capsule, has the composition of an ultrafiltrate of the plasma, containing all the normal constituents except proteins, in quantitatively the same concentration: chloride (Westfall, Findley and Richards, 1934), dextrose, urea, and so forth; and also foreign filtrable substances that have been injected, such as *dyes* (indigo-carmine, methylene blue, phenolsulfonphthalein). While the glomerular filter holds back the normal *proteins* of the plasma, it passes egg albumen readily. The size of the pores of the glomerular membrane is therefore between that of the molecules of serum- and egg-albumen, in man as well as in frogs. The polysaccharide *inulin* (of the molecular weight of about 50,000), which passes the filter readily and is not reabsorbed in the tubules, is especially suitable for estimating the rate of glomerular filtration. In man this averages 120 cc. per minute, regardless of the final volume of the urine proper, which may be reduced to 0.5 cc. per minute by water deprivation, or to only 15 cc. per minute in water diuresis (Richards, 1938).

Tubular Reabsorption.—The modifications in the composition of the final urine are produced in the tubules (Wearn and Richards, 1924, 1925). These reabsorb water and the "threshold solutes," which the body finds it is useful to conserve. Sucrose and xylose are also reabsorbed, but to a much smaller degree (review, J. A. Shannon, 1939). The tubules also excrete directly a minor portion of the creatinine and the major portion of some foreign substances, such as phenol red. The reabsorption is abolished if the tubules are poisoned by cyanide or by mercuric chloride, and the urine then approaches the glomerular fluid in composition (also in mammals, Starling and Verney, 1925). The *site of tubular reabsorption* has been localized by catheterization of various levels of the tubules in mammals (A. M. Walker and Oliver, 1941), as well as in frogs (A. M. Walker *et al.,* 1937). The absorption of dextrose occurs in the proximal tubules of all glomerulate kidneys; that of the other components differs somewhat in amphibians and mammals. In guinea pigs at least two-thirds of the water is reabsorbed in the proximal tubules. The chloride concentration of the fluid at this level is considerably greater than that of the plasma, probably by preferential absorption of bicarbonate. Farther along in the tubules the chloride falls, generally to less than the plasma. Concentration of the urine above the osmotic pressure of the blood plasma occurs only in animals provided with Henle loops (Starling and Verney, 1925). *Phlorhizin glycosuria* is attributed to prevention of the tubular reabsorption of dextrose (Walker and Hudson, 1937).

The tubular reabsorption of water is promoted by the pressor *posterior pituitary hormone;* that of sodium chloride by the *adrenal cortical hormone.*

The *magnitude of glomerular filtration and of tubular reabsorption* of water may be estimated in man by the injection of a substance, such as inulin, which is excreted purely by filtration in glomeruli and not reabsorbed in the tubule; or somewhat less accurately by creatinine "clearance" (Richards, 1936). These methods confirm the original estimate of Ludwig, that the volume of the glomerular filtrate is fifty to a hundred times greater than the volume of the urine as finally elaborated. This has also been shown directly by catherization of the amphibian glomeruli and tubules (Richards, 1929). This brings the reabsorption for man, per twenty-four hours, to about 25 gallons (99 liters) of water, 2 pounds (800 Gm.) of NaCl and ½ pound (200 Gm.) each of dextrose and bicarbonate (Richards, 1938).

The *mechanism of tubular reabsorption* may perhaps be explained by the assumption that the concentrated and inspissated blood which flows from the glomeruli along the tubules acts as a chemical stimulus to the tubular epithelium, causing it to absorb some substances, including water, and perhaps to secrete others, in a degree conditioned by the quantitative composition of this blood. The stimulus for any ingredient would thus operate automatically until the blood becomes normal, and cease automatically at this point. The sensation of thirst and the respiratory stimulation of acidosis are illustrations of analogous stimulation by small changes in the composition of the blood. The energy to overcome the osmotic equilibrium would be generated in the high epithelium of the tubules.

Tubular excretion appears significant only for a few substances. Phenol red, *f. i.*, is excreted to 90 or 95 per cent by the proximal tubules and only 5 to 10 per cent by the glomeruli (Richards, 1938). Diodrast, hippuran and p-amino hippuric acid (PAHA) are excreted copiously by the tubules in mammals; also uric acid in birds and reptiles. The secreting capacity of the mammalian tubules is limited, so that the secretion of one substance inhibits the secretion of the others. This has been utilized for delaying the excretion of penicillin, which appears to take this path. A similar mutual inhibition obtains for the reabsorption of dextrose and xylose (H. W. Smith *et al.*, 1938; review, J. A. Shannon, 1939). The tubular excretion of phenol red is demonstrable in *tissue cultures* of the proximal tubules of the chick mesonephros, which take the dye from the surrounding media and accumulate it in the lumen of the blind tubules. This is hindered by cyanide and inhibited by iodoacetate, the latter being restored by lactate. It appears therefore that the energy for the secretion of the dye is derived from an oxygen activation process, probably involving lactic acid (R. Chambers, Belkin and Beck, 1934).

The *aglomerular kidneys of the lower fishes* correspond in structure to the proximal convoluted tubules of the higher vertebrates. Their function was studied especially in the toad fish, Opsanus tau, by H. K. Marshall and his associates, 1929, 1934. They do not excrete dextrose, but secrete salts, urea, certain foreign substances (dyes: Hoeber, 1935) and fluid, even when the ureter pressure is raised considerably above the blood pressure. Intravenous injections of hypertonic solutions of urea, magnesium salts or sulfates produce diuresis; isotonic sodium chloride has no effect; caffeine and theophylline cause oliguria (Bieter, 1935). The evolution of the renal function and structure in fish is reviewed by H. W. Smith, 1933. The gills of fishes take the place of the kidneys to a considerable extent: By simple diffusion they excrete six to ten times more urea and ammonium than the kidneys. The less diffusible metabolites, creatine, creatinine and uric acid, are excreted chiefly by the kidneys (H. W. Smith, 1929).

Functional responses to osmotic changes consist in mild or strong stimulation, often irritative, passing into depression and finally disorganization of the cell if the changes are large. Abstraction of water from a *nerve or muscle* causes contraction; the unfertilized eggs of certain marine animals undergo parthenogenetic development, and so on (J. Loeb, 1899, 1901). If a strong salt solution is injected directly into the circulation, the main symptoms arise from the central nervous system. They consist in stimulation, with subsequent paralysis, with death from respiratory failure, presumably by dehydration of the cells of the respiratory center (A. W. Winkler *et al.*, 1944).

Local irritation by anisotonic solutions is chiefly sensory, and varies in different situations. Exposed nerves, including those in open wounds, are especially sensitive to hypertonic solutions. The mucous membrane of the mouth is insensitive to hypotonic solutions, but responds to hypertonic solutions by nausea. The mucosa of the nose is more sensitive to irritation by hypotonic solutions; so also are the conjunctiva and cornea; the latter is rendered turbid. *Eye-waters and nasal douches* should be made approximately isotonic by 1.4 per cent of sodium chloride, approximately 2 teaspoonfuls in a liter or quart of water; or by boric acid, or sodium bicarbonate, 2 to 3 per cent (4 to 5 level teaspoonfuls to a liter); or sodium borate, 4 per cent, 8 teaspoonfuls to a liter (or a fourth of these quantities to a tumbler). The *p*H is also important, 8 being best; definite irritation is produced above 9 or below 6.6 (Massart, 1889; Fantus).

Opacity of the lens results if salt is placed in the stomach of a frog. Transparency is restored if the frog is placed in water (Claude Bernard, "Anesthétiques").

Phagocytosis is decreased by small changes of the osmotic concentration of the serum, such as may occur under physiologic conditions. All anisotonic solutions are injurious, especially increased concentrations. The leukocytes recover when the normal concentration is restored. NaCl causes but little injury apart from the osmotic effect. A slight excess of calcium stimulates, while decreased activity results from a larger excess, and from reduction of calcium as by fluorides or citrates. Diminution of the normal alkalinity is deleterious, and to a less degree also an excessive alkalinity (H. Hamburger *et al.*, 1908 to 1910).

Brain Volume.—Intravenous injection of hypotonic solutions increases the bulk of the brain, and therefore the intracranial and cerebrospinal pressure. Hypertonic injections, after an initial rise, produce marked shrinkage of the brain and fall of cerebrospinal pressure. The alterations may be so great as to produce histologic changes (Weed and McKibben, 1919). Haden, 1919, introduced this means for the relief of the cerebral compression of meningitis, injecting 250 cc. of 25 per cent sterile *dextrose* solution, intravenously, two or three times a day. It was noted, however, that this reduces the cerebrospinal fluid pressure for only two or three hours, and is followed by a rise above the control pressure; this cannot be overcome by repeating the injections (E. Sachs, 1933; A. Blau, 1936), for the dextrose is deposited as glycogen, leaving the water behind, so that the blood soon becomes isotonic, and perhaps hypotonic, and the cerebral tissue swells

Sucrose does not produce this secondary rise, since it is not transformed and therefore remains hypertonic. It also causes more profuse diuresis, which eliminates further fluid. It is injected intravenously as 100 cc. of the 50 per cent solution, at the rate of 5 cc. per minute. This lowers the cerebrospinal pressure for five to eight hours, without after-rise. It may be repeated three to five times as needed (Bullock, Gregerson and Kinney, 1935; Hahn, Ramsey and Kohlstaedt, 1937). Intravenous injection of *water*, in large quantity, has little effect on the cerebrospinal fluid pressure or on the water content of the brain (Biancalana, 1930).

Intravenous Hypertonic Injection on Blood Pressure.—Injections of 10 per cent NaCl or 50 per cent dextrose or ten times concentrated Ringer solution, into the femoral vein of dogs, at the rate of 2 cc. per Kg. of body weight, cause immediate temporary fall of blood pressure, with increased heart rate and pulse pressure. The fall occurs even when the spinal cord has been pithed, so that it is apparently due to a direct vasodilator action (A. Bernstein, 1930). The plasma volume is well maintained, and the pressure and renal function are soon restored (A. W. Winkler *et al.*, 1944). Stewart and Rogoff, 1919, found *epinephrine output* markedly increased by the intravenous injection of small amounts of concentrated sodium carbonate solution. They attribute this to osmotic stimulation of the bulbospinal centers. Clinically, hypertonic injections cause a sensation of heat, sometimes with brief pain. Strongly hypertonic solutions are injected into varicose veins to produce obliterative phlebitis and thrombosis. The intravenous injection of 50 per cent dextrose is reported to shorten the bleeding time (H. Opitz, 1932).

Osmotic Effects on Heart.—In the perfused *turtle heart*, hypotonic solutions increase the tonus and the height of the contractions, shorten the A-V interval, but slow the rate. Hypertonic solutions produce the opposite effects (Goto, 1916). The isolated auricle of frogs responds similarly. Hypertonic dextrose is less depressant than NaCl. Hypertonic solutions also cause disappearance of the striations, which reappear in isotonic solution (Granemitzky, 1937).

Response of Muscles and Nerves to Osmotic Changes.—All forms of muscle, striped, cardiac and especially smooth, are stimulated by moderately hypotonic, and depressed by hypertonic, solutions. *Nerve trunks*, on the other hand, are stimulated by hypertonic and depressed by hypotonic media (Ishikawa, 1912). *Skeletal muscle* goes into contracture on immersion in *hypertonic* solutions, Ringer's, NaCl or dextrose. *Hypotonic* solutions produce twitching, contracture and rigor ("water rigor"), with accumulation of lactic acid, which may be the immediate cause of the contraction.

Osmotic Response of Uterus.—Marked stimulation occurs with even slight hypotonicity (Dale, 1912; Goto, 1916; Voegtlin and Lake, 1917); the depression by hypertonicity can be evoked even by oral administration in intact animals (Barbour and Rappoport, 1922). Hypotonicity also increases and hypertonicity depresses the response to anaphylactic stimulation (Dale, 1912).

Osmotic Response of Intestines.—The tonus and excitability are increased by hypotonic solutions, in living animals as well as in excised intestines. Hypertonic solutions depress, after a brief stimulation. This tends to expel the hypertonic solution from the lumen before it can become depressant, so that the practical effect in living animals may appear entirely stimulating (v. Oettingen and Sollmann, 1926).

The *gastric motility* is increased by hypertonic NaCl, even on intravenous injection, causing strong peristalsis of the stomach, with spastic closure of the pylorus and sometimes of the antrum (Jonkees, 1934). Oral administration of hypertonic salt or sugar solutions delays the emptying of the stomach (Gershon-Cohen *et al.*, 1938); 3 to 4 per cent NaCl provokes emesis.

Thirst is felt promptly after intravenous injection of hypertonic NaCl solution. It does not go strictly parallel to the increased osmotic concentration of the plasma. Decreased flow of saliva is a factor. The thirst may be temporarily suppressed by the injection of pitressin (J. H. Holmes and Gregerson, 1939).

Drinking of sea water is a common cause of death in men adrift on the ocean. The effects are due to hypertonicity, since large amounts are tolerated if they are sufficiently diluted with fresh water. The excess of salt does not go into the cells, but draws water from them into the extracellular fluid, producing progressive intracellular dehydration, while the volume of the extracellular fluid is not decreased. Various nervous disturbances set in shortly before death, including tremors, hyperactive reflexes, motor incoordination, and finally irregularity and arrest of respiration. The circulation functions well until the end, the plasma volume is not decreased, and renal function remains active (J. R. Elkinton and Winkler, 1944).

The functions of electrolytes in salt actions involve several factors. Aside from being the most important substances in maintaining the normal osmotic concentration, they are indispensable to cell function by regulating the electrical potential of the colloids and through this the aggregation of the colloids, their water affinity and the permeability of the surface membranes. In addition, reactive ions may enter into ordinary chemical reactions, but these are beyond the scope of "salt actions."

Importance of Electrolytes.—Muscles soon lose their excitability completely in solutions of nonelectrolytes; but this returns when they are replaced in saline solutions. A medium containing electrolytes is therefore essential to muscular contraction. The different ions are not equally effective. The nature of the cations is more important than that of the anions.

The ions arrange themselves in the usual lyotropic series, the Na and I end being the most favorable, and the K and citrate end the most unfavorable to striped muscle, and to the rhythm of the heart. With smooth muscle, on the other hand, moderate concentrations of potassium increase the tonus and the peristaltic contractions (uterus, Tate and Clark, 1921). Potassium also stimulates the tonus waves of turtle's auricle. Calcium is generally antagonistic to the effects of potassium, on all forms of muscle.

There is usually an *optimal concentration and ratio* of ions for a given set of conditions, so that addition or withdrawal has contradictory effects according to whether they lead toward or away from the optimum. Immersion in any *solution of a single salt* also renders muscle inexcitable, but with different rapidity. These differences follow the lyotropic series in the same sense.

Surface Actions of Electrolytes.—There are reasons for believing that the ion actions may be exerted only on the surface of the cells, especially by altering the permeability of the plasma membrane. The high resistance of cells to the penetration of ions makes internal effects improbable. The promptness with which the effects can be removed by the addition of a second salt also speaks against absorption. It is probable that the single salt solutions disturb the semipermeability of the membrane (J. Loeb, 1905, 1914), thus interfering with the maintenance of the electric potential which determines irritability. Cells denuded of their plasma membranes undergo complete disintegration. Calcium tends to produce coagulation of the disintegrating material where the plasma membrane has been punctured, and so repair the injury (R. Chambers, 1943). The *intracellular cations* are chiefly K and Mn; the anions are chiefly various phosphorus compounds (O. H. Lowry, 1943). Histological localization of ions by precipitating reactions is misleading, since the precipitates tend to prevent penetration of the reagent (G. H. Scott and Packer, 1939).

The practical importance of general electrolyte actions in disease and treatment is limited perhaps because their biological importance is so great that alterations of the normal are not easily maintained, being resisted by rapid passage out of the blood into inactive storage systems and by elimination. The more important disturbances of ion balance in disease are the calcium deficiency of parathyroid tetany, and the sodium deficiency of pernicious vomiting, cholera, sweating and Addison's disease. Important examples in toxicology are the disionization of calcium by citrate and oxalate, and the circulatory disturbances of intravenous injection of potassium salts.

Balanced Salt Ratios.—A solution containing a single electrolyte, no matter what the chemic nature of the latter, is fatal to all forms of life. The toxicity can be greatly lessened by the addition of a second salt. This is called the *"antitoxic action" of ions.* For perfect functionation, several salts are necessary, in a definite "balanced" ratio (J. Loeb, 1900). Departures from this ratio modify the function of the cell; larger changes are fatal.

The optimal ratios differ for various tissues, and indeed for different functions of the same tissue; for instance, a small quantity of magnesium added to Ringer's solution bathing excised intestines decreases the tonus and the height of the contractions, but prolongs the life of the preparation. Very small quantities of a second electrolyte may suffice for antagonism: the addition of $\frac{1}{4000}$ m. $CaCl_2$ neutralizes the toxic action of $\frac{5}{8}$ m. NaCl on Fundulus ova (J. Loeb, 1901, 1911). The antagonism is mutual, at least to some extent.

Even when the antagonism of two salts is at its best, it is never perfect; it requires the addition of one or more further salts to enable the cell to perform its functions properly. Indeed, *a strictly normal condition is not reached until the cell is placed in a solution, the cations of which are within narrow limits the same, qualitatively and quantitatively, as those of its normal surroundings.*

The *magnesium and calcium antagonism* presents special features. Increase of either Ca or Mg ions depresses muscle and nervous structures. Nevertheless, the effects of the Mg may be removed by addition of Ca. Ca also antagonizes the inhibitory effects of K, as well as the stimulated effects of Na (Meltzer and Auer, 1908). Strontium does not take the place of Ca in these reactions. Even more complex relations were discovered (Joseph and Meltzer, 1914).

Ions Essential to Life.—The bulk of the electrolytes of animals are made up of the cations Na, K, Ca and Mg, and the anions Cl, HCO_3, PO_4 and SO_4. All these are indispensable to animals; Na and Cl are not necessary to plants. Small amounts of iodine, Fe, Cu, Co, Zn and other metals, and perhaps many other chemical elements are also more or less indispensable, but not necessarily in the form of electrolytes. Plants require boron and manganese, copper and zinc, in field crops as well as in cultures. These *"trace elements"* form part of the essential *electron-transfer enzyme systems;* Mn in arginase, Zn in carbonic anhydrase, Al in succino-oxidase, Mg in phosphatase and carboxylase, Fe in cytochrome oxidase (review, O. Baudisch, 1943; M. E. Shils and McCollum, 1942). Excess quantities are toxic, and the margin is often narrow (review, Hoagland, 1940).

"Physiologic" or "Normal" Saline Solutions (Artificial Serums).—The deleterious effects of single-salt solutions led to the introduction of solutions better adjusted to physiologic requirements. These balanced solutions are necessary when experimenting on excised tissues. They are less important for injections into living animals, in which even single-salt solutions are rapidly adjusted by exchange with the tissues. The solutions have been devised partly empirically, partly by imitating the salts of the blood serum or sea water. Different tissues may require modifications to secure the optimal effects. The following are the most important:

Isotonic NaCl Solutions.—Nasse, 1869, determined experimentally that 0.6 per cent is the best concentration for preserving the irritability of *frog's* tissues. Later, it was shown that this solution was not indifferent: Kronecker and Stirling observed stoppage of the heart; Ringer, twitching of muscles; Locke, contractures and increased irritability; Carslaw and Locke, curare action, and so forth. These effects can be overcome by balancing the solution with other salts. However, the solution is practically isotonic with frog's blood, and therefore obviates osmotic changes. On the other hand, it is hypotonic to *mammalian blood*, which requires about 0.9 per cent NaCl. Solutions of 0.8 to 0.9 per cent are therefore generally preferred for mammals. The concentration of the U.S.P. is 0.85 per cent. Abel, however, found in vividiffusion that a lower concentration, about 0.6 per cent, prevented edema more effectively.

KCl, 0.01 to 0.04 per cent. The lower the concentration, the higher the rhythmicity.

$CaCl_2$, 0.01 to 0.26 per cent of the anhydrous salt. The concentration is adjusted to balance the potassium. "Crystals" of calcium chloride contain varying proportions of water, so that their molecular formula should be stated.

$MgCl_2$ (0.01 per cent) is added to a few solutions, especially those intended for excised intestines. It depresses the rhythmicity and so prolongs survival.

Buffer alkali is secured by sodium bicarbonate, 0.003 to 0.15 per cent, sometimes with the addition of the sodium phosphates, although these are likely to precipitate the calcium.

Dextrose, 0.1 to 0.15 per cent, is added for the more active muscles as nutrient.

TABLE OF COMMONLY USED BALANCED SOLUTIONS

Percentages

Author	Adapted to	NaCl	KCl	$CaCl_2$ (Anhydrous)	$NaHCO_3$	Other Ingredients
Ringer	Frogs	0.6	0.0075	0.01	0.01	
Howell	Frogs	0.7	0.03	0.026	0.003	
Clark	Frogs	0.7	0.014	0.012 (dried)	0.02	
Locke	Mammals	0.92	0.042	0.018	0.15	Dextrose, 0.1
Tyrode	Mammals	0.8	0.02	0.01	0.1	$MgCl_2$, 0.01 NaH_2PO_4, 0.005 Glucose, 0.1

In making solutions containing $NaHCO_3$, this must be completely dissolved before the $CaCl_2$ is added.

Balanced Solutions.—The ideal solution for maintaining the functions of excised tissues should presumably reproduce the ion ratio of blood plasma. This cannot be deduced accurately from the serum ash, since the degree of ionization in the plasma is problematical, particularly as regards calcium. The formulas in actual use represent modifications of the ash ratio that have been found practically useful. They embody the following features (the number referring to the *anhydrous* constituents):

NaCl, 0.6 to 0.7 per cent for frogs, 0.6 to 0.92 per cent for mammals. The lower concentrations are more stimulant; this means better functionation, but shorter survival of the excised tissue. The same contrast between functionation and duration of survival applies to the other ingredients.

Aeration assists both functionation and survival.

The above table gives the actual composition of the more commonly used solutions. The Howell solution may be recommended for frogs and turtles, the Locke solution for mammals.

Locke's solution is intended to be used with a stream of oxygen. It was originally devised for the mammalian heart, but it also maintains the vitality of nervous and other tissues (Hedon and Fleig, 1905). Herlitska, 1910, found the addition of *urea* and glycerin to Locke's solution essential for the excitability of the nervous system of frogs. Bombiani, 1913, found that the favorable effect of urea on the selachian heart is not shared by related substances and therefore considered it chemic. It dilates the perfused vessels of the frog (Hooker, 1911).

Cations in Human Serum.—A. B. Macallum, 1926, obtained the following percentages, which for convenience are also expressed as the chlorides:

	Na	K	Ca	Mg
Cations	0.30 to 0.31	0.020 to 0.022	0.008 to 0.011	0.0018 to 0.0034
Chlorides	0.76 to 0.80	0.038 to 0.42	0.022 to 0.030	0.007 to 0.014

Sea water has three to four times the molecular concentration of the mammalian plasma. The ratio of Na to K is approximately that of the Locke solution, but its Ca and especially the Mg are notably higher. The composition varies somewhat in different oceans; that of the English Channel may be taken as representative, with the following percentages of its principal salts: NaCl, 2.7; KCl, 0.075; $MgCl_2$, 0.37; $MgSO_4$, 0.23; CaSO, 0.14.

American analyses are furnished by Wheeler, J. Am. Chem. Soc., *32:* 646, 1910.

The freezing point of sea water is: −2.29° C. at Naples (Bottazzi, 1897); −1.90° at Pacific Grove, California; and −1.82° at Wood's Hole, Massachusetts (Garrey, 1905). Intravenous injection of sea water is more toxic to rabbits than is sodium chloride in the same concentration (A. Rabbeno, 1929). A. B. Macallum, 1910, suggested the interesting theory that the composition of the blood is a survival of the evolutionary adaptation of animals to their original marine environment.

Ion Actions on Special Tissues and Organs.—Nerve fibers lose their irritability in solutions of nonelectrolytes, and recover in salts. The cation series is similar for muscle, but the anion series is reversed. The *reaction of motor nerves to electrolytes* is an additive function of the two ions: the anions (alkalis or increase of valency) stimulate the sciatic nerve of the frog, while cations (acids) lower its irritability (A. P. Mathews, 1902). This agrees with the old observation of Galvani (confirmed by Grandis, 1902), that the nerve is stimulated when it is charged by induction with negative electricity, and depressed by a positive charge. The *oxygen consumption* of isolated frog sciatic nerve is decreased by KCl, increased or unchanged by $CaCl_2$ (Kaganovskaia and Shlykova, 1935).

Skeletal muscle, immersed in isotonic solutions of various electrolytes, may lengthen or shorten; the excitability may be diminished or increased; spontaneous rhythmic contractions may appear; or the muscle may develop "contact irritability" so that it will react to stimuli which are ordinarily ineffective. Invertebrate and mammalian muscles exhibit similar phenomena if proper conditions are maintained. *Rhythmic contractions of skeletal muscle* generally develop before the irritability is lost, when muscle is immersed in solutions of a single electrolyte (Loeb, 1899). If a certain proportion of a calcium salt is added, the rhythmic property disappears again. Rhythmic contractibility is inherent in all muscular tissues. The reason why the contraction of the heart is ordinarily rhythmic, and that of skeletal muscle not, is that the ions in the heart are balanced so as to favor rhythmic contractions, and in the skeletal muscle they are not so balanced.

Muscle electrolytes are reviewed by W. O. Fenn, 1936.

Ciliary and Muscular Movement.—R. S. Lillie (1902) studied the effects of ions on the larvae of a sea worm (Arenicola), which executes both ciliary and muscular movements. The presence of magnesium in the mixture favors the contraction of the cilia, calcium of the muscles; potassium hinders both. Parker (1905) found that potassium reverses the stroke of certain cilia.

Injection of isotonic saline solution into a serous cavity is an effective method of securing emigration of leukocytes (D. R. Coman, 1939).

Ion actions on heart are highly important for the cardiac contractions. The excised hearts of cold-blooded animals soon stop their beat when immersed in solutions of nonelectrolytes (Carlson); but they continue to contract rhythmically for a long time in certain salt solutions. Analogous phenomena are observed in the perfusion of mammalian hearts. The solutions must contain Na, K and Ca ions; and these must be in a fairly definite "balanced" ratio, as in Ringer's or Locke's solutions or their modifications. Deficiency or excess of these ions causes derangement of function; both are equally fatal. For moderate changes, the ratio is much more important than the absolute quantity of the ions. The anions are relatively indifferent. The *effects of the individual cations on the heart* are complex and rather confusing, because the response of each is modified by the presence of other cations. There are also marked but generally only quantitative differences between the different portions of the heart. *In living animals,* departures from the normal ion ratio can not be maintained sufficiently long to be of practical importance (Schafir, 1915) or even to be conveniently investigated.

Perfused hearts respond to changes of the ion ratio of the Ringer's solution according to the direction of the K:Ca ratio, practically regardless of whether the ratio is changed by increasing the one ion or by decreasing the other. The K or Ca predominance becomes conspicuous when the percentage of the one is about three or four times that of the other (Boehm, 1914).

Functions of the individual ions may be studied in segments from the various regions of the *turtle's heart.* These do not beat rhythmically in solutions of the nonelectrolytes, but do so only if NaCl or other appropriate sodium salts are added. Sodium is therefore indispensable to the rhythmicity. The addition of Ca does not appear to be especially important for the rhythmicity, but rather to antagonize the eventual toxicity of Na and of K. The addition of potassium has a marked inhibitory effect on the rhythm, which is much more marked for the cardiac muscle proper than for the nodal tissue, and may therefore be important chiefly for subjecting the cardiac muscle to the control of the normal pacemaker (Chu and Sollmann, 1925). Localized application of KCl solution, on filter paper, to the sinus of mammals shifts the pacemaking function to lower regions (B. Kisch, 1927).

Increase of the K:Ca Ratio, i. e., Potassium Excess or Calcium Deficiency.—The effects resemble those of vagus stimulation; *i. e.*, weakening of the contractions and decrease of the rhythmicity, resulting in heart block, intermissions and arrest; and in synergism with the parasympathetic stimulants (acetylcholine, and the like) and mutual antagonism with sympathetic stimulation, through the accelerator nerve or by epinephrine; and with the muscular stimulations, *i. e.*, the digitalis group. Contradictory results are reported as to the excitability of the vagus trunk. The resistance to potassium increases with the inherent rhythmicity of the cardiac tissue, in order of: sinus (most resistant), ventricle base, ventricle apex and auricular muscle (least resistant). The percentage of potassium in normal blood tends to inhibit spontaneous ventricular and auricular rhythm, and therefore renders the heart muscle more amenable to the pacemaking function of the nodal tissue.

Increase of the Ca:K ratio, i. e., calcium excess or potassium deficiency, has essentially the opposite effects, resembling both accelerator stimulation with epinephrine, and muscular stimulation with digitalis. The contractions are strengthened and often quickened, with a systolic tendency which increases to prolongation and fusion of the systoles, and culminates in systolic arrest. Calcium excess is synergistic with accelerator stimulation by epinephrine and with the systolic effects of digitalis. It is antagonistic to vagus stimulation and to the parasympathetic stimulants and may apparently cause these to produce abnormal effects.

Hydrogen-Ions on Heart.—In the perfused turtle heart, increase of alkalinity (to *p*H 7.8) increases the tonus and rather decreases the amplitude; decrease of alkalinity (to *p*H 7.3) increases the output by lowering the tonus, thus permitting greater distention and excursions (Andrus, 1918).

Abnormal ions were studied, *e. g.*, by Lussano, 1913, by modifying the constituents of Ringer's solution. Sr and Ba can not replace Ca, but their effects correspond to those of excessive Ca. Li is not toxic, but causes some osmotic slowing; NH_4 slows, but increases, the irritability and strength. The effects of lithium, and so forth, on turtle heart strips were studied by Lingle, 1902.

Radioactive Metals.—Zwaaredemaker, 1918, claimed that the potassium in Ringer's fluid may be replaced by any radioactive elements in equi-radioactive proportions. A. J. Clark, 1920, failed to confirm this generalization.

Nonelectrolytes, urea, dextrose or saccharose replacing isotonic equivalents of NaCl in Ringer's solution, behave similarly to Ca, and are antagonistic to Na and to K (Mita, 1926).

Cardiovascular effects of cations as they occur in dogs on slow intravenous infusion of single salts are described by Winkler *et al.*, 1940: *Potassium* produces intraventricular block and diastolic arrest. *Calcium* produces vagal bradycardia, ventricular arrythmias and ventricular fibrillation. *Magnesium* produces vasodilatation with fall of blood pressure. The heart is affected only with doses that cause respiratory arrest.

Blood vessels perfused with modified Ringer's solutions give somewhat inconstant results, but they are generally *dilated* by excess of Na or absence of Ca; and *constricted* by excess of Ca or of K and also by absence of K (Gramenitzki, 1927; Yamada and Yoshida, 1927). Lack of Ca and excess of Na increase the constrictor *response to epinephrine*, and this is diminished by excess of K. It persists eight times as long if dextrose is added to Ringer's solution (Hatcher, 1906). The tonus is raised by replacing the Cl with other haloid *anions*, F > I > Br (Prochnow, 1911).

The *coronary vessels of dogs*, perfused with heparinized blood, are dilated by the addition of Na and Ca in all concentrations. Dilatation also occurs if a small quantity of K is added, but larger amounts constrict, sometimes to complete coronary occlusion (Katz and Lindner, 1938).

Smooth muscle gives inconstant and contradictory results. In general, increase of Na increases the amplitude of rhythmic contractions but has little effect on tonus. Increase of the Ca:K ratio increases tone and rate, but depresses amplitude; increase of K:Ca increases the amplitude.

Details for excised intestines are reported by Whitehead, 1929; for *uterus* by Turold, 1922; for *iris* by Regniers, 1926. *Anions* arrange themselves according to the Hofmeister lyotropic series, the rhythmicity increasing in sequence from citrate to sulfate, chloride, iodide and thiocyanate (Gellhorn and Moldavsky, 1934).

Central Nervous System.—With perfusion of the *medulla* of dogs, increase of Ca:K stimulates, and increase of K:Ca inhibits response (Hooker, 1915). The perfused *central nervous system of mammals* preserves its activity best with a solution of 0.9 per cent NaCl and 0.05 per cent $CaCl_2$. These can not be replaced by related cations. Even traces of potassium are harmful (P. Gerlach, 1914). With perfusion of the *respiratory center of frogs*, increase or omission of K from balanced solutions produces depression; decrease of K causes stimulation. With Ca, increase and omission produce stimulation; diminution, depression (Hooker, 1913). The perfused *spinal cord* of frogs gave similar results (Hooker and Reese, 1914). As to the perfusion of the *medullary cardiac centers*, predominance of K stimulates the vagus and inhibits the accelerator; predominance of Ca stimulates the accelerator (Hooker, 1915).

Ion Effects on the Kidneys.—The polyuria and glycosuria which follow the intravenous injection of large quantities of most sodium salts are arrested by adding a small proportion of $CaCl_2$ (W. H. Fischer and O. H. Brown, 1903). Sr or Ba salts prevent the *glycosuria* without affecting the polyuria. Calcium also hinders the filtration of urine and impedes the circulation in excised kidneys, while magnesium favors them. The effects of most others ions investigated in this manner are referable to osmotic changes, due to differences of penetrability (Sollmann, 1905).

◆

WATER

Direct application of water to semipermeable cells produces osmotic changes. If the semipermeability is imperfect or impaired, there results a leaching-out of salts and, with this, a disturbance of the ion ratio. Instances of these deleterious actions are the water laking of blood and the swelling and water rigor of muscle. The surfaces normally exposed to contact with water are protected against these actions, either by impermeability, as the skin and bladder, or by the rapid passage of salts into the water, as in the alimentary tract. Even in these situations, however, the water causes more or less swelling, stimulation or irritation of the cells. Water constitutes about two-thirds of the body weight (65 per cent for dogs, 70 for macacus monkeys, 75 for rabbits; H. E. Harrison *et al.*, 1936). It is 75 to 90 per cent of the active tissues, 40 per cent of bones. The water content of the tissues decreases with age, both before and after birth. About a fourth of the available water is normally in the skin and muscles, the skin being the most flexible depot, chiefly by its interstitial fluid (L. J. Flemister, 1942).

Water is constantly lost to the body by the urine, lungs, perspiration and feces, but before this reaches a demonstrable degree of drying and concentration of the tissues, the sensation of thirst prompts the replacement of the water. Absorption of fluid, however, from the alimentary canal is not an effective protection to the water and salt content of the body, for it does not cease when this normal level is exceeded (J. P. Peters, 1944). Excess water is promptly eliminated by the excretions, which are correspondingly increased and diluted, but there is a temporary increase of the water content of the fluids and cells of the body; removal of their salts; and alterations in the proportions of their ions. These changes in turn produce functional phenomena, characterized especially by increased secretions, and by changes in metabolism. The effects vary according to whether the quantity of water is normal or excessive, and according to the channel by which it is introduced.

Water Capital and Turnover.—The tissues of an adult man contain about 40 Kg. (10 gallons) of water. Its daily turnover is by far the largest of all components of the body. From $3\frac{1}{3}$ to 10 liters, $\frac{1}{12}$ to $\frac{1}{4}$ of the total water of the body, are eliminated and must be replaced every day.

The sources of water income are food and drink, about equally (Maddock and Coller, 1937). The amount drunk as *fluids* is 800 to 2000 cc. per day. It is the most easily adjusted source, and is regulated by the thirst, according to the other sources of income and to balance the elimination. The *food* contains considerable water, averaging about 70 per cent; additional water is formed by its oxidation. From both sources, each gram of "solid" food furnishes about 0.9 Gm. of water, amounting to 1000 to 1500 cc. per day. Even in starvation, up to 500 cc. become available by oxidation of the tissues.

The *quantity of water formed by oxidation* of food materials, in terms of cubic centimeters of water per 100 Gm. of dry food, amounts to 90 to 100 cc. for fat, 50 to 60 cc. for starch, 40 to 50 cc. for proteins. Alcohol forms 117.4 cc. The oxidation of mixed food of 3000 calories furnishes about 360 cc. of water. *In starvation*, dogs drink only about half the normal quantity of water, bringing their total water intake down to $\frac{1}{5}$ to $\frac{1}{3}$ (Kleitman, 1927).

Absorption from Alimentary Canal.—Water is rather slowly absorbed from the *stomach*, where it also delays absorption of other substances. It passes rapidly, however, into the duodenum, and is absorbed readily from the *intestines*, small and large. In addition to the ingested fluid, from 3 to 5 or even 10 liters, about 2 gallons, of fluid are poured daily into the upper half of the alimentary canal as digestive secretions, and less than 150 cc. are normally lost with the stools, the remainder being reabsorbed (Maddock and Coller, 1937). In health, the absorption of ingested water occurs chiefly in the upper portions of the small intestines (von Mering, 1893; Moritz, 1893). The contents are still fluid, however, at the lower end of the ileum, with 92 to 97 per cent of water (ileocecal fistula, human; Landt and Daum, 1933). The further concentration to the consistency of the feces, which contain about 75 per cent of water, occurs chiefly in the cecum and rectum, very little in the colon proper, for man and dogs (Steggerda, 1933, 1935). With guinea pigs, water absorption takes place chiefly from the proximal colon (W. Straub and Lee, 1933).

Absorption by the Skin.—Water is not appreciably absorbed through the normal skin, although it is slowly absorbed into the epithelium and produces swelling of the epidermis. Bathing in cold water contracts the cutaneous vessels, and diminishes the loss of water by perspiration; hot water increases the loss by favoring diaphoresis.

The **excretion of water** occurs by the kidneys, skin, lungs and intestines (feces). The relative importance of these channels varies with conditions. At rest, in temperate climate, the ratio averages about 6:2:2:1; but if water is taken hot, so as to favor dilatation of the cutaneous vessels, it acts as a *diaphoretic.* Excessive quantities of water may also be excreted by the *intestine* and lead to diarrhea. Normally, however, the kidneys have the chief part in maintaining the volume and composition of the body fluid.

The *range of minimal and liberal water loss* for adult man is given in the review of T. F. Adolph, 1933, as follows: Urine, 600 to 2000 cc.; feces, 50 to 200; insensible perspiration, 350 to 700; sweat, 50 to 4000; pulmonary ventilation, 300 to ?; milk, 0 to 900.

Elimination by the skin, especially by sweating, is the widest variable in water excretion and may be much greater than is generally recognized; but it is used for heat regulation rather than for water regulation. It increases when the external temperature or the internal heat production rises. In contrast to the renal water output, it is but little affected by the amount of water available. It is the chief element in *quick reduction of body weight* by hot baths and exercise.

F. G. Benedict, 1931, cites a football player who lost 14 pounds during a hot afternoon. The total dry tissue burned was only ½ pound, so that practically 98 per cent was lost as water, mostly through perspiration.

Water Lost by Evaporation.—Under conditions of comfort, at rest and with normal basal metabolism, about 25 per cent of the body heat is dissipated by evaporation from the skin and lungs of 1000 to 1500 cc. of water per day (Wiley and Newburgh, 1931). It may amount to 60 Gm. per hour, even in sleep (G. E. Wilson, 1933). It rises to 1500 to 2500 cc. in fever (Maddock and Coller, 1937). Dehydration by more than 6 per cent of the total body water lowers the loss by evaporation (J. F. Hall and McClure, 1936).

Cutaneous elimination of water occurs by the secretion of sweat, *sensible perspiration;* and evaporation from the epidermis, *insensible perspiration.* Both are regulated by the amount of blood circulating in the skin (J. D. Hardy and Soderstrom, 1938), but they do not necessarily go parallel. Dry heat increases both; moist heat increases sweating, but diminishes evaporation and therefore insensible perspiration (Vasti, 1932). Exercise increases the sensible perspiration much more than the insensible perspiration.

The *insensible perspiration* emerges as a watery vapor, not as fluid, and does not contain solutes. It averages 200 to 400 cc. per square meter of skin per day, more for the arms and legs than for the trunk (Adolph, 1933). Its total may rise to 50 cc. per hour. It is not increased significantly by ingestion of water or normal saline solution, but is markedly increased by ingestion of sucrose, which raises the cutaneous temperature. Injection of posterior pituitary solution along with water ingestion tends to increase the insensible perspiration (Hall and McClure, 1936).

The *pulmonary water excretion* comprises the evaporation of water from the alveoli and respiratory mucosae. It depends on the unsaturation of the inspired air and on the air movement, panting being more effective than deep respiration. It is important for furred animals, but relatively unimportant for man, averaging 300 cc. per day under basal conditions (Adolph, 1933). It increases with pulmonary ventilation and therefore with exertion and fever.

In small animals, the extrarenal loss of water, chiefly respiratory, often equals the urinary output: In a rat at room temperature it amounted to 1.25 Gm. per 100 Gm. of body weight per hour; in a rabbit, to 0.3 Gm.; in man, to 0.04 Gm. (H. Heller and Smith, 1932).

The **urinary excretion of water** varies with the excess of water in the body, chiefly by diminished reabsorption from the urinary tubules, probably involving inhibition of the output of posterior pituitary hormone. The depression of freezing point of the urine therefore falls, and may be as low as −0.12° C., less than a fifth of that of the blood. When the water is absorbed from the alimentary tract, the diuresis is prompt, strong and certain so long as the kidneys are normal. If more than the customary amount of water is ingested, an approximately equal amount is usually excreted in two or three hours, in addition to the customary excretion. The capacity of urinary water output is normally large, to 10 liters or more per day, but has limits. One extreme is seen in diabetes insipidus, the other in nephritis and after posterior pituitary injection. Other forms of nephritis are characterized by inability to concentrate the urine; or both may coexist.

High Water Consumption.—Three to 5 and even 10 liters may be taken and absorbed in the day, in man, with out altering the consistence of the feces. If a large quantity is ingested, a half to three-fourths may be excreted by the urine within forty-five to ninety minutes (Mattill and Hawk, 1911). With moderately large volumes of water, 1 to 1.5 liters, diuresis does not begin until some time after detectable reduction of the salt level of the serum (review, J. P. Peters, 1944). The excretion may be forced above 10 liters per day, and continued for several weeks, apparently without deleterious effects to the kidneys or otherwise; this does not even create salt hunger (Sollmann and Hoffmann, 1905). With adequate diet and a constant NaCl intake of 16.5 Gm. daily, Kunstmann, 1933, found that 7 to 18 liters of tap water daily for eighteen weeks did not impair the kidney functions, or cause any significant change in the osmotic pressure or Cl content of the blood, nor in the nitrogen excretion. Severe thirst developed, and persisted after the high water intake was concluded. The diuretic action of moderate quantities of water can be enhanced by the addition of other diuretics, but if large quantities of water are given, the addition of diuretics has no further effect.

Composition of the Urine.—The urine in water diuresis becomes very dilute, although the total or daily excretion of the dissolved constituents is generally raised as the increased ingestion of water flushes salts and metabolites from the tissues. There is no simple relation, however, between the increase of the different constituents, for instance N and Cl (Heilner, 1906).

Administration of large quantities of water causes a considerable *temporary increase in the urinary nitrogen*, as much as 34 per cent (Neumann, 1899). The excess is excreted mainly as urea, the uric acid being often unchanged. Fairhall and Hawk, 1912, found the *uric acid output* in man decreased, while the allantoin was increased. The excretion of the *phosphates and sulfates* is also increased. The removal of *chlorides* is so extensive that their percentage in the urine soon falls to a low figure. Wilson and Hawk, 1914, reported that the ingestion of additional water, moderate or abundant, causes a temporary decrease in the daily output of *chloride*, presumably through the need of equalizing the osmotic pressure of the retained water. The *ammonium* is increased (presumably as a consequence of the heightened gastric acidity), the *phosphate* unchanged, the *acidity* variable.

Increased Metabolism.—The excessive excretion of metabolites is mainly due to the "*flushing out*" of the tissues by the diuresis (Haas, 1908). If this were the only cause, the continued excessive administration of water would soon exhaust the stored waste products, and their excretion would fall rather below the normal figure. Actual results show that this holds for the chlorides, but not for N, P or S; their excretion remains permanently increased, although it does not remain at the original high figure (Edsall, 1900). There must therefore be *increased production of these metabolites.*

Conditions that Modify Urinary Water Excretion.—The degree of diuretic response to water ingestion is modified by the needs of the body and by the competence of the kidneys. Disturbances of urinary water excretion are among the most conspicuous functional manifestations of *nephritis* (Peters, 1932). The *tissue needs* for water are not necessarily reflected in the blood; *i.e.*, the diuretic response is not definitely related to the hemoglobin concentration (Haldane and Priestley, 1916). *Isotonic solution* of sodium chloride or bicarbonate, taken by mouth, produces diuresis much more slowly than equal quantities of water, in twenty-four to forty-eight hours, instead of two to three hours (Adolph), probably owing to slower absorption.

Temperature regulation is one of the principal factors of water diuresis. Warm environment reduces diuresis more than corresponds to the extrarenal loss of water, or to diminished absorption (Heller and Smirk, 1932). In fever, water is retained during the rise of temperature, and mobilized in defervescence. Binding down a rabbit alters its temperature regulation and therefore its diuresis. This is related to the *sugar level of the blood* (Barbour). Hyperglycemia, as by the ingestion of sugar, produces hydremia and diuresis; *insulin* hypoglycemia results in blood concentration (H. Marx, 1937). *Muscular exertion* diminishes diuresis, partly by leading to water loss by evaporation. Violent exercise, entailing accumulation of lactic acid and large oxygen debt, may suppress renal water excretion for an hour, presumably by the rise of osmotic concentration in the muscles (Hellebrandt, Walters and Miller, 1936). *Hemorrhage* leads to marked water retention, and water administration is as effective for restoring the blood volume as saline injection, though not so rapid. *Laparotomy,* even under local anesthesia and without handling of the intestines, reduces water diuresis by 90 per cent, in rabbits, because of retardation of intestinal water absorption (Heller and Smirk, 1933).

Parenteral administration of water, as such, produces little or no diuresis. For intravenous injections, this could be explained by the osmotic swelling of the renal epithelium, owing to hypotonicity of the blood, leading to compression of the blood vessels. Laking of the blood corpuscles would also diminish urine flow. Grindsberg, 1912, and Cow, 1914, however, suggested that the presence of water in the intestinal canal leads to the production and absorption of a diuretic substance. This has found experimental support in the extraction of potent diuretic substance from small intestines (Schmid, 1938).

General Effects of Water by Intravenous Injection.—The immediate effects of small amounts, slowly introduced (and especially of *hypodermic injections*), resemble those following the injection of isotonic salt solutions. The changes in metabolism and urine constituents are probably similar to those which occur on taking water by mouth. Larger doses and rapid injection introduce important modifications. Hemoglobin appears in the urine, from the laking of the blood corpuscles. The respiration is slowed and the blood pressure is lowered. The central nervous system shows rather late paralysis and convulsions. The excretion of water occurs mainly by other channels, so that there is usually a serous diarrhea, increased salivation, and so forth. The fatal dose of water (by intravenous injection) is somewhat smaller than that of normal saline solutions; distilled water is again somewhat more toxic than well water.

The *therapeutic uses of water diuresis* are chiefly to dilute the urine, to diminish its irritation and to flush out bacteria in *inflammations of the urinary passages*, in acute and chronic cystitis and in prostatic obstruction. The dilution is also useful to check the formation of urinary calculi of all kinds. The increased flow serves *to flush out tubular detritus* in nephritic oliguria; but the limited capacity of water excretion by such patients must not be exceeded. The increased N elimination following liberal water administration lowers the abnormally high N figures of the nephritic blood.

A certain minimum amount of water must be excreted by the kidneys *to carry the normal metabolites in solution.*

The quantity depends on the concentrating ability of the kidneys, which is reflected in the maximal specific gravity. To excrete the daily normal of 35 Gm. of waste products requires 473 cc. of urine, of sp. gr. 1.029 to 1.032; but 1439 cc. at 1.010 to 1.014. Less water leads to nitrogen retention (Lashmet and Newburgh, 1932). An output of 1500 cc. suffices for all ranges of function; larger quantities are needed only for flushing the urinary passages in infection (Maddock and Coller, 1937).

The *removal of poisons by diuresis* is not very successful, for poisons are generally nonthreshold substances, and their elimination is therefore not increased by hastening the passage through the tubules, but only by increased glomerular filtration. Water diuresis acts chiefly to lower the concentration of the excreted poisons. Energetic diuresis, by water or by intravenous saline or glucose, can save animals from *slightly* superfatal doses of strychnine (Eggleston and Hatcher, 1917; Kleiner and Meltzer, 1917), but is quite inefficient against diphtheria toxin (Sansum, 1918).

Retention of water does not occur under normal conditions, as the water-excreting capacity of normal kidneys is fully equal to the capacity of water absorption from the alimentary tract—as may be imagined when it is remembered that over 100 liters of fluid normally filter through the glomeruli. Water retention therefore occurs only when the renal functions are seriously upset by nephritis, by cardiovascular disease or by pitressin. All tissues participate in temporary storage of water. In cardiovascular disease, the excess fluid is chiefly in the lymph spaces; with nephritis and pitressin it is also intracellular.

The *water content of muscle* (and similarly of liver), as determined by biopsy, is increased by isotonic infusions, pitressin injection, starvation, morphine withdrawal. It is decreased by hypertonic saline infusion and by caffeine. It is not altered by anesthetics or by epinephrine (review, Adolph).

The *pituitary control* of water elimination is discussed under that subject (see Index). It is responsible for the antidiuretic effect of certain sensory reflexes (Verney; Haterius, 1939), and probably also for the effect of water deprivation and of temperature. The loss of water by frogs in dry environment is inhibited by the injection of pitressin and of pitocin (Boyd and Whyte, 1938).

Hydremia.—The drinking of a large quantity of water produces slight hydremia, shown by slight decrease in the electric conductivity of the serum (T. M. Wilson, 1905). Haldane and Priestley, 1916, attributed this to the passage of salts into the intestines. Blix, 1916, found that the administration of water to well fed rabbits could increase the water content of their body by a maximum of 11 per cent. Fasting and withholding water diminished it, also by a maximum of 11 per cent on the second day. After that it remained constant. Mercuric chloride nephritis also produced hydremia.

Blood Pressure.—Increased ingestion of water (for man, 3 liters beyond the normal) is said to produce a material lowering of the systolic and diastolic pressure, normally and in hypertension (J. B. Orr and Innes, 1922).

"Water Intoxication."—Excessive retention of water produced experimentally by intensive forcing of water (administering 500 cc. every hour to a dog by stomach tube) reduces the hemoglobin by about 15 per cent, the serum protein by somewhat more, and serum chloride by about 30 per cent (C. H. Greene and Rowntree, 1924). If posterior pituitary solution is injected at the same time, still greater retention is obtained, and the animals develop serious and fatal symptoms. They are not due to increased volume of extracellular body fluid, but to reduction of its osmotic concentration, and consequent increase of intracellular fluid, particularly cerebral edema (review, J. P. Peters, 1944). The phenomena begin with restlessness, asthenia, diarrhea, salivation, nausea, retching and vomiting. Motor symptoms develop tremors, twitching and ataxy, progressing to attacks of extremely violent tonic and clonic convulsions, alternating with collapse. Electroencephalogram changes in rats are described by E. Gellhorn and Ballin, 1946. The intracranial pressure is increased and the temperature falls. The animal passes into stupor and coma, and dies in four to twelve hours, or after several days. The only characteristic lesion found at necropsy is cerebral edema. Pressure symptoms may be relieved by intravenous injection of hypertonic saline solution (Rowntree, 1926).

The threshold for electric shock and metrazol convulsions is lowered by cellular hydration, raised by excessive administration of water or by depletion of extracellular electrolytes, or additively by both. Anti-epileptic drugs raise the convulsive threshold more effectively in animals in which cellular hydration is high (E. A. Swinyard *et al.*, 1946).

Dehydration, a deficit of tissue water, causes collapse and shock. It may be produced through excessive loss of fluid, or when water is withheld, or not absorbed, as in diarrhea. It occurs frequently in surgical patients. Loss of 10 per cent of the body water is totally disabling to men (review, J. P. Peters, 1944).

Men walking in the hot desert without drinking water become exhausted when the water loss reaches 4 to 8 per cent of the body weight; with external temperature of 105° F. this occurs in four to seven hours. Thirst sensation is usually only moderately unpleasant. Drinking water freely prevents the exhaustion, and it is greatly relieved in fifteen minutes by drinking as much as desired. The blood volume is markedly diminished (E. Adolph *et al.*, 1944). In normal subjects dehydrated by withholding fluids, febrile phenomena appear when the loss of water reaches about 6 per cent of the body weight (3600 cc. for a 60 Kg. individual), coincident with the reduction of the urine output to a degree insufficient to remove the normal waste materials, so that the nonprotein nitrogen of the serum rises above 40 mg. per 100 cc. When water is again given, almost the whole of the intake is retained until the tissue fluid deficit (*i. e.*, about 3600 cc.) has been made good (Maddock and Coller, 1937). *Renal clearances* indicate that dehydration does not affect glomerular filtration, but solely tubular reabsorption (D. A. K. Black *et al.*, 1942), probably by release of posterior pituitary antidiuretic hormone, through a central, not through a peripheral mechanism (review, M. Pickford, 1945). The *sodium and chloride* of the urine become minimal as dehydration advances, and their concentration in the plasma rises (J. R. Elkinton and Taffel, 1942). The destruction of protein is increased during the withdrawal, and when water is resumed the stored metabolites are washed out, leading to a greatly increased excretion (Landauer, 1895; Straub, 1899; Spiegler, 1901).

Thirst is a delicate reaction, attuned both to the volume of fluid in the body and to the concentration of solutes (A. Gilman, 1937). It does not originate in dryness of the oral mucosa, for it is not affected by cutting the oral nerves (R. T. Bellows and van Wagenen, 1939), and it can be slaked by giving water by stomach tube (C. Fisher *et al.*, 1938).

A *dehydration therapy of epilepsy* was proposed by McQuarrie, 1929, who conceived epilepsy as caused by hydration pressure. Other observers, however, have failed to find that the seizures are either benefited by water limitation, or increased by overconsumption, acute or prolonged (Wilson and Limberger, 1933).

Treatment of Dehydration.—If fluid can be absorbed from the intestines, as in hemorrhage and often in traumatic shock, oral or rectal administration of water appears to maintain the blood volume better than the intravenous injection of saline or even of acacia solution, although it does not act so promptly (O. H. Robertson and Bock, 1919).

Intravenous injection of dextrose is preferable for parenteral administration in surgical dehydration, as it has a food value, prevents ketosis and protects the liver. Sodium chloride disposes to excessive salt retention, but should be used if there has also been excessive loss of salt, through vomiting or sweating (Maddock and Coller, 1937).

Alleviation of Water Deprivation.—Sea water contains almost twice as much salt as the most concentrated urine, and is therefore so greatly hypertonic that it actually increases dehydration and hastens death if consumed undiluted by mouth or by enema (R. F. Bradish *et al.*, 1942). The problem must therefore be met by restricting the need for water (avoidance of heat and exertion), stretching the available supply by dilution with sea water, and by methods of desalting.

The minimum daily requirement of water, under working conditions and with enough carbohydrates to prevent ketosis, is 825 to 1000 cc. Under stress, the daily allowance may be reduced to a pint. Sea water may be added to this in the ratio of not more than 1:4 or 5, not to exceed 200 cc. per day, equivalent to 6 Gm. of salt (A. C. Ivy, 1944). The most practical method of desalting is by adsorbents. A silver and urate method is described by C. R. Seagrave, 1944.

Rats, unlike man and dog, are able to concentrate their urine somewhat above sea water, and therefore survive slightly longer when drinking sea water than with complete water deprivation (E. F. Adolph, 1943).

Local Actions.—Water is mildly stimulant and irritant to sensitive surfaces.

The growth of artificial cultures of frog's tissues is hastened by diluting the serum of the culture fluid (Ruth, 1911).

The effects of baths and similar hydrotherapeutic measures depend upon reflexes due to the physical action of temperature and so forth.

Digestion and Absorption of Food.—Ingestion of water with meals has decidedly beneficial effects upon all the digestive organs, even when the quantity of water is large (1 liter with each meal), provided that the food is thoroughly masticated. It aids the digestive action of the saliva, increases the flow of gastric juice, its pepsin and acidity, and thus presumably the flow of pancreatic juice. It secures better absorption of the food, leaving less material for the intestinal bacteria, decreasing their number and the putrefactive processes. The same beneficial effects are secured with distilled water, which has no detrimental effects even in prolonged fasting experiments (Hawk, 1914). These actions are utilized in the treatment of dyspepsias. Water is often useful in nausea. It is also valuable as a diluent for irritant drugs. Excessive water consumption would probably be harmful in gastric atony.

Up to 1 liter of water has no effect on the gastric emptying time of the farina-barium test meal in normal men (E. J. Van Liere and Northup, 1944). The secretion of *acid gastric juice* is increased (Heidenhaim, 1879; Pavlov; Foster and Lambert, 1908). Even 50 cc. strongly increases the acidity and peptic activity (Bergheim, Rehfuss and Hawk, 1914). The gastric stimulation does not occur in all cases. It is perhaps due to the washing of the hormone gastric into the intestine (Ivy, 1918). The flow of *pancreatic juice and bile* is also stimulated. The dilution would accelerate the action of the digestive *enzymes*. The diastatic efficiency of saliva is increased, the optimum being reached with 1:7 dilution (Bergheim and Hawk, 1913). The *discharge of the gastric contents* is hastened (at least after a meal of meat, although not with potatoes; Hedbom and Cannon, 1909). The water does not actually mix with the gastric contents, but passes along a trough formed on the surface (Cohnheim). The *rate of discharge* of water from the fasting human stomach varies normally between 100 and 400 cc. per minute. Older figures were higher, but misleading (Ivy, 1918). *Hunger contractions* are allayed by drinking water (Carlson, 1913). The utilization of fats and carbohydrates is not affected (Blatherwick and Hawk, 1914).

Distilled water is more injurious than ordinary water to aquatic animals and to excised tissues, partly because of the total absence of salts (especially of calcium, thus probably altering the permeability of the plasma membrane; R. H. True, 1914), and partly because it often contains traces of copper and ammonium compounds. *This toxic action can not occur by the drinking of distilled water by higher animals,* which obtain their salts from food; nor is distilled water detrimental in nephritis (Marcus, 1907).

The U.S.P. describes *Distilled Water, Sterilized Distilled Water* (which must not be used for parenteral administration) and ***Water for Injection,** "distilled, sterilized and stored in sealed or other suitable containers, so that it is free and remains free from pyrogens." It is tested for this on rabbits. The *pyrogenic effects* observed with intravenous injections of solutions prepared from ordinary distilled water are due to substances formed by bacterial contamination, which is transmitted by flasks and tubing. The pyrogenic substance is destroyed by boiling for six hours, or autoclaving from three to four hours; but the ordinary time of sterilization tends to increase its activity (F. Seibert, 1923, 1924; review, C. M. Nelson, 1939).

◆

MINERAL WATERS

The action of natural mineral waters has been known empirically since remote times. Their use came about probably by accidental observation and also through the marked taste which they possess.

Spring and Artificial Mineral Waters.—A striking observation was early made that these mineral waters, when used at their source, appear to be more effective than artificial compounds of practically the same composition, or even than the same water when used at a distance. Diverse explanations for this were advanced, such as "tellurial" forces, some mysterious property imparted to them by the earth. Some mineral waters are slightly radioactive. Others stress minimal traces of rare elements. Still others professed that the artificial waters—even if they contain the same elements in the same proportions—do not contain them in the same state of combination. In fact, however, mineral waters are simply solutions of the ingredients of the soil, and have only the action of those ingredients present in notable amount. The difference between the waters taken at the natural source and the artificial solutions is due to the accessory conditions, chiefly *hygiene and climate;* the rest, the freedom from care and business pursuits, the exhilarating effect of improved hygienic, atmospheric and scenic conditions, better regulation of all the habits, of diet, exercise, and so forth. The mere drinking of large quantities of fluid is also something which it is difficult to enforce at home, but which the patient does regularly in watering places. The effect of mineral *baths* is purely local and reflex. There is practically *no absorption* of the dissolved salts through the skin. The effects are in general the same as with hydrotherapy, except that they are somewhat stronger.

Mineral waters are usually *classified* according to the contained salts into: 1. Plain saline (NaCl). 2. Carbonated: (*a*) plain; (*b*) alkaline ($NaHCO_3$); (*c*) saline (Na_2SO_4). 3. Magnesia. 4. Sulfur. 5. Chalybeate. Many mineral waters belong partly to several classes. Occasional constituents of small importance are Ca, I, Br, Li and As.

DEUTERIUM OXIDE (HEAVY WATER)

Water formed from the heavier isotope of hydrogen, D_2O, does not appear to be directly toxic, but to become so by displacing ordinary water, the place of which it cannot quite take because it greatly reduces the rate of all physico-chemical processes (H. S. Taylor, 1934).

Living cells cannot distinguish between the isotopes of the same element, and treat them practically alike. This is utilized for "*tagging*" atoms to learn their fate in the body (review, R. Schoenheimer and Rittenberg, 1940).

Hydrogen occurs as three isotopes, protium, deuterium and tritium, with the atomic weights of 1, 2 and 3 (E. J. Crane, 1934). Protium is by far the most abundant, but is mixed with small amounts of the others. Deuterium constitutes 0.02 per cent of all hydrogen and its combinations in nature, including all water, free and bound, and all organic hydrogen compounds. The viscosity of deuterium oxide is 23 per cent greater than that of ordinary distilled water.

Toxicity.—White mice die in about a week if they drink heavy water exclusively, or if it is administered at the rate of 1 cc. per 10 Gm. per day, orally or hypodermically, 40 to 50 per cent of the body water being replaced by deuterium oxide by this time.

Course.—The symptoms begin on the first day, with pilomotor stimulation; then follow anorexia and weight loss. The temperature and metabolic rate begin to decline about the fourth or fifth day, and the latter falls to about a third of the normal on the day before death. Marked jumping reflexes appear on the fifth day, then ataxia, and toward the end, cyanosis and dyspnea. The same phenomena develop, but more slowly, if half of the drinking water is replaced by deuterium oxide (Barbour and Tracy, 1936).

Sympatheticomimetic Actions.—Replacement of a fifth of the body water by deuterium oxide is not fatal to mice, but causes symptoms of sympathetic stimulation, erection of the hairs, exophthalmos, increase of basal metabolism by 20 per cent, usually rise of temperature. These are abolished by ergotoxine. These effects increase with replacement of half of the body water (Barbour, 1937; Barbour and Herrmann, 1938). The melanophores of the isolated scales of the fish Fundulus are contracted as with epinephrine, and this is prevented by ergotoxine (Barbour and Bogdanovitch, 1937). Barbour suggests that deuterium oxide protects epinephrine from decomposition.

Excised hearts of frogs and turtles are slowed by immersion in Ringer's solution made with 20 to 96 per cent deuterium oxide (Barnes and Warren, 1935, 1937).

Cataleptic contractions are produced by the direct application of deuterium oxide to the cerebral cortex of rats, cats and monkeys, or by meningeal injection into the parietal region, provided that the local concentration reaches about 20 per cent (J. B. Herrmann and Barbour, 1937). Encephalograms indicate depression. No effects result from application to the spinal centers of cats and frogs, or to nerves or skeletal muscles of frogs (Herrmann, 1939).

Water Loss and Hyperthermia.—When 40 per cent or more of the water consumed by mice is replaced by deuterium oxide, the insensible water loss is decreased, relative to the CO_2 output. The effect is prevented by ergotoxine. When a third of the body water has been replaced, metabolism is also increased, resulting in hyperthermia (Barbour and Rice, 1938).

Metabolism.—Continued oral administration of 40 per cent D_2O to mice at the rate of 1 cc. per Gm. of body weight per day, leads to increased metabolic rate, beginning on the fifth to tenth day. This effect is not produced by more dilute (30 per cent) or more concentrated (50 per cent) solutions. With hypodermic injection of 4 cc. of 99 per cent D_2O, the metabolic rate is reduced by more than 50 per cent, within forty-eight hours; without other symptoms, except temporary respiratory depression (Barbour and Rice, 1938).

The *normal growth rate of young mice* is decreased by replacing 8 to 9 per cent of their body water with D_2O for two weeks. No pathological lesions were found. Smaller doses, replacing more slowly to 8 per cent, did not interfere with development to maturity and reproduction, but the litters were small and their mortality was high (Hansen and Wülfert, 1938).

Tumor growth in mice is retarded at least 50 per cent when 20 per cent of their water content has been replaced by D_2O, by keeping the animals on 40 per cent D_2O. Normal mice survive this for at least four months, but the treated tumor mice die earlier (Barbour and Allen, 1938).

The *segmentation of frog eggs* is retarded by D_2O, above 5 per cent (Ussing, 1935). *Yeast fermentation* and *catalase action* are also retarded (H. S. Taylor, 1934).

Osmotic Effects.—Because of its lower vapor pressure, D_2O is hypertonic to corresponding solutions in H_2O. This may explain the thirst it causes and the burning sensation on mucous membranes (S. C. Brooks, 1937). *Hemolysis* of mammalian erythrocytes requires about twice as long as with ordinary water. This is probably explained by the higher viscosity and lower motility of D_2O (Parpart, 1935).

Deutero-alcohol, C_2O_5OD, is 1.1 to 1.6 times more narcotic than C_2H_5OH for fish and larvae (Hansen and Dybing, 1938).

◆

CATHARTIC SALTS

A number of soluble salts are not absorbed readily from the alimentary canal and do not produce marked direct systemic actions, unless they are injected into the circulation. When they are given by the mouth, their direct action is confined to the intestine, producing catharsis with soft or fluid, painless stools. The salts of magnesium, and the sulfates, phosphates, tartrates and citrates of sodium or potassium are chiefly used as saline cathartics. The cathartic action is mainly the result of the retention of fluid in the intestine by the osmotic action of the unabsorbed salt, for this must retain sufficient fluid to preserve itself isotonic with the blood (Wallace and Cushny, 1898). The distention by this fluid provokes the intestines to contraction, and the contents are thus rapidly propelled (Trendelenburg, 1917). The passage through the intestines is therefore hastened, although the salts as such do not directly increase peristalsis (Legros, 1869; Hay, 1883; Padtberg, 1909). The contraction waves so set up may travel rapidly over the intestines, and secure evacuation before the cathartic salt itself has reached the rectum

(Herz *et al.*, 1908). Hypotonic solutions also cause direct stimulation of the muscles; hypertonic solutions produce short stimulation followed by depression; but the stimulation may expel the solution before the depression sets in (Baur, 1925; v. Oettingen and Sollmann, 1926). In any event, the solutions would soon become isotonic. Magnesium is directly depressant to the intestinal muscles, and is utilized against the spastic contractions of barium and of lead colic. Ordinarily this depression is more than offset by the distensive stimulus; but it may be important for overcoming intestinal spasm (Sollmann and Rademaekers, 1925).

The *popular synonyms* of the cathartic salts testify to their extensive use. Those that occur in natural mineral waters were named after the springs, such as "*Epsom salts*" (magnesium sulfate), "*Carlsbad salts*" (sodium sulfate and bicarbonate). "*Glauber's salt*" (sodium sulfate) was named for a German chemist and physician of the seventeenth century; "*Seidlitz powders*" (effervescing sodium and potassium tartrate) for a Bohemian carbonated spring; "*Rochelle salts*" (sodium and potassium tartrate) for the French city where this salt was made from the "tartar" of wine casks; "*Cream of tartar*" (acid potassium tartrate) and "*Salts of tartar*" (potassium carbonate, obtained originally by the calcination of the preceding) are derived from this source.

Two types of cathartic response may occur, as has been indicated: the *early*, within an hour, due to the "duodeno-colonic reflex" (probably not a reflex, but the propagation of a distention and contraction wave); and the *delayed*, in three to twenty-four hours, due to the retention of fluid in the intestine by the osmotic pressure of the unabsorbed salt.

The *early type* is illustrated by the observations of Herz *et al.*, 1908, in man, that drachm doses of epsom salt may cause watery evacuations within an hour of greater volume than could be explained by osmosis. The stools of the following morning, which contain distinctly more of the salt, had a normal solid consistency. The salt itself may travel rapidly through the intestines; for instance, 5.7 Gm. of magnesium sulfate were recovered from a stool that was passed three hours after the administration of 10 Gm. of magnesium sulfate in 400 cc. of water (Ury).

Roentgenoscopic observations of A. Bergmann, 1929, on man show that before the magnesium sulfate has left the stomach, it hastens the passage of the contents of the large intestines, from the cecum and through the colon, from the normal time of three to six hours to less than half an hour. The passage through the small intestines was shortened to forty to sixty minutes (by distensive stimulation), when the salt reached the intestines. This coincides with the early x-ray studies of Padtberg, 1909, that the emptying of the stomach is delayed, but that the passage through the intestines is quickened. Colon antiperistalsis is not inhibited; but it does not lead to the concentration of the contents, because of the osmotic retention. The fecal matters are therefore more fluid, and this hastens their expulsion. The saline catharsis is not checked by morphine, unless this is timed so as to secure gastric retention of the salts.

With *permanent fistulas* in dogs, G. B. Roth and Crittenden, 1934, observed no effect on gastric or intestinal motility when isotonic solutions of sodium or magnesium sulfate were confined to the stomach; hypertonic solutions decreased gastric and increased intestinal motility. When introduced directly into the intestines, hypertonic as well as isotonic solutions increased intestinal motility. When solutions at body temperature are infused through Thiry-Vella *jejunal loops* of trained unanesthetized dogs, isotonic sodium sulfate and magnesium sulfate produce moderate stimulation of motility, followed by depression of motility and tonus if the magnesium infusion is prolonged. Hypertonic sodium chloride or of sodium or magnesium sulfate depresses the motility, with brief periods of spasticity (E. W. Ligon, 1943).

Osmotic Factor in Cathartic Action.—Buchheim, 1854, claimed that the increased water in saline catharsis comes from the alimentary canal and not from the blood. Colin, 1854, showed that concentrated solutions of cathartic salts increase in volume when placed in an intestinal loop. Wallace and Cushny, 1898, demonstrated conclusively that saline solutions placed in the intestines become and remain isotonic with the blood, and that therefore the amount of fluid held in the intestines depends on the amount of salt which remains unabsorbed.

Difficultly Absorbable Ions.—The most important cathartic ions are: of the cations, Mg; of the inorganic anions, SO_4 and PO_4; of the organic, tartrates, citrates, fumarates, lactates and malates. Certain sugars, particularly milk-sugar and mannite, also act as osmotic cathartics. Many other solutes that are difficultly absorbable are not available as cathartics; *f. i.*, Ca and Sr are largely converted into insoluble carbonates, and so become osmotically inactive; oxalates and fluorides are toxic; the metallic ions precipitate proteins and act as astringents.

Easily Absorbable Ions.—Of the *cations*, ammonium is the most readily absorbed; then come the alkali metals. The earthy metals are not easily absorbable. Of the *anions*, the chlorides, bromides, iodides, nitrates and acetates are rapidly absorbed. The *cause of the different absorbability* has not been satisfactorily explained. There are striking analogies between the absorption of ions by the intestine and by muscle, and the solubility of their soaps and calcium salts, but it is not yet clear whether this is a coincidence or has a deeper meaning.

Conditions that Influence Absorption.—The cathartic salts are not completely unabsorbable. The ratio of unabsorbed to absorbed varies with conditions, but generally the amount in the feces and urines is about equal for sodium sulfate; the feces contain relatively more magnesium. The degree of absorption depends primarily on the time of sojourn in the intestines, so that the urinary excretion and its accompanying diuresis are reciprocal to the catharsis. Absorption of the salt and diuresis are favored (and catharsis therefore decreased) by dryness of the tissues, restriction of fluid income, and concentration of the solution (Matthew Hay, 1883). Conversely, *dilution favors catharsis.* Cathartic salts should therefore be administered as dilute or isotonic solutions, if the object is merely the evacuation of the intestines. Hypertonic solutions are indicated for the removal of fluid, especially edemas, as they utilize diuresis as well as catharsis.

Fate of the Cathartic Salts.—The portion which is not absorbed is eliminated promptly by the *feces.* The other salts of the feces are also markedly increased; the organic matter only slightly (Hay). The sulfates are in part reduced in the colon to sulfides, which give their characteristic odor to the feces (R. Kochmann, 1920). *After absorption,* the cathartic ions are eliminated largely by the urine, producing a diuretic action. With sodium sulfate, one-third to one-half of the excreted salt is in the urine. A considerable portion of the sulfate of magnesium may be retained in the tissues, the excretion extending over several weeks (Mendel and Benedict, 1909). The urinary excretion of the sulfate ion follows a characteristic curve, independent of the water excretion (Möller, 1927).

Absorption of other substances is in general delayed and diminished by saline catharsis. This may be of some importance in the treatment of poisoning (Macht and Finesilver, 1922).

Diuretic Action.—All the cathartic anions are readily excreted by the urine, and therefore act as saline diuretics, rather more effectively than equivalent amounts of sodium chloride. Because of the abstraction of water by the feces, the urine flow is generally decreased in the first twelve hours; it is then increased for about a day (Hay). The diuretic effect is proportional to the quantity of the salt absorbed, and therefore inverse to the catharsis. It is greatly increased by the oral administration of theophylline (Möller, 1927). Sodium sulfate diuresis increases the gas consumption of the kidney (Bainbridge and Evans, 1914).

Reaction of Urine.—$MgSO_4$ markedly increases the ammonium and acidity of the urine; Na_2SO_4 and MgO decrease the acidity, with subsequent return to the normal reaction (de Jager, 1911).

Concentration of the Blood.—Hay found that this is increased shortly after the administration of concentrated, but not of dilute, solutions of cathartic salts. The blood count rises from 5,000,000 to 7,000,000 by the abstraction or retention of fluid in the intestines. It returns to normal within four hours, even if no fluid has been taken, since the saline solution is gradually absorbed from the intestines. When diuresis sets in, the blood count again rises to 6,000,000, even if the salt has been taken diluted.

Metabolism is not measurably increased by the increased peristalsis of saline cathartics (Benedict, 1914).

Temperature.—Saline cathartics were used in fevers, for their supposed "cooling" effect. Hay found no reduction of the internal temperature.

Other Theories of Saline Catharsis.—A number of other factors have been suggested, such as inflammatory irritation, stimulation of intestinal secretion, and muscular stimulation by osmosis, ion action, or the withdrawal of calcium. None of these rests on adequate evidence, and they probably play at most a minor part.

M. Hay, 1883, believed that the salts excite a secretion of fluid into the intestines, which is partly balanced by absorption. His experimental results are explainable more simply on the basis of osmosis. Headland, 1867, believed that the salts are first absorbed, but reexcreted into the intestines, and that they stimulate secretion during their elimination; but Thiry, 1864, found no secretion in his fistula. The theory of Carl Schmidt, 1850, that the fluid is a transudate is without foundation. Chiari, 1910, suggested that the precipitant effect of most of the cathartic ions for calcium could increase the excitability of the intestine. This is only hypothetical.

Parenteral Administration.—Catharsis was reported from intravenous, hypodermic or intramuscular injection of sodium or magnesium sulfate by Bernard, 1857, and by J. B. MacCallum, 1903 and 1906. Most observers, however, have failed to obtain increase of peristalsis and catharsis when proper precautions were taken to exclude exposure and asphyxia (Auer, 1906, 1908; Mendel and Benedict, 1909). Joseph and Meltzer, 1910, and Sollmann and Rademaekers, 1925, found, with a careful technic, that intravenous or intramuscular injection of magnesium inhibits peristalsis. *Hypodermic injection* is also without result, except when made under the abdominal skin. The success in this case is reflex, for injections of NaCl or $ZnSO_4$ in this region are also cathartic (Hay).

Excised Intestines.—The phenomena are described under the respective ions.

Therapeutic Uses.—The cathartic salts are used to empty the intestines in constipation and the like, and to dry the tissues in edemas.

They are useful and effective as simple cathartics, especially in digestive disturbances, in hyperchlorhydria, with alkalis, as magnesium hydroxide or Carlsbad salt; and against occasional constipation in alternation with emodin or demulcent laxatives. They do not meet the motor deficiency of chronic constipation so efficiently as the cascara group; they are often rather unpleasant to the patient; they may lose in efficiency on continued use, their prolonged employment accustoms to an abnormal type of peristalsis (Bastedo, 1914), and they are not very effective in obstinate constipation. As hydragogue cathartic for the removal of edemas, the absence of irritation renders them generally superior to the drastic vegetable cathartics; their diuretic effect is a further aid.

Administration as Laxatives.—For this purpose, the salts should be given in dilute solution, a teaspoonful to tumbler, since they are less distasteful and act more promptly (one to four hours). The laxative dose of the usual salts is 5 to 10 Gm. (1 to 2 drachms). They are best administered before breakfast, to hasten their passage through the stomach. If this is delayed, as with bedridden patients, they are less efficient and somewhat irritant. Some exercise is useful after taking salts.

Administration in Dropsy.—Large doses (15 to 30 Gm., $\frac{1}{2}$ to 1 ounce) should be given in concentrated solution ($\frac{1}{2}$ tumbler), also before breakfast. The concentrated solutions act more slowly than the dilute mainly because they tend to close the pyloric sphincter; but they remove more fluid since they also increase diuresis. They are used especially in cardiac edemas. Retention and accumulation of the salt may occur in nephritis, and magnesium salts may become dangerous. Concentrated solutions are also employed to reduce the secretion of milk.

Source of the Fluid in the Stools.—If the cathartic salt is administered in hypertonic solution, it withdraws some fluid from the tissues (unless water is swallowed at practically the same time), but the amount of fluid needed for this is insignificant. Ordinarily, however, the quickened peristalsis interferes with the reabsorption of other fluids present in the intestines, and this may increase the fluid of the feces by considerably more than the amount held by the unabsorbed salt. Three to 10 liters of fluid are daily excreted into the digestive tract of man, and 1 or 2 liters more are introduced with the drink and food. As the normal daily feces contain only about 100 cc. of water, the daily absorption of liquid from the intestines is over 4 liters; *i. e.*, considerably more than is needed to furnish all the liquid of severe saline catharsis. The latter, therefore, does not directly abstract water from the tissues or effusions, but tends to dry them in the same manner as if the water income were restricted by any other means.

The *choice between the cathartic salts* is largely determined by their *taste*. The sodium sulfate has, perhaps, the most disagreeable taste; the magnesium sulfate somewhat less so. Sodium phosphate and Rochelle salt are materially less disagreeable and act promptly, usually within an hour after breakfast. MgO and $MgCO_3$ act as alkalis as well as cathartics. Acid sodium phosphate renders the urine acid. The best corrective for the *taste* of the salts is ample dilution with water, when this is permissible. Some of the salts are official in *effervescent form; i. e.*, mixed with sodium bicarbonate and citric or tartaric acid.

SODIUM SULFATE

This is a typical cathartic salt, almost free from ion action. On account of its disagreeable taste it is not much used, except in veterinary practice, but it forms an important ingredient of many mineral waters, *e. g.*, Carlsbad. The kidneys are more permeable to sulfate than to chloride ions, so that its intravenous injection produces a copious diuresis. The secretion of gastric juice is not increased.

The *stimulant actions of hypodermic or intravenous injections* of sodium sulfate on the circulation and respiration appear to surpass those of sodium chloride. An isotonic solution (2 per cent of the dried or 4 per cent of the crystalline salt) is used in quantities of 500 to 1000 cc. The addition of sodium sulfate, 1:1000 of blood, perfused through the vessels of *excised* intestines stimulates peristalsis and is antagonistic to magnesium depression (Glénard, 1913).

Sodium Sulfate, U.S.P. (*Glauber's Salt*); $Na_2SO_4.10H_2O$. Large or granular colorless crystals, of bitter saline taste. Freely sol. in water (1:1.5); practically insol. in alc. All sulfates are *incompatible* with calcium and lead. Dose, 2 to 15 Gm., $\frac{1}{2}$ to 4 drachms, diluted.

Sodium persulfate, $Na_2S_2O_8$, is fifty times more toxic than the sulfate, for rabbits, on intravenous injection. It destroys the red blood corpuscles and produces severe changes in the kidneys, lungs and liver (Da Val, 1933).

TARTRATES

These are difficultly absorbable, and are therefore saline cathartics having the advantage of a relatively unobjectionable taste. The potassium-sodium tartrate or Rochelle salt is commonly used. Acid potassium tartrate (cream of tartar) acts as a mild acid; being relatively insoluble, the acid action extends into the intestines and here stimulates peristalsis. It is therefore more actively cathartic. Cream of tartar and tartaric acid effervesce with sodium bicarbonate, and are used in baking powders (see Index), effervescent drinks, and so forth. The tartrates are not readily burned in the body, and therefore do not act as alkalis and diuretics so strongly as do most other organic anions. When introduced into the circulation, they have a rather high toxicity by immobilizing calcium and by injuring the renal epithelium; but this need not be feared from therapeutic doses (Post, 1914). The toxicity is probably also lower for man, as the tartrates are more readily destroyed.

Fate.—But little tartrate is destroyed after absorption. Dogs, rabbits and rats excrete it promptly and completely by the urine, both after oral and parenteral administration. This would probably also hold with man for parenteral administration; but with oral administration, less than 20 per cent appears in the urine, and none in the feces, even after purgative doses. The remaining 80 per cent is probably destroyed by bacterial action in the large intestine. Guinea pigs behave as man in this respect (Underhill *et al.*, 1911). Although tartrates are not oxidized, the administration is said to render the urine alkaline (Pratt and Swartout, 1933).

Toxic Actions of Tartrates.—The effects on calcium are similar to those described under citrates. Small doses produce only the renal injury; larger doses, also muscular and nervous symptoms. The cardiac excursions are decreased, especially in systole, with moderate slowing. The blood pressure is unchanged, the kidney volume slightly increased. The effects may be acute or subacute, according to dose (Salant and Smith, 1914). The four stereochemic isomers behave somewhat differently toward calcium and therefore have a different toxicity (Chio, 1912). Salant and Smith, 1913, found that the d. and l. had the same toxicity for frogs and rabbits; but the resistance of different animals varies greatly.

Excised Intestine and Isolated Frog Heart.—The effects of the various tartrates, succinates and malates, on the small and large intestines are complex. The isolated heart is depressed (Salant *et al.*, 1917).

Renal Action.—Underhill, Wells and Goldschmidt, 1913, and Pearce and Ringer, 1913, found that Rochelle salt produces marked renal changes when given hypodermically in doses of 0.25 Gm. per kilogram to phlorhizin rabbits; somewhat larger doses caused the same changes without phlorhizin. Oral administration also produced nephritis, with doses of 3 Gm. per kilogram. Five Gm. per kilogram was fatal in fasting animals. The toxicity is not so great in well fed animals; when diarrhea occurs; or when alkalis are administered. Acetates, citrates and carbonates do not produce these renal changes. Analogous effects occur in dogs. The *epithelial changes* are confined mainly to the convoluted tubules, with some extension to Henle's loops. The glomeruli and interstitial tissue are intact. The lesions result in retention of the tartrate, so that only traces are excreted by the urine even on intravenous injection. In the acute nephritis of rabbits, the *phthalein excretion* is materially diminished. In chronic cases, the excretion again improves somewhat with time. The nitrogen excretion is scarcely altered (Underhill and Blatherwick, 1914). *Hippuric acid synthesis* is not impaired (Kingsbury and Bell, 1915). The excretion of injected *urea* and the excretion of N and dextrose in phlorhizin animals are hindered, but the NaCl excretion is normal (Baer and Blum; Underhill, 1912). The restoration of the blood volume after injection of saline solution is delayed (Bogert, Underhill and Mendel, 1916). The *vascular reactions* of the kidney in dogs are practically unaffected by the tartrate nephritis. The diuretic response to caffeine is somewhat diminished (Karsner, 1917).

Diet on Nephritis.—With rabbits, but not with cats, the diet has a marked influence on the resistance to tartrates. The toxicity is highest when rabbits are fed with oats, hay or cabbage; considerable protection is conferred by food rich in sugar, especially by young carrots. The factors involved have not been differentiated (Salant and Swanson, 1918).

Habituation.—Continuous administration of tartrates to rabbits somewhat increases the tolerance; citrates and oxalates lead to cumulation (Salant and Swanson, 1918).

Potassium bitartrate has been recommended as *dusting powder for rubber gloves.* These may be sterilized with 15 pounds of steam for fifteen minutes, without injury. Higher or more prolonged heat is deleterious.

PREPARATIONS.—***Potassium and Sodium Tartrate,** U.S.P. (Rochelle Salt); $KNaC_4H_4O_6 \cdot 4H_2O$; occurs as a white powder or colorless crystals of cooling saline taste. Freely sol. in water (1:1). Dose, 8 to 15 Gm., 2 to 4 drachms. *Potassium Bitartrate,* U.S.P. (Cream of Tartar); $KHC_4H_4O_6$; sparingly sol. in water (1:165). Dose, 1 to 4 Gm., 15 to 60 grains. *Tartaric Acid,* U.S.P., $C_2H_2(OH)_2(COOH)_2$, is freely sol. in water or alc. *Compound Effervescent Powders,* U.S.P. (Seidlitz Powders), are dispensed in two papers; the blue, Pot. et Sod. Tart., 7.5 Gm. and Sod. Bicarb., 2.5 Gm.; the white, Tartaric Acid, 2.2 Gm. The contents of the white and blue paper are each dissolved in a fourth of a tumbler of water, and these solutions are mixed and administered when the effervescence begins to subside.

Sodium fumarate, $NaO_2C.\ CH{:}CH.\ COONa$, acts as saline laxative with about the same potency as the tartrate, and without renal injury in animals. In man, 10 Gm. cause a bowel movement in the average of six hours, in about three-fourths of constipated patients (H. Gold and Zahm, 1943).

Sodium hydroxyacetate(glycollate), $CH_2(OH).\ COONa$, has a nephrotoxic action similar to tartrate, with prolonged oral administration to cats. Dogs are more tolerant (S. Krop and Gold, 1945).

MAGNESIUM COMPOUNDS

The magnesium ion depresses all nervous and muscular functions, and this even in very dilute solutions (1:25,000). The salts of magnesium are relatively little absorbed, however, and therefore act as osmotic cathartics. With magnesium sulfate, both ions have this effect, so that it is particularly effective. Magnesium oxide and carbonate act also as alkalis. Being very sparingly soluble, their antacid action extends into the intestines, with but little interference with the stomach. They are converted in the alimentary tract into the soluble and therefore cathartic magnesium bicarbonate. MgO (magnesia) is preferred to the usual alkaline carbonates when the stomach should not be burdened with CO_2 gas. It is therefore the best antidote against poisoning by acids. A fair amount of magnesium is absorbed by the alimentary canal, so as to produce some diuresis, but not sufficiently to cause toxic effects, unless large doses of a concentrated solution are taken. When injected hypodermically or into the circulation, it is highly toxic by depressing the heart muscle and the central and peripheral nervous system. It is antagonized by calcium. Magnesium sulfate has been used as a local intraspinal and general anesthetic, and against tetanus, but the effective dose is dangerously close to the fatal (paralysis of respiration), so that its usefulness is limited. A saturated solution of magnesium sulfate is used as a local dressing in *erysipelas* and similar inflammations, but it is doubtful whether it is more effective than other moist dressings.

The *chlorophyl molecule* contains magnesium, somewhat analogous to the iron in hemoglobin (Willstätter).

Normal Occurrence and Requirement of Magnesium.—Magnesium occurs in the body mainly as phosphate and in association with calcium, in the bones, and in larger absolute quantity in the other tissues. The concentration of magnesium in the plasma is about 18 to 34 mg. per liter.

The red corpuscles (Abderhalden, 1898) and striped muscle (Katz, 1896; Huerthle, 1903) contain more Mg than Ca. The ash of bone normally contains 0.8 to 1 per cent of magnesium. This increases with calcium-poor diet, rickets, osteomalacia and fluorosis (Huggins, 1937). The *daily requirement* of adults is generally estimated as 200 to 600 mg.; Duckworth, 1939 (review), considered 200 mg. more nearly correct. Pregnant women probably require 350 to 450 mg. The *ordinary diet* contains 0.19 to 1.2 Gm. (H. C. Sherman *et al.*, 1910). *Children* of four to seven years require at least 13 mg. per Kg. daily; most children of preschool age receive less than the optimal income (A. L. Daniels and Everson, 1936). *Cows, during lactation,* lose considerable Mg, Ca and P, even on a liberal diet. The Mg and Ca loss can not be corrected by the addition of these elements to the diet (Forbes *et al.*, 1917).

Absorption.—When compounds of magnesium are ingested by mouth in food (Forbes and Pitts, 1935) or as medicine, about 30 to 40 per cent is absorbed, practically regardless of the quantity taken, within ordinary limits. The absorption occurs chiefly from the small intestines (Hirschfelder). During their passage through the small intestines, the magnesium salts are mainly changed to the soluble bicarbonate ($MgSO_4 + 2NaHCO_3 = Mg(HCO_3)_2 + Na_2SO_4$). The difficultly absorbable sulfate ion acts independently as an osmotic cathartic. Magnesium oxide, hydroxide and carbonate are first partly converted into chlorides, by neutralizing the gastric acid. The magnesium bicarbonate is likely to form soaps with free fats in the intestine. When Epsom salts and olive oil are given together, this soap may be passed as lumps which have been mistaken for gallstones.

Excretion.—After absorption, and with parenteral administration, the excretion occurs practically exclusively by the kidneys (Meltzer and Lucas, 1907), only in small part from the large intestine. Some is excreted by the bile, in proportion to the amount ingested (Delbet and Bretau, 1931). M. Jacoby claims that in the human subject after parenteral injection of large doses of magnesium against tetanus, the greater part is excreted by the intestines, although its concentration in the urine exceeds that of calcium. A considerable quantity may be retained in the body over two weeks. The urinary excretion of calcium is increased (Mendel and Benedict, 1909). This lessens the lime deposition in young animals (Malcolm, 1905). The *normal human urine* contains 0.2 to 0.3 Gm. of magnesium per day (Nelson and Burns, 1916). The administration of *hydochloric acid* increases the urinary excretion of magnesium, and still more that of calcium (Stehle, 1917; Givens and Mendel, 1917). The *normal food magnesium* is also excreted mainly by the urine (Forbes *et al.*, 1918).

The magnesium content of plasma in clinical conditions was investigated especially by Hirschfelder, 1934. The normal range of magnesium in man, dog and rabbit is between 1.8 and 2.75 mg. per 100 cc. The level in the corpuscles is about twice as high, but is not parallel. If a single dose up to 20–40 Gm. of magnesium sulfate is administered orally to normal persons, the plasma magnesium does not change significantly, although some 40 per cent of the magnesium is absorbed and excreted by the urine within twenty-four hours. In animals, also, the plasma content remains unaltered by corresponding oral doses; but animals with renal injury, either tubular by mercury or glomerular by cantharidin, excrete much less magnesium, and its plasma concentration rises, closely parallel to the phenolsulfonphthalein retention. With kidney excision, and sometimes with mercury nephrosis, the plasma magnesium attains the *coma level*, which normally develops at 17 mg. per 100 cc. with all methods of administration. A single purgative dose administered to patients with kidney disease was found to raise the plasma magnesium to 9–11 mg. in four to six hours, and the patients became drowsy, and some slightly comatose. It may be assumed that repeated doses would reach the actual coma level, and that some "nephritic" comas have been really magnesium coma. It seems advisable, therefore, to administer sodium sulfate rather than magnesium, if saline catharsis is indicated in nephritis. A relatively small rise of magnesium level, by 5 mg., also renders animals much more sensitive to the depressant actions of morphine.

The *magnesium content of red blood corpuscles* is higher than that of the plasma in all animals studied, except beef (Eveleth, 1937). For man (healthy young adults), D. M. Greenberg *et al.*, 1933, found the averages (mg. per 100 cc.) as: plasma 2.74 ± 0.3; whole blood, 4.55 ± 0.38; corpuscles, 6.61 ± 0.53. The content of cells and plasma varied independently. Expressed in milliequivalents per liter, the average for human blood serum is 1.6 (range to 2.2); for corpuscles, 4.6 (3.5 to 6.2) (Hald and Eisenman, 1937). *The tissue distribution of magnesium* after intravenous injection of the sulfate in dogs, resembles that of Na rather than K, being confined practically exclusively to the extracellular fluids for several hours (P. K. Smith *et al.*, 1939).

Low plasma-magnesium levels (1 to 1.5 mg. per 100 cc.) were found by Hirschfelder in ten patients, who showed convulsions or twitchings; two of these were parathyroid tetany. Patients with *essential epilepsy* also had low plasma magnesium, 1.7 mg. or less, during the attacks, with normal values in the intervals. The plasma potassium was doubled during the attacks. Oral administration of magnesium sulfate, 2 Gm. four times daily, did not decrease the convulsions; but these were generally inhibited if 30 Gm. were given by rectum and 1 Gm. intramuscularly (Hirschfelder and Haury, 1936). Earlier workers had also found the plasma magnesium low in many cases of *parathyroid deficiency*, but not in all. In parathyroidectomized dogs, magnesium administration, even orally, helps to prevent tetany (W. F. Wermer, 1927).

Dietary magnesium deficiency is induced in rats by food in which the Mg content has been reduced to less than two per million of dry food. The effects begin in three days, are marked in eleven days and are fatal in 80 per cent of the animals, after an average of thirty-five days. They comprise: *Cutaneous changes:* hyperemia, rough sticky coat, loss of hair, hemorrhages, eschars, exfoliation, lacrimation and salivation. *Erethismus:* the animals are nervous and easily startled, progressing till tonic and clonic convulsions occur spontaneously or on slight stimulation. *Nutritional disturbances:* retarded growth, emaciation, cachexia, occasionally edema of the feet. Marked visceral degeneration, especially in the kidneys, less often in the liver, some in the heart. The *teeth* lose calcium after some two or three weeks, then the peridental tissue. Deficiency extending over six weeks caused degeneration of the enamel epithelium (Becks and Furuta, 1942). The *bones* become heavy with increased content of Ca and P (E. V. McCollum, 1931; Kruse, Schmidt and McCollum, 1933; Orent, Kruse and McCollum, 1934; Brookfield, 1934; Greenberg, Anderson and Tufts, 1936; Schrader, Prichett and Salmon, 1937). A portion of the skeletal magnesium is mobilized (Duckworth *et al.*, 1941). Extensive calcium deposition occurs in the endocardium and aorta and in large arteries and veins, in calves. The percentage of calcium is increased in the heart, kidneys and muscle of rats (Duckworth, 1939). *If the deficiency is less marked* (food of 1 to 2:100,000), convulsions occur only on rather strong stimulation. The nutritional changes can be prevented by providing liberal vitamin G. The magnesium of the body, and its concentration in the plasma, fell to about a third that of the litter controls. With food of 5:100,000, the rats can be carried through pregnancy and lactation (Greenberg and Tufts, 1935).

Magnesium Administration on Bones and Rickets.—In rats with adequate Ca and P income and suitable Ca:P ratio, excess of Mg income to ten times the optimal has no deleterious effects on the growth or ash content of the bones. It is also without effect with a Ca-poor diet; but with a low P or excessive Ca income, increase of dietary Mg has a favorable effect on the mineral content of bone (Rogozinski and Glowczynski, 1934), and the addition of Mg to McCollum's rachitic diet lessens the incidence of rickets (von Euler and Rydbom, 1931). Guinea pigs on diets deficient in vitamins C and D survive longer if magnesium chloride is added (Delbert and Palios, 1929). Mg salts activate bone phosphatase (Jenner and Kay, 1931).

Cathartic Action.—*Magnesium sulfate* is employed as laxative in doses of 2 to 10 Gm., 1 to 2 drachms, in dilute solution; and especially as hydragogue cathartic in doses of 10 to 15 Gm., 2 to 4 drachms, in concentrated solution. The dilute solution may be mixed with $NaHCO_3$, but not with Na_2CO_3. It may also be given as an effervescent salt. *Solution of Magnesium Citrate* is a pleasantly flavored and effervescent draught, dispensed in bottles containing 350 cc. The dose is from $\frac{1}{4}$ to 1 bottle. An enema of magnesium sulfate, 60 Gm., glycerol, 30 Gm., and water q.s. ad 120 cc., is an effective purgative (Fantus). *Magnesium carbonate* and the oxide are administered as powder, $\frac{1}{4}$ to 2 Gm., 5 to 30 grains. "*Milk of Magnesia*" (Magma Magnesiae) is a suspension of magnesium hydroxide, used as a laxative in doses of 1 to 4 teaspoonfuls; and as alkaline dentrifice.

Mechanism of Catharsis.—The available data indicate that this is due to the distensive stimulus of the retained fluid. The direct effects of magnesium on intestinal muscle appear to be purely depressant, but ordinarily this is overbalanced by the mechanical stimulus. The depression is seen especially in excised intestine, and with intravenous or hypodermic injection, where it antagonizes excessive peristalsis induced by ergot, physostigmine or barium (Meltzer and Auer, 1906); but it may also be demonstrated by perfusing isotonic magnesium sulfate solution through the lumen of the intestines of living animals (Sollmann and Rademaekers, 1925). The tone and peristalsis are decreased more markedly than the pendulum movements, and the normal propulsion of the contents is therefore diminished by all effective doses (contrary to the suggestion of Meltzer, 1914). In conditions of excessive tonus or spasm of the intestines, however, magnesium may result in increased propulsion, by relieving the spasmodic closure. This may explain its special usefulness in colics; for instance, in chronic lead poisoning.

The sensitiveness of the intestinal muscle to magnesium is high: 1:25,000 of magnesium salts, *i. e.*, half of the plasma concentration, is distinctly depressant to the excised intestines; but the zone of action is wide, so that the pendulum movement may still be quite vigorous in 1:1250 (Rademaekers and Sollmann, 1924). For the lumen of the intestines of living animals the concentrations must be much higher, because the magnesium ions are but slowly absorbed, and are rapidly diluted by the blood stream before they reach the muscle. However, isotonic solutions (3.5 per cent) are definitely, though only slightly, depressant (Sollmann and Rademaekers, 1925).

Very large doses of magnesium oxide increase somewhat the movements of the human *stomach* (W. H. Dickson and Wilson, 1924).

Duodenol Bile Reflex (*Meltzer-Lyon Test*).—The magnesium sulfate relaxes the tonus of Oddi's sphincter when 40 cc. of 33 per cent solution are administered by duodenal tube; this leads to evacuation of the gallbladder.

The duodenal contents contain at first little or no bile; shortly after, they contain a light yellow bile, and a little later, a darker and more viscid bile, the so-called "B" bile. B. B. V. Lyon, 1919, 1922, assumed that the latter comes directly from the gallbladder, as suggested by S. J. Meltzer, 1917, and believed that its content of pus cells, bacteria, crystalline material, and so forth, reflects the condition of the gallbladder, and that repeated "drainage" by this means would be beneficial in cholecystitis. A similar flow of bile is produced by a variety of substances; for instance, by hypertonic salt solutions in general; by 0.5 per cent HCl; by egg yolk; and by 5 per cent peptone. The latter is preferred by some clinicians as less irritant than the magnesium test (E. A. Boyden *et al.*, 1943).

Application of magnesium to the duodenal surface relaxes Oddi's sphincter (Reach, 1924), and this is sometimes, though not always, followed by evacuation of the gallbladder (Matsuo, 1924); but the bile may also be increased if the gallbladder has been excised (Dunn and Cornell, 1921), or the cystic duct ligated (Mendenhall *et al.*, 1926). This is probably due to the diminished resistance to the bile flow, and not to hepatic stimulation, as was suggested by Einhorn, 1921, but it makes it uncertain whether, in a given case, the bile comes from the liver or the gallbladder (at least unless the test is used in conjunction with the injection of dyes, as suggested by Matsuo). Therapeutically, the "drainage" could scarcely be made sufficiently thorough or frequent to be of material value in cholecystitis.

Isolated bronchial muscle is relaxed by magnesium (Trendelenburg, 1912; Sollmann and Gilbert, 1938).

Systemic actions of magnesium do not ordinarily occur when magnesium salts are taken by mouth, because of the relatively slow absorption and the rapid excretion. However, toxic effects may follow on large doses of the sulfate, and more readily of the nitrate (Meltzer, 1907; C. Fraser, 1909), particularly if kidney injury interferes with elimination (Hirschfelder, 1934). Fatalities have also occurred from enemas (D. W. Fawcett and Gens, 1943). They are most frequent with hypodermic or intravenous injection. They consist in muscular and nervous depression or paralysis. The chief phenomena are analgesia, anesthesia, paralysis of the respiration; and with intravenous injection, direct paralysis of the heart. The motor depression is useful in the symptomatic treatment of traumatic tetanus, but great caution is necessary to obviate respiratory paralysis. The analgetic action is not sufficiently marked, with safe doses, to be useful in itself. It has been employed in obstetric practice to reinforce the analgetic action of morphine and ether, but is ineffective.

Intravenous injection produces immediate and severe, often fatal, depression of the heart and central nervous system. The effects resemble those of potassium, but this acts more on the heart; magnesium, on the respiration. The effects are also seen in blood pressure experiments if the magnesium sulfate solution of the manometer inadvertently enters the artery. The first and most constant result is a *fall of blood pressure*, noticeable before the magnesium concentration of the serum has reached 5 milliequivalents per liter (6.1 mg. of Mg per 100 cc.), and continuing progressively till death. The blood vessels are markedly dilated. The *pulse rate* rises up to 5-7 m. eq. per liter, then declines. The PR interval increases progressively. *Death* occurs from cardiac arrest before 27 to 38 m. eq. per liter (with artificial respiration), occasionally at 15 to 17 m. eq. per liter, simultaneously with the failure of natural respiration, which usually occurs at 17 to 27 m. eq. l. or 18 to 31 mg. per 100 cc. (R. M. Moore and Wingo, 1941; review, P. K. Smith *et al.*, 1942, serum magnesium concentration and effects). With abrupt injection, the heart may be arrested instantly. If the effect is not fatal, recovery occurs quickly, since excretion is rapid.

Cardiac effects are serious only with doses that produce respiratory arrest (A. W. Winkler *et al.*, 1940). They consist in slowing with moderate dilatation; then incoordination; then sudden dilatation and standstill. The arrested heart is in good tonus and responds well to mechanical stimulation (Rothberger and Zwillinger, 1936). The heart may be kept beating by electric stimulation, by stimulation of the accelerators, and by epinephrine (Matthews and Brooks, 1910). Small doses (10 mg. of $MgCl_2$ per Kg.) augment the accelerator response of the heart to epinephrine, but not the response of the heart to direct faradic stimulation (Hazard and Wurmser, 1931).

Paroxysmal tachycardia is arrested immediately by slow intravenous injection of 15 to 20 cc. of 20 per cent solution of magnesium sulfate, without untoward effects (L. Zwillinger, 1935: L. J. Boyd and Scherf, 1943). This also prevents ventricular tachycardia by strophanthin or barium, or converts it into cardiac arrest (Rothberger and Zwillinger, 1936).

Estimation of Circulation Time.—A complex solution containing 42 per cent of magnesium sulfate and 16 per cent of calcium gluconate has been used intravenously. A wave of heat sensation sweeps over the body, and its arrival at any location is timed (Spier, Wright and Saylor, 1936). The sensation is perhaps due to the osmotic action of the hypertonic solution.

Respiration.—The cessation is due mainly to the curare action, the center being ordinarily not paralyzed except with considerably larger doses (Matthews and Brooks, 1910).

Deglutition.—Graded doses paralyze the central mechanism before the peripheral (Auer and Meltzer, 1916).

Curare Action.—This was discovered by Jolyet and Cahours, 1869, and has been confirmed by Guthrie, Meltzer and others (Bresnan and Boyd, 1937). Meltzer and Auer, 1906, found that, like curare, it antagonizes the physostigmine twitchings. Further antagonisms to physostigmine were studied by Joseph, 1909. The curare effect is also antagonized by Ca, K, acetylcholine and epinephrine. The resemblance to curare is not complete, for the threhold of stimulation is also increased in denervated skeletal muscle of dogs (Maaske and Gibson, 1939). Magnesium ions suppress the calcium ion activation of the adenosine triphosphatase of myosin (G. D. Greville and Lehmann, 1943). In spinal dogs, the flexion reflex is abolished (through a central action) by smaller doses than those required to abolish response to motor-nerve stimulation (G. W. Bryant *et al.*, 1939). In intact animals the corneal reflex is the least, the tendon reflexes are the most sensitive to magnesium; the latter are suppressed when the plasma concentration reaches 6 to 14 m. eq. l. The suppression of reflexes by magnesium is due to neuromuscular block, but the anesthetic action is central (H. E. Hoff *et al.*, 1940).

Temperature **is lowered in rabbits by magnesium injection, parallel to the paralytic action, but preceding the latter. It is an independent phenomenon, for it occurs also** if the narcosis is prevented by calcium (Schuetz, 1915, 1916).

Effects on Urine Ions.—The injection of magnesium chloride causes a marked rise of urinary acidity; the phosphate excretion is only slightly increased (C. Mayer, 1917).

Renal Irritation.— The intramuscular or intravenous injection of magnesium salts or sulfates into dogs causes the appearance of *hyaline casts* in the urine. There are no other casts, albumin or other signs of nephritis (Gates and Meltzer, 1914). These occur also when toxic doses of magnesium are injected into the ligated small intestines (Gates, 1914).

Glycosuria.—Parenteral injections produce moderate hyperglycemia and glycosuria. Underhill and Glosson ascribed these to asphyxia; E. Hirsch, 1915, to narcosis and asphyxia; but Kleiner and Meltzer, 1916, found them even with artificial respiration. On the other hand, Airila and Bardy, 1915, stated that intravenous injections of magnesium inhibit epinephrine glycosuria and clinical diabetes, presumably by depression of the sympathetic system.

Magnesium Anesthesia.—Meltzer and Auer (1905) found that a general anesthesia, with abolition of reflexes, may be produced by the subcutaneous injection of magnesium salts (1.5 Gm. of crystalline magnesium sulfate per kilogram of body weight, used as 25 per cent solution). The injection causes but little pain, since the magnesium is also a local anesthetic. The anesthesia is complete in half an hour or an hour, and lasts about two hours. The blood pressure is but little lowered; there is some diuresis, but no diarrhea. Recovery is perfect. Somewhat larger doses are fatal, paralyzing the respiration before the heart. Analgesia is produced when the serum level of magnesium reaches 15 mg. per 100 cc; surgical anesthesia with 23 mg.; respiratory arrest with 33 mg. (R. M. Moore and Wingo, 1942). The effective dose approaches the fatal so closely that this method is not generally advisable for man. Gwathmey, 1921, 1925, in his obstetric anesthesia, used two or three intramuscular injections of 2 cc. of 50 per cent magnesium sulfate with the intention of reinforcing the rectal ether-oil anesthesia; but these raise the plasma magnesium at most to 3 mg. per 100 cc., and no symptoms of depression appear below 5 mg. (Neuwirth and Wallace, 1929). Nor is there any notable potentiation with ether or morphine; their effects are simply additive (Beckman, 1925). Magnesium abolishes the tetanic contraction induced by oxytocic drugs in gravid human uterus (Abarbanel, 1945).

Magnesium produces direct sensory paralysis, both central and peripheral. Meltzer and Auer found that, with proper dosage, it is possible to secure anesthesia when the asphyxial factor is entirely excluded and the muscles are still responsive; although the curare effect may contribute to the immobilization (Guthrie and Ryan, 1910). Careful *intravenous injection in human subjects* (Peck and Meltzer, 1916) produced unconsciousness and complete surgical anesthesia, with incomplete motor paralysis. The *alkali reserve* modifies the degree of narcotic response in rabbits; it is increased by injection of sodium bicarbonate, and decreased by hydrochloric acid (Martini, 1934).

Local Anesthesia.—Meltzer and Auer, 1906, maintained that concentrated solutions paralyze exposed nerve without previous stimulation. Liljestrand, 1909, and Guthrie and Ryan, 1910, claimed that the paralysis is preceded by stimulation.

Spinal anesthesia by lumbar subdural injection of 1 cc. of the 25 per cent solution of magnesium sulfate produces sensory and motor paralysis of the legs and pelvic region, occurring in three to four hours, and lasting eight to fourteen hours (Meltzer and Auer, 1909). There is also retention of urine for one or two days. *Untoward results have occurred.*

Use Against Convulsions.—Injection of magnesium salts is effective against various convulsions (Seremini, 1929), by depression of the neuromuscular junction; but potent doses may arrest respiration and make it necessary to resort to artificial respiration and physostigmine or calcium injection.

Magnesium suppresses *strychnine spasm* (Underhill and Wood, 1929), but other anesthetics, especially barbiturates, are safer and better. In *traumatic tetanus* it is perhaps more effective in relatively small doses (Auer and Meltzer, 1919). It is used in combination with antitoxin. Kocher considered it the best remedy in developed cases. The relief is temporary, so that the injections must be repeated at least daily. It is used to control therapeutic metrazol convulsions (P. K. Smith *et al.*, 1942), and has some value against the twitchings and convulsions of advanced chronic nephritis and eclampsia, although the effects are not dramatic (Winkler *et al.*, 1943).

Administration in Tetanus.—The doses refer to crystalline magnesium sulfate (Kocher, 1915; Meltzer, 1916). *For slight initial symptoms, hypodermic* injections may be used, 1.2 cc. of a 25 per cent solution, per kilogram of body weight, three to five times daily. This has been continued for six to eighteen days without damage. It causes but little irritation. It is safe, but not sufficiently effective for severe cases. In these, the salt may be used *intramuscularly,* 0.6 cc. of 25 per cent per kilogram, six times daily. *Intraspinal injection* uses 1 cc. of 25 per cent per 20 pounds of body weight (0.1 cc. of 25 per cent per kilogram), by lumbar injection. This gives prompt relief, generally lasting twenty-four hours, when the procedure may be repeated. If the respiration should become depressed, the solution should be washed out of the canal. *Intravenous administration* of suitable doses appears safe, injecting 2 per cent solution of magnesium sulfate crystals ($MgSO_4 . 7H_2O$), 500 cc., during thirty to sixty minutes; the action is brief, but the injection may be repeated after a few hours, to a total of not more than 1000 cc. in twenty-four hours; for after two injections the serum concentration may depress the central nervous system. This dosage produces cutaneous vasodilatation. The blood pressure falls in patients with acute nephritis or eclampsia, but not with chronic cardiovascular disease (Winkler *et al.*, 1943).

In *asthmatic crises,* in which epinephrine, ephedrine and atropine have failed, immediate sedation is obtained by slow intravenous injection of 10 to 20 cc. of 10 per cent of magnesium sulfate, but the relief is transient and the injections must be repeated (Rosello and Pla, 1936).

Treatment of Magnesium Poisoning.—When using effective doses of magnesium, the physician should be prepared to combat failure of respiration, by artificial respiration, together with physostigmine (1 to 2 mg. hypodermically) or calcium chloride, 0.02 per cent in normal saline, intravenously, to 600 cc. Extra caution must be used in children. The doses of magnesium should generally be somewhat smaller, supplementing them if necessary by ether or the aliphatic hypnotics. Morphine potentiates the respiratory depression, and should therefore not be combined with magnesium (Issekutz, 1915). The administration of liberal quantities of water, to induce diuresis, would be useful especially in subacute poisoning (Meltzer, 1907).

The **antagonism of magnesium and calcium** was mentioned in the general discussion. *Oxalates* enhance the action of Mg, presumably by removing the antagonistic effect of the tissue calcium. On the other hand, small doses of Mg reduce the toxicity of oxalate, by diminishing the overstimulation (Gates and Meltzer, 1913, 1917). It extends to both central and peripheral actions, including the curare effect (G. W. Bryant *et al.*, 1939). Magnesium narcosis can also be antagonized by intravenous injection of KCl, RbCl, NaCl or LiCl, in descending order of efficiency (A. D. Hirschfelder, 1929). Sodium citrate is also antagonistic (Sollmann).

Magnesium against erysipelas and other inflammations was introduced by H. Hucker, 1907 and 1908. A thick compress (15 layers of gauze) is immersed in a 10 per cent to saturated solution of $MgSO_4$, applied to the inflamed region, covered with oiled silk, and renewed every two hours (Choky, 1911). It is claimed that this subdues the inflammation, the pain, swelling and temperature, if applied in cellulitis, arthritis, epididymitis and similar conditions, and its use has been suggested particularly for facial erysipelas. It probably acts merely by its water content, *i. e.,* like any evaporating lotion; but its high osmotic concentration prevents maceration of the skin, draws fluid from edematous tissue, and washes off detritus from ulcers. It is also somewhat anesthetic to open surfaces.

Delbet and Karajanspoulo, 1915, claimed that intravenous injection of magnesium chloride (dogs, about 15 cc. of 1.21 per cent anhydrous, per kilogram) greatly increases *phagocytosis.* It does not inhibit the migration of leukocytes from the inflamed mesentery of frogs (Ikeda, 1916).

Tumor Growth.—Itani, 1919, failed to confirm any effect on experimental tumors; but Sugiura and Benedict, 1935, reported that a diet deficient in Mg decreases the growth of the tumor; these resume growth if magnesium sulfate is added, and are indeed slightly accelerated by high Mg diets.

Magnesium Sulfate as Insecticide.—V. B. Haber claimed that spraying with solutions of this salt is effective against moths and various other insects, and that grasshoppers are killed by bait containing 20 to 25 per cent of magnesium sulfate. Controlled tests, however, show that it is ineffective (N. F. Howard, 1937; R. C. Smith, 1937).

Inhalation of fumes of magnesium oxide, as generated by the burning of metallic magnesium ribbon or foil, produces fever and leukocytosis, as do the fumes of zinc oxide and other metallic oxides, but less readily (Drinker, Thomson and Finn, 1927).

Metallic magnesium, as used in surgery, dissolves slowly with the formation of magnesium hydroxide and hydrogen gas (Fromherz, 1909). These produce alkali necrosis and mechanical gas trauma, resulting in granulomatous reactions which compress adjacent tissue and cause degenerative changes (R. Z. Schulz and Water, 1942). S. F. Meek *et al.*, 1942, attribute the necrosis to proteolytic action. Inhalation of finely powdered magnesium does not produce gas tumors, since the hydrogen is not confined (L. U. Gardner and Delahant, 1943).

PREPARATIONS.—***Magnesium Sulfate,** U.S.P. (Epsom Salt); $MgSO_4 . 7H_2O$; small prismatic crystals, of cooling, saline, bitter taste; corresponds to about half of its weight of the anhydrous salt; very sol. in water (1:1). A saturated aqueous solution contains about 50 per cent of the crystals, or 25 per cent of the absolute $MgSO_4$. Dose, 2 to 15 Gm., ½ to 4 drachms. ***Magnesium Citrate Solution,** U.S.P., is an effervescent, sweetened and lemon-flavored solution containing a mixture of neutral and acid magnesium citrate, corresponding to about 1.75 per cent of MgO; prepared in bottles of 350 cc., 12 ounces, or 200 cc., 7 ounces, which may be taken as a single dose or be divided. ***Magnesium Carbonate,** U.S.P., hydrated magnesium carbonate, basic or normal; equivalent to about 42 per cent MgO. According to its preparation, it occurs as a more or less bulky powder, "*Light*" or "*Heavy*" *Magnesium Carbonate*, or as white, friable masses, of slightly earthy taste. Practically insol. in water. Average dose, as antacid, 0.6 Gm., 10 grains; as laxative, 2 to 8 Gm., ½ to 2 drachms. ***Magnesium Oxide, Heavy,** U.S.P. (Mag. Oxidum Ponderosum; Heavy Magnesia), is a white, dense, very fine powder; insol. in water. Dose, as antacid, 0.25 Gm., 4 grains; as laxative, 1 to 4 Gm., 15 to 60 grains. *Magnesium Oxide*, U.S.P., *Light Magnesia*, differs from the Heavy in being bulky. ***Magnesia Magma,** U.S.P. (Milk of Magnesia), is a creamy, smooth, aqueous suspension containing about 8 per cent of $Mg(OH)_2$; 0.1 per cent of citric acid may be added, and it may be flavored with aromatic oils. Dose, antacid, 4 cc., 1 drachm; as laxative, 15 cc., 4 drachms. *Tribasic Magnesium Phosphate*, $Mg_3(PO_4)_2O. 5H_2O$, is a white powder, almost insoluble in water, readily sol. in dilute acids. Dose, 1 to 5 Gm., 15 to 75 grains. It is used as antacid, avoiding systemic alkalization. It may be laxative.

SODIUM PHOSPHATE

This name is used in medicine and pharmacy for the disodium salt, Na_2HPO_4. The dihydrogen salt, NaH_2PO_4, is official as "sodium biphosphate," and since it is of feebly acid reaction, it is also called "acid sodium phosphate." The disodium salt is a feeble alkali. Both salts have considerable buffer value, and together they help to maintain the normal reaction of body fluids, especially of the urine. The phosphate ion is relatively nonabsorbable, so that sodium phosphate is a typical saline cathartic. The biphosphate is also cathartic, but produces more local irritation because of its acidity. It is administered to increase the acidity of the urine, especially to permit the liberation of formaldehyde from methenamine (Hanzlik and Collins, 1913). Sodium phosphate does not alter the true reaction of normal urine. The acute systemic effects of phosphates are slight, even on intravenous injection, and quite insignificant on oral administration. The phosphate content of the body has important relations to the ionization of calcium, and therefore to calcium concentration. It is ordinarily maintained at a constant level, and cannot be materially modified by the administration of phosphate. Even parenteral injection is rapidly compensated. Disturbance of the normal phosphate level is a characteristic feature of rickets. Creatine phosphate, hexose phosphate, adenyl pyrophosphate, are essential sources of energy in muscular contraction. Many biological reactions, particularly those involving marked energy changes, depend on phosphorus-containing compounds and frequently involve phosphorus transfer. Co-enzymes generally contain phosphorus (review, C. A. Baumann and Stare, 1939). Phospholipids, especially lecithin (see Index), occur in all living cells, but their functions are not clearly understood.

Use as Cathartic.—A solution of 2 to 4 Gm. of sodium phosphate in a glass of hot water (it is but slowly soluble in cold water) does not have a very disagreeable taste, and when taken before breakfast it usually produces a single soft but not liquid stool, within an hour. It may be administered for considerable periods, without producing habituation.

Effects of Intravenous Injection of Sodium Phosphate.—Moderate quantities act mainly as indifferent saline fluids. They are said to stimulate the vagus endings. Large doses (0.7 Gm. per Kg.) of sodium phosphate (absolute) injected into dogs produce tetany. The Ca content of the blood drops by 40 per cent.

Phosphoric acid injection produces a similar fall of Ca without tetany (C. Binger, 1917; Greenwald, 1918), presumably because the more acid reaction increases the ionization of the calcium.

Pyrophosphates.—Crawford, 1900, found sodium pyrophosphate, $Na_4P_2O_7$, markedly toxic, producing gastrointestinal irritation, hemorrhages and ulcerations; changes in the liver; with continued administration, nephritis and edema. *Metaphosphate*, $Na_4P_4O_{12}$, acted similarly but weaker; the ordinary orthophosphate was nontoxic. Behrens and Seelkopf, 1933, attributed the toxic effects of pyrophosphates and metaphosphates to precipitation of calcium from the blood; K. K. Jones and Murray, 197,3 confirmed that they are antagonized by intravenous injection of calcium salts. *Sodium hexametaphosphate* disionizes calcium without precipitation; indeed, it dissolves most of the insoluble calcium salts. It is reported to be the best solvent for phosphatic renal calculi, *in vitro* (D. R. McCullagh *et al.*, 1941). Blood coagulation is prevented by 1:1000 (C. E. Larson, 1941). It therefore produces the effects of acute calcium deficiency (Jones and Murray, 1937). It is used as a detergent, and for the preparation of a soft-curd milk (C. Schwartz, 1940).

Buffer Functions.—The system Na_2HPO_4:-NaH_2PO_4 functions in the blood plasma and especially in the urine. Its use in Ringer solutions is not satisfactory (Sollmann and von Oettingen), because if CO_2 is removed by aeration, insoluble calcium phosphate, $Ca_3(PO_4)_2$, is formed. The phosphate of plasma is in labile balance with HCO_3 ions, and forms the more soluble $Ca(HCO_3)_2$.

Absorption of Phosphates and Other Phosphorus Compounds.—A considerable but variable fraction of the phosphates is absorbed, mainly from the upper portions of the small intestines (Patwardhan and Nhavi, 1939). The quantity depends partly on the time that the phosphate sojourns in the intestines, as limited by the cathartic action of soluble phosphates; partly on the amount of calcium in the intestines, for this tends to deflect a large proportion of the phosphate to the feces. The insoluble calcium phosphate, administered as such, or as milk, is largely dissolved by the hydrochloric acid of the stomach, so that a part may be absorbed. It is doubtful whether preformed acid phosphate has a material advantage. *Hypophosphites* are absorbed, and for the most part excreted unchanged. *Glycerophosphates* and organic phosphorus compounds are almost completely hydrolyzed in the digestive tract (Plimmer, 1913), and absorbed and excreted as inorganic phosphate (Oeri, 1909), with the same absorption rate (Patwardhan and Nhavi, 1939).

The **excretion of phosphates** occurs by the urine and feces. With a high calcium income, the phosphate is excreted mainly by the feces as calcium phosphate; the urinary phosphates increase with a lime-poor diet (Zuelzer, 1905). "*Phosphaturia*," the deposition of phosphates in the urine, is due to alkaline reaction of the urine, and not to increased phosphate excretion; indeed, the excretion is generally diminished.

When injected subcutaneously, phosphates are rapidly excreted by the intestine and kidneys. The feces contain phosphates even in starvation. The urinary phosphates are generally increased by water diuresis (Baetzner, 1913). They are decreased by increase of plasma Ca, chloralose, epinephrine, insulin and removal of the pituitary body. This is due to a rise of the renal threshold, for the plasma PO_4 may be at normal level (Brull, 1928).

Phosphorus Compounds of Urine.—Practically all the phosphorus of the urine is normally in the form of inorganic mono- and di-hydrogen phosphates. A variable fraction may exist in organic form, as glycerophosphoric and phosphocarnic acid. The organic phosphorus is increased in fasting, chloroform anethesia, morphine poisoning and some pathologic conditions.

Phosphorus compounds of the feces are derived partly from unabsorbed phosphates, from intestinal secretions and from the bacteria. They include various organic forms, nucleins, lecithins, and so forth, as well as calcium and other inorganic phosphates.

PHOSPHORUS COMPOUNDS IN METABOLISM

Occurrence.—Phosphorus compounds make up a considerable proportion of the weight of the body, equivalent to about 0.7 per cent of P (young dog, Heubner, 1914), corresponding to 400 to 450 Gm. of phosphorus for a human adult. It occurs in three classes of compounds: in the bones as insoluble calcium and magnesium phosphate; as soluble phosphate ions in the plasma and other body fluids; as organic compounds, nucleins, phosphocreatine, hexose phosphate, lecithins and phosphatides, in the tissues and plasma. The organic phosphorus compounds of the serum are almost exclusively phospholipids (Greenwald, 1916; Bloor, 1918; Meigs *et al.*, 1919.) About three-fourths of the total phosphorus is in the bones; the muscles contain more than the combined total of the central nervous system, skin, liver and kidneys (Heubner, 1914). Milk contains a considerable amount of phosphorus compounds. (A comprehensive review, with bibliography, is given by Forbes and Keith, 1914.)

The *source of phosphorus* is almost entirely the inorganic phosphates of the food, from which all classes of phosphorus compounds in the body can be constructed. Animals which receive an adequate supply of inorganic phosphates require little, if any, organic phosphorus compounds (review, Marshall, 1915). The presence of some organic phosphorus in the food appears to favor nutrition; but this is probably due to contamination with vitamin (see Index, Lecithin).

Addition of radioactive phosphate to the ingested phosphate shows that it is distributed through all organs, including bones and teeth, so that these must be continually renewed. This also holds for phospholipids, which are built up from PO_4 (Chievitz and Hevesy, 1935). With parenteral administration it passes from the blood through the dentine into the enamel of the teeth; a small amount also from the saliva through the enamel to the dentine (C. B. Barnum and Armstrong, 1942). In the bony tissues of rats, the radioactive P is deposited chiefly in the epiphyses and in the roots of the incisors; but some is found also in the incisor tips, in the molars and in compact bone. A considerable amount is retained in the bones for more than three weeks (M. L. Manly and Bale, 1939).

Daily Phosphorus Requirements.—Under ordinary conditions, the daily phosphorus excretion of normal human adults is equivalent to about 1.5 to 1.75 Gm. of P, or about 3.5 Gm. of PO_4. This must be replaced by a corresponding income to preserve a balance. The ordinary diet contains about this amount (from 1.52 to 5.88 Gm., average 3 Gm., of PO_4; Sherman, Mettler and Sinclair, 1910). Under special conditions of diet, equilibrium may be preserved temporarily with 0.9 Gm. of P. This is the average daily excretion in fasting.

Phosphorus Balance.—Increased intake of phosphorus compounds is followed by increased elimination: in carnivora mainly by the urine; in herbivora mainly by the feces; in omnivora by either, according to the diet. A portion of the excess is retained, especially in growing animals or after wasting diseases. The retention is diminished by deficiency of calcium or excess of magnesium in the food. The bones constitute important depots for a phosphate reserve. The deposition of phosphate in them is hindered by inorganic acids, calcium-precipitating ions, or high potassium or low sodium content of the ration. Cows during *lactation* lose considerable phosphate. This may be corrected by the addition of bone and calcium carbonate to the food (Forbes *et al.*, 1917, 1918). *Excision of the parathyroids* is followed by marked retention of phosphorus, increasing its concentration in the blood (Greenwald, 1916).

Excess of sodium phosphate, when added to the *diet* of young rats, results in permanent renal lesions, necrosis of the cells of the convoluted tubules, beginning on the first day and reaching a maximum about the fifth day, followed by regeneration of atypical cells (E. M. McKay and Oliver, 1933).

Deficient phosphorus income is not likely to occur under normal conditions, as the ordinary diet suffices, not only for maintenance, but for growth. Deficiency may arise by fasting, by general malnutrition, by injudicious selection of food abnormally poor in phosphate or excessively rich in calcium, and probably during lactation. The deficiency should be easily remedied by taking milk. If the phosphorus income falls below the normal requirement, the excretion and finally the phosphorus content of the tissues are diminished.

The phosphorus of the plasma, both organic and inorganic, varies rather widely and is influenced by the food (Meigs *et al.*, 1919). Its diminution soon leads to disturbances of growth and nutrition, the spongy tissue of the bones being most affected (Masslow, 1914). The bones become soft and flexible when their phosphorus content has fallen by one-sixth (Heubner, 1914). The development of the jaws is markedly retarded (D. Y. Burrill, 1943, dogs). Growth that has been interrupted by phosphorus deficiency is resumed when phosphorus compounds are added. Inorganic phosphates are efficient for their purpose (Osborne and Mendel, 1918).

Rickets involves serious disturbance of phosphate metabolism, reflected by a marked diminution of the *phosphate content of the plasma.* This lies normally between 7 and 9 mg. per 100 cc.; in rickets it falls to 3 or 4 mg. The calcium is but little decreased (Howland and Marriott, 1917). It is also reflected in the impaired calcification of the bones, which consist normally mainly of calcium phosphate. In rickets the cellular tissue proliferates, but the mineral matter diminishes, sometimes to half of the normal. The condition may be induced in young animals by food deficient either in inorganic phosphate (Sherman *et al.*, 1918) or in vitamin D, especially if the Ca:P ratio is 4:1 or higher (or by decreasing the absorption of phosphate by administering alum or beryllium). Animals so prepared may be used to test the effectiveness of antirachitic agents (rats, McCollum *et al.*, 1921; rabbits, Goldblatt and Moritz, 1926). The most effective antirachitic agents are cod liver oil (see Index) and actinic light, but rickets of young rats are also promptly healed without these by diets with Ca:P ration of 1:1 (Karelitz and Shohl, 1927). *Phosphatase* is discussed under Calcium.

Hyperglycemia lowers the PO_4 concentration of the plasma. The oral administration of 100 Gm. of glucose to normal adults induces an average fall of 0.6 mg. per 100 cc. in two to three hours (D. R. McCullagh, 1931).

Contraction of skeletal muscle depends for its energy largely on the cleavage and resynthesis of organic phosphate compounds, creatine phosphate (phosphocreatine, phosphagen), hexose mono- and di-phosphate and adenyl pyrophosphate (review, J. Sacks, 1941), by specific enzyme and co-enzyme systems, which may take alternative paths according to circumstances. The interlocking of these processes with each other and with the lactic acid process is obscure. Phosphorylation processes are also concerned in the energy metabolism of cardiac muscle, of nerve, of the liver, kidney and salivary glands, and in the assimilation of sugar and formation of glycogen (reviews, J. Sacks, 1941; C. F. Cori *et al.*, 1943).

The use of *sodium phosphate to increase muscular energy* was tried in Germany during the first World War with the claim that it diminished fatigue in soldiers, and increased the capacity for work and caused euphoria in miners; and that excess of the phosphate produced sleeplessness and palpitation! The response was presumably due to suggestion, for it does not appear to have been confirmed (M. Morse, 1939; Bøje, 1939). Sodium formate was (seriously) suggested for the same purpose, on the basis that Formica the Ant is an indefatigable worker. The role of phosphate in muscular contraction may appear to furnish a more rational basis; but as phosphate is not destroyed in this use, it is not necessary to furnish an extra supply, unless its income were lastingly deficient, and in that case the bones would suffer, not the muscles.

Use of Lecithin and Other Phospho-Lipids and Nucleins, Glycerophosphates and Hypophosphites as Tonics.—The unfounded assumption that these compounds would be more easily assimilated by the tissues, and particularly by the brain, gave rise to their employment as tonics and "brain food" in all sorts of depressed conditions: scrofula, incipient phthisis and cachexia; neurasthenia and tabes; neuritis and neuralgia, and so on. There is no evidence for the better utilization of these compounds; and in any case the ordinary diet furnishes a free supply of lecithin and other phosphorus compounds, so that it is difficult to see how the small quantities added in the form of more or less expensive medicines could have any other than psychic effects. When the psychic element is excluded, they are ineffective.

Glycerophosphates are absorbed in part unchanged, but for the greater part are decomposed in the intestines into ordinary phosphates (Plimmer, 1913). The excretion is entirely as phosphate. Since lecithin is split into glycerophosphates in the intestines, it was suggested that the direct administration of the cheaper glycerophosphates (especially the calcium salt) should accomplish the same results. However, according to Willstätter, the synthetic glycerophosphoric acid is not identical with that formed from lecithin. The evidence of its usefulness is even less convincing than for lecithin (report, Council on Pharmacy and Chemistry, 1916, J.A.M.A., *67:* 1033). A proprietary compound of glycerophosphates and casein was extravagantly advertised as "Sanatogen." It was a costly food, in no sense superior to ordinary casein, such as cottage cheese (Street, 1914).

Hypophosphites were introduced by Churchill, 1855, against tuberculosis on the theory that phthisis is caused by lack of oxidation and that this would be stimulated by organic phosphorus; and that the hypophosphites would be converted into this "phosphatide element." On the basis of this fantastic theory, they were used considerably as tonics in tuberculosis. The clinical evidence is too indefinite and the experimental evidence is generally negative (Report, Council on Pharmacy and Chemistry, 1916, J.A.M.A., *67:* 760). The hypophosphites are *excreted* rapidly and almost completely unchanged (85 per cent; Marriott, 1916) by the urine (Paquelin and Joly; Boddaert, 1895; Massol and Gammel, 1901); a trace may possibly be oxidized (Delaini, 1911). (Patto, 1910, claimed that only a fraction is excreted unchanged.) They are not diuretic. The unscientific status of the hypophosphites is reflected in the polypharmacal syrups in which they are generally prescribed, such as the Syrupus Hypophosphitum Compositus (dose, 8 cc.), containing five hypophosphites besides quinine and strychnine; there is also an emulsion of cod liver oil with hypophosphites. The hypophosphites are easily soluble in water; dose, 0.1 to 1 Gm.; 1 to 15 grains. *Hypophosphorous Acid,* U.S.P., contains about 31 per cent of HPH_2O_2.

Radioactive dibasic sodium phosphate, an artificially produced isotope (P^{32}), is used as a means of internal therapeutic radiation. It has a half-life of fourteen and a half days, sufficiently short to avoid long-range harmful effects. Its disintegration produces only beta particles which do not penetrate farther than 2 to 4 mm. of tissue. The final degradation product is non-radioactive and harmless sulfur. Injected by vein, about three-fourths is retained at the end of three days; half at the end of a week. It diffuses through all tissues, but rapidly growing cells and leukemic cells absorb it preferentially. Its concentration is relatively high in the liver, kidney, spleen and bone marrow; fat and brain contain very little. Its excretion after intravenous injection is practically entirely by the urine; with oral administration, about a fourth escapes unabsorbed in the feces.

The beta rays are capable of producing profound effects on the bone marrow, and thereby the blood cell formation, with minimal harm to the patient. Its therapeutic results are about the same as with x-ray therapy and avoid the serum sickness. It increases the leukocytes, thrombocytes and red corpuscles, almost always with prompt recovery of the white and slower restoration of the red cells (L. A. Hempelman *et al.*, 1944). The results are palliative rather than curative. It is especially useful in polycythemia vera, producing long-lasting remissions (S. Warren, 1945; B. E. Hall *et al.*, 1945). Hodgkin's disease, lymphosarcoma, reticulum cell sarcoma and myeloma do not respond so well as they do to x-ray (E. H. Reinhard, *et al.* 1945; normal tissues, W. R. Platt, 1947).

Radioactive sodium phosphate, NaH_2PO_4, may be administered by mouth or vein, in a dosage of 5 to 10 millicuries (C. C. Sturgis, 1946).

PREPARATIONS.—***Sodium Phosphate,** U.S.P.; dibasic sodium phosphate, disodium orthophosphate, disodium hydrogen phosphate; $Na_2HPO_4 . 7H_2O$; large colorless crystals or granular powder, of cooling saline taste. Freely sol. in water (1:4); practically insol. in alc. Dose, 2 to 15 Gm., ½ to 4 drachms. *Effervescent Sodium Phosphate,* U.S.P., represents about 50 per cent of the phosphate. Dose, 10 Gm., 2½ drachms. *Exsiccated Sodium Phosphate,* U.S.P., has had the water of crystallization expelled by heat. It is about twice as strong as the ordinary phosphate. ***Sodium Biphosphate,** U.S.P. (Sodium Acid Phosphate, Monosodium Orthophosphate, Sodium Dihydrogen Phosphate), contains at least 85 per cent of NaH_2PO_4. Large colorless crystals or granular powder, of saline and somewhat acid taste. Very sol. in water; insol. in alc. Dose, 1 to 1.5 Gm., 15 to 20 grains, in water; repeated every one to four hours until the urine becomes acid. It should not be mixed with methenamine.

ELEMENTARY PHOSPHORUS

Yellow phosphorus (to which this discussion refers, unless otherwise noted) is an active poison producing death by acute hepatitis, with alterations of nitrogen metabolism, and fatty changes of the liver and other organs. The continued administration of small doses modifies nutrition and bone formation, and was formerly used against rickets, but it is not effective, nor safe. Phosphorus acts as such: Its actions are not shared by any of its compounds, which are for the most part harmless. Long-continued exposure to the vapors of phosphorus may produce osteitis and necrosis of the jaw.

Amorphous or red phosphorus is nonvolatile, insoluble, inabsorbable and therefore nontoxic when taken by mouth; but since it may contain traces of ordinary phosphorus (to 0.6 per cent—Blythe), large doses could become toxic. Intravenous injections (Nasse, 1885) produced the effects of ordinary phosphorus, probably by conversion into this form.

Fate.—Yellow phosphorus is practically insoluble in water, but diffuses through this as vapor, and forms a dilute colloidal solution, the "phosphorus water." It is soluble in fats and in bile (Hartmann, 1866), and is therefore absorbed from the intestines and from subcutaneous injections, especially if it is administered in finely divided form. Toxic quantities may be absorbed from the skin (Zernik, 1930), and by inhalation of the vapor. The absorption is slow, and the systemic effects are therefore delayed several days. It is finally *excreted* in oxidized form (hypophosphoric acid, Poulet, 1872), but its *fate* is imperfectly known. Although it oxidizes readily in the air, its oxidation in the blood requires days (H. Meyer, 1881); perhaps it has an inhibitory action on oxidizing ferments like that of hydrocyanic acid (Schultzen and Riess, 1869). During its action it exists unchanged in the organs and in the expired air (Claude Bernard).

Etiology of Phosphorus Poisoning.—Phosphorus is accessible in the form of matches or phosphorus rat and roach paste (which contains 3 to 5 per cent), so that accidental or suicidal poisoning is not uncommon. (Sixteen cases, four fatal, from eating of roach paste are reported by J. S. LaDue *et al.*, 1944.) Infusions of matches have been taken as abortifacients, with serious results. Chronic poisoning of somewhat different character is seen from its fumes, in chemical works and formerly in match factories. This, as well as the poisoning by matches, has been greatly diminished since the introduction of amorphous (red) phosphorus. At present, yellow phosphorus is rarely used in making matches.

Phosphorus Matches.—The first phosphorus friction matches were made by Derosne, in Paris, 1816, but they did not become practical until 1833, when processes for their manufacture were invented in several countries. These all employed yellow phosphorus; each match contained ⅓ to 5 mg., so that 16 could be fatal for an adult. The use of the dangerous yellow phosphorus in matches is now prohibited by law in practically all European countries. In the United States, a prohibitive tax has been placed on their manufacture. *Phosphorus sesquisulfide* is now used in ordinary matches, which strike anywhere. This has a low toxicity; guinea pigs are said to show no effects from doses of 0.3 Gm. per day (Brouardel). The "safety matches" have no phosphorus on the sticks, which are usually headed with Sb_2SO_3, $KClO_3$ and glue· the red phosphorus is on the friction surface coating of the box.

The symptoms of poisoning are peculiar in that they occur in two well defined stages: at first, there is local gastro-intestinal irritation: then more or less complete recovery; then, after two or three days, the phenomena of the systemic actions appear. These are distinguished by fatty enlargement of the liver, intense icterus, and the metabolic changes of acute hepatitis. They extend over several days and generally terminate in death by heart failure. Gastric, syncopal or cerebral phenomena may predominate. About half the clinical cases end in death, usually in four or five days, but recovery may occur even in advanced cases. Cerebral symptoms may last a long time, perhaps because of hemorrhages.

Acute symptoms generally start after some hours with gastric pain and burning, eructations with garlic odor, and finally vomiting, which may be luminous in the dark. Later there is often diarrhea. After twenty-four to thirty-six hours, there is more or less remission of the symptoms, usually of short duration, but it may last two or three days.

The *later phenomena* begin with nausea; then gradually slight icterus; abdominal pain and tenderness; vomiting and soft stools, both often streaked with blood; coated tongue and fetor oris. The symptoms become gradually more severe; within two days the area of liver dulness has rapidly increased; the hepatic region is painful and tender, and the icterus more intense. Icterus is noted in about half the cases; it appears generally on the second to the fourth day, but may be delayed till the twenty-fifth (Jaksch). If death occurs within the first two days of the second stage, there is usually no icterus (Magnus, 1914). All foods and liquids are vomited. The patient becomes profoundly prostrated with insomnia, anxiety, headache, muscle pains, spasm and feebleness. The temperature is normal, the skin dry, the respiration increased, the pulse soft but of normal rate. The *urine* is scanty, acid, dark brown from bile and blood and contains albumin, casts and abnormal nitrogenous substances. Multiple *hemorrhages* may occur as petechiae or in larger areas, in the skin, mucosae, lungs and other viscera.

Agonal Stage.—The pulse becomes thready and intermittent; the heart dilated, with systolic murmurs; the respirat on dyspneic or Cheyne-Stokes. Consciousness may bei undisturbed, but generally there is somnolence, sometimes delirium and disturbances of temperature; finally coma.

Diagnostic postmortem features are: the icterus; phosphorus odor on opening abdomen; blood tarry and difficultly coagulable; multiple hemorrhages; fatty enlargement of the liver and other organs. Gastric lesions are slight or absent. The *mitochondria of the pancreatic cells,* according to W. J. M. Scott, 1916, are the first structures to show changes in phosphorus poisoning.

The *course* runs from two to fifteen, averaging perhaps eight, days. In the fatal cases, death occurs usually before the eighth day, most commonly in four to five days (Jaksch, Tardieu); it has occurred exceptionally in four to eight hours. Serial experiments on rats with a dosage of 4 mg. per 100 Gm. show that the hepatic changes appear in eighteen to twenty-four hours and increase to seventy-two hours. If this time is survived, the liver returns rapidly and completely to normal (Love, 1932). The *fatality* is high, about 55 per cent (Falck); with larger quantities, such as are used for abortion, it may reach 95 per cent (Kobert). The *fatal dose* may be as low as 50 mg., generally about 100 mg.; but 15 mg. may be severely toxic. It is much more dangerous in solution or when finely divided than when larger lumps are taken. Monti administered as high as 7 mg. daily for three weeks against rickets, but this dosage proved toxic. A two year old child has been severely poisoned by therapeutic doses (1.2 mg. distributed over three days; Nebelthau). Magnus, 1914, stated that no dangerous effects have ever occurred (in children up to eight years) from 0.5 mg. per day, although there may be some vomiting at first. He reported the smallest dose that has exceptionally produced dangerous effects as 1 mg. per day.

The *effects on the liver* dominate the picture. They may be summarized as disappearance of glycogen, incomplete combustion of lactic acid, increased excretion of ammonia, increased protein destruction with incomplete desamidization of certain amino acids, fatty infiltration, mechanical interference with bile formation, increased postmortem autolysis, decrease of fibrinogen. The excretion of p.-s.-phthaleine is delayed (Whipply and Sperry, 1915). The liver, heart, ganglion and other nerve cells show degenerative changes similar to those of chloroform intoxication (Lissauer, 1914).

Bile and Icterus.—The swelling and subsequent cirrhosis of the liver obstruct the bile capillaries, so that bile secretion is diminished or suppressed; the gallbladder contains only a little mucous fluid. The retention of the bile constituents produces the characteristic intense icterus. It was formerly believed that the formation of bile was also increased by the destruction of the blood, but there is no evidence for such destruction.

The *coagulability of the blood* is diminished, probably by destruction of fibrinogen or of fibrin ferment, or possibly by the production of peptone bodies from the destruction of proteins (Cevidalli, 1902). Denny and Minot, 1915, also found the antithrombin content of the blood diminished. The *hemorrhagic tendency* is explained by the lessened coagulability of the blood and by the fatty changes in the capillary endothelium. The *ecbolic action* which occurs with fatal doses may be referred to degeneration of the blood vessels. However, phosphorus also passes to the fetus in sufficient amount to produce fatty hepatic degeneration. Lewin records twenty-seven cases in which phosphorus was used as abortifacient; it induced abortion in twenty-three of these, and death of the mother in over half of the cases.

The *action on metabolism* occurs in chronic poisoning, or as a secondary process after a single larger dose. The phenomena consist in increased tissue destruction with disturbances of syntheses, oxidations and dissociations; deposition of fat in the liver; increased but incomplete nitrogen metabolism; interference with glycogen deposition; increased lactic acid and ammonia excretion; inhibition of other synthetic processes. The mechanism is not understood. It appears to involve interference with ferment actions, primarily with some of those involved in carbohydrate metabolism.

Fatty Changes.—Extensive deposition of fat occurs particularly in the liver cells, whose fat content may reach three or four times the normal; but it is seen also in practically all other cellular organs: muscle, skeletal, smooth and cardiac; kidneys; blood vessels; epithelium of stomach and intestine, and so on. The fatty changes are preceded by "cloudy swelling," which is probably an intermediate stage. They are followed by proliferation of interstitial connective tissue (cirrhosis). *Similar fatty changes,* especially in the liver, occur in poisoning by: Phlorhizin, arsenic, antimony, many volatile oils, the alcohol group, chloroform, carbon tetrachloride, benzene, phallin, and the like, in starvation and in diets rich in fats, in experimental diabetes, on injection of anterior pituitary extract, on feeding cholesterol. They may be decreased or prevented by feeding lecithin or *choline.* The latter hastens especially the disappearance of fat from the liver in the recovery phase of phosphorus poisoning. Its mechanism is not explained: histological studies indicate that it does not affect the duration of the degenerative changes in the liver, other than the fat accumulation (C. H. Best, Maclean and Ridout, 1935). The *mechanism of the fatty degeneration* has been studied especially in the liver. It was originally assumed that the fat was formed *in situ,* by true degeneration of the protoplasm of the liver cells (Bauer, 1878). However, Lebedeff, 1883, disproved this, finding that fat is deposited in the liver only if the fat store of the body is ample, and that if some foreign fat is introduced into the subcutaneous tissue, the fat deposited in the phosphorus liver agrees in composition with this foreign fat. This suggests that the liver fat is merely transported from the fat depots. These observations were confirmed by Rosenfeld, 1897; Pflueger, 1898; Foulerton, 1921; and others. (However, Salvioli and Sacchetto, 1922, claimed that the phosphorus increased the visible fat in the liver, even in animals starved to the last degree; but the organ fat had not entirely disappeared.) Similar observations were made in regard to the other poisons that cause "fatty degeneration" of the liver. The conclusion was strengthened by the observation of Athanasiu, 1898, that the total fat of the body is not increased by phosphorus. In fact, it is rather diminished (Shibata, 1911). The increased fat of the liver must therefore have been drawn from other parts of the body so that the process is one of infiltration. Lusk found that the combustion of fat in phosphorus poisoning is not changed. Some of the "fat" consists partly of other lipoids (Dastre and Morat, 1879); Heffter, 1890, claimed that the percentage of lecithin is decreased. The fat in the heart (studied by Rosenfeld, 1906) is also infiltrated (Leik and Winckler).

Autolysis.—In advanced phosphorus poisoning, the postmortem autolysis of the liver is greatly accelerated (Jacoby, 1900; Porges and Pribram, 1908), probably by decreased resistance of the liver cells to the normal autolytic ferments (Wells). Direct addition of phosphorus to excised normal liver does not hasten autolysis (Jacoby).

Tissue cultures from the livers of rabbits poisoned by phosphorus or carbon tetrachloride show the injury by deformed growth and atypical cells (Adlersberg and Minibeck, 1936).

The *nitrogen metabolism* is greatly increased. The urinary nitrogen may rise by 300 per cent (Storch, 1865). The excretion of phosphate and sulfur is also increased, while the chlorides are diminished by the inanition (Welsch, 1905). All the nitrogenous metabolites may participate in the increase (v. Jaksch, 1903), but not to the same extent (Muenzer, 1894). The urea is not nearly so much increased as the others and may even be diminished. It is to a large extent replaced by ammonia. This may be attributed to an increased production of sarcolactic and other organic acids. The uric acid excretion does not show characteristic changes; the creatinine output is scarcely affected (Lusk). The hippuric synthesis of excised kidneys is checked (Hauser, 1895). The blood of dogs poisoned with phosphorus shows increase of nonprotein nitrogen, urea and amino acids, partly through increased metabolism, and partly because of diminished excretion. There is generally a terminal acidosis (E. K. Marshall and Rowntree, 1915, 1918). The total N:urea ratio of the blood rises (Desqueyroux, 1922). The protein cleavage products may play a part in the production of the symptoms (Moriani, 1916).

The appearance in the urine of *amino acids*, leucine, tyrosine, cystine; and peptone-like substances (Schultzen and Riess, 1869) is diagnostically important. Clinical cases may not show the tyrosine. The peptone-like substances are present especially in the early stages. Their nature is not known (Harnack, 1893).

Carbohydrate Metabolism.—The *blood sugar* level is temporarily increased; after large doses, this is followed by severe hypoglycemia (Ivancevic, 1927). The diastase of the serum is greatly increased, with decrease in lipase and no change in protease. These results occur also after excision of the pancreas and are presumably due to the action on the liver (Falkenhausen, 1928). Phosphorus causes the disappearance of glycogen from the liver. This is not due to increased glycogenolysis. Phosphorus must therefore inhibit glycogen synthesis, especially from noncarbohydrate sources (E. Franck and Isaak, 1911; Desqueyroux, 1922). This would explain the prevention of epinephrine glycosuria by phosphorus, and the noncombustion of lactic acid. According to v. Fuerth, 1914, lactic acid appears in the urine only when the rabbits are fed on an excess of sugar. Dextrose is not converted into glycogen (E. Neubauer, 1909), thus explaining the occurrence of glycosuria when carbohydrates are fed. Glycogen may be still formed from levulose. The tolerance for galactose and levulose is lowered (E. K. Marshall and Rowntree, 1915). Phosphorus poisoning disturbs the conjugation of glycuronic phenols by slices of liver; chloroform poisoning apparently does not interfere (E. Bueding and Ladewig, 1939).

The *increase of nitrogen excretion may be due to carbohydrate disturbance.* Franck and Isaak, 1911, believed that this interference with glycogen synthesis is the primary action of phosphorus; they attributed the increased protein destruction to the necessity of making up for the lessened supply of energy material. The fat transportation to the liver could be similarly explained. Accordingly, Rettig, 1914, found that a diet rich in carbohydrates prevents the increased protein catabolism and the fatty changes. Ray, McDermott and Lusk, 1899, also showed that with dogs rendered glycosuric by phlorhizin, phosphorus does not increase the nitrogen excretion, again indicating that the nitrogen excretion is not due to direct destruction of the protoplasm, but is in some way connected with the disturbed carbohydrate metabolism. Lusk, 1907, suggested that the primary action is to inhibit the ferment which burns lactic acid, and that the nitrogen changes are due to the resulting acidosis.

Oxygen Consumption.—The metabolic effects of phosphorus resemble those of oxygen deprivation (*e. g.*, Porges and Pribram, 1908), and it has been suggested that phosphorus renders the cells less capable of utilizing oxygen. However, it is also possible that the metabolic changes in both cases are the secondary result of some other common factor. Indeed, Lusk, 1907, showed that the oxygen consumption is not diminished, but rather is somewhat increased, partly by fever, and probably also by the toxic action of increased protein destruction.

Circulation.—Phosphorus appears to have direct toxic effects on the heart muscle, for the isolated frog heart is depressed by the direct application of phosphorus solutions (Okuto, 1926); with intravenous injection the heart is paralyzed before anatomic degeneration has set in (Meyer, 1881). In the collapse, splanchnic stimulation is ineffective. In clinical poisoning, the syncopal cases may be due to this cardiac paralysis, but generally the circulation suffers but little until the agonal state.

Electrocardiogram changes, similar to those of glomerulonephritis and severe anemia, with recovery, were recorded in a patient by R. A. Dathe and Nathan, 1946.

Muscle and nerve are not directly affected.

The *central nervous system* plays a subsidiary role, but is said to show histologic changes (Rossi, 1897).

Changes in the Blood.—On the basis of experiments on birds (Fraenkel and Roehmann), it was formerly believed that the *red corpuscles* are rapidly destroyed, in man and mammals (Taussig, 1892; v. Jacksch, 1893); no destruction occurs, however, even in severe poisoning. In fact, the corpuscles are often increased (Ragazzi, 1910; Leoncini, 1914), and this is the typical effect of therapeutic doses. The *hemoglobin* is not altered (Leoncini). The viscosity and electrical resistance of the blood are increased by the polycythemia, and remain so until death approaches, when they suddenly decrease. The osmotic pressure of the blood was found increased by Bottazzi, 1896, unchanged by Ragazzi. The *alkalinity* is diminished. The catalase action is moderately decreased (Duncker and Jodlbauer, 1911). The *diastase* of the serum is greatly increased, the lipase somewhat decreased, and the protease unchanged (similar changes follow excision of the pancreas; Falkenhausen, 1928). The statements as to the *leukocytes* are confusing: Ragazzi describes increase of the polynuclears, and disappearance of eosinophils. According to Leoncini, the leukocytes are at first diminished, then sometimes moderately increased.

Local Actions.—Irritation of the mucosae is shown by the early acute symptoms, but phosphorus is not corrosive. *Phosphorus burns* are no more dangerous than other burns of similar extent and do not produce any of the symptoms of phosphorus poisoning. Contact with copper sulfate, in 1 per cent solution, stops fuming immediately (D. D. Walton, 1942).

Treatment of Acute Poisoning.—Any phosphorus remaining in the alimentary tract should be oxidized and removed. In view of the slow absorption of the phosphorus, gastric lavage may be successful even when started two hours after the ingestion. A large quantity of fluid should be used (5 to 10 gallons). Copper sulfate, 0.1 to 0.2 Gm. in water every ten minutes until emesis, acts as a prompt emetic, and meanwhile oxidizes the phosphorus and envelops the globules with a coating of reduced copper which retards absorption (Woehler and Vogel, 1836), but it was not very successful in dogs. Gastric lavage with other oxidizing agents may be substituted: $KMnO_4$, 0.1 per cent (Bokai and Antal; Koranyi, 1889), or H_2O_2, 2 per cent of the official solution. These should be followed by 2 to 4 ounces of liquid petrolatum and a full dose of a saline cathartic. Oils, fats and milk should be avoided while any phosphorus remains in the intestines, since they increase its solubility and absorption. Sodium bicarbonate, glucose and insulin may be given if hepatitis threatens. When the systemic symptoms have set in, these measures are practically useless and the treatment must be mainly symptomatic. Transfusion of blood is said to give good results.

In phosphorus-poisoned animals, the *feeding of sugar* was found to replenish the hepatic glycogen, and to diminish the other toxic manifestations (Simonds, 1919).

Oil of turpentine, 0.5 Gm. several times daily for a week, may be tried (Andant, 1868; Koehler, 1872), but its benefits are doubtful, or at least inconstant. They seem to vary with different varieties of the turpentine, the fresh being often as effective as old ozonized samples. The action is not due to simple oxidation of the phosphorus, but to the formation of complex compounds (Busch and Fischer); Kobert believes that it may be effective even after the phosphorus has been absorbed.

Chronic Phosphorus Poisoning.—This is seen especially in factories using yellow phosphorus and also in the manufacture of phosphor bronze. The most common manifestation is necrosis of the jaw; sometimes bronchitis, to which tolerance is acquired; and cachexia resembling mild acute poisoning. Strict *prophylaxis* should be enforced. The manufacture of yellow phosphorus matches has been prohibited in most civilized countries. Exposed workers should attend to ventilation, cleanliness and strict oral hygiene (Ivy, 1911). Persons with defective teeth should not be subjected to the risks. The literature is reviewed by H. Heimann, 1946.

Necrosis of the jawbone, "phossy jaw," is due, not to a direct action of phosphorus, but to a lowered resistance to infection and defective repair which are induced by the effects of phosphorus on the blood vessels in the Haversian canals of the bone (see below). Identical necroses in the teeth and other bones have been produced experimentally (Wegner, 1872) by prolonged exposure of rabbits to phosphorus vapor, after laying bare the periosteum. The greater liability of the jawbone is due merely to its greater exposure to infection, through diseased teeth and alveoli. Clinically, only a small proportion of the exposed workers, 2 or 3 per cent, develop the necrosis. It may occur several years after the subjects have been removed from exposure to phosphorus, but this generally arrests the advance of the disease. The symptoms begin with salivation and toothache, more often in the lower jaw, with suppurative ulceration of the gums around a carious tooth or generally a root abscess which does not heal after extraction, with suppurating fistula and gradual progressive necrosis of the maxilla. The absorption of the necrotic tissue causes cachexia. The mortality in serious cases is 15 to 20 per cent. Excision of the diseased bone is the only treatment. Large sequestra are now rarely allowed to develop. Caries should prompt removal from exposure (Kennon and Hallam, 1944).

Bone Changes.—Continued administration of small doses of phosphorus to growing animals results in the characteristic "phosphorus band," a layer of dense bone under the proliferating epiphyseal cartilage of the long bones (Wegner, 1872). In adults, the Haversian and marrow canals are gradually filled with dense bone of normal composition and structure (Kassowitz). The densifying effect is probably due to delayed reabsorption of bone tissue from scanty formation of blood vessels. The roentgen and histologic bone and tooth changes have been studied by C. O. Adams and Sarnat, 1940.

This action would not be useful against rickets, as was assumed by Kassowitz, 1884, for it would not accelerate the calcification of cartilage, which is the characteristic deficiency of this disease; indeed, it is possible to produce the two conditions, phosphorus band and defective cartilage calcification, concurrently (A. F. Hess). Phosphorus administration does not even improve the effects of cod liver oil. The densifying action might be of some use in osteoporosis and perhaps in fractures (Phemister, 1918), but the results are not uniform and its use is not advisable, since the effective dose (1 mg. per day in cod liver oil or in pills) may cause some gastro-intestinal disturbance; sometimes the jaw necrosis; and rarely typical phosphorus poisoning. Engelhardt and Winters, 1915, found the pills and spirit fairly stable, but not always. Compound elixirs are less stable.

Growth.—Phosphorus in doses proportional to those used clinically, administered to young rats with their food over long periods, produced marked and progressive retardation of growth. The animals remained stunted even when replaced on poison-free food. This suggests that the failure of growth may be due to premature solidification of bone, but no observations were made in this direction. With $\frac{1}{25}$ of the clinical dosage, there was first a doubtful retardation of growth; but after four months on this dosage the weight increased markedly above the normal, especially in old animals; with young animals this increase occurred when they were replaced on the poison-free food. No observations were made as to the nature of the overweight tissue, or of the metabolism (Sollmann, 1924).

Hepatic *cirrhosis* was reported by F. B. Mallory, 1933, after prolonged administration (five months) of small doses of phosphorus (0.33 mg. per Kg.) to rabbits and guinea pigs.

Phosphorus in Nervous Diseases.—It has been advised as a tonic in alcoholism, neurasthenia, sexual exhaustion, neuralgia, tabes, cerebral degeneration, and the like, and in chlorosis and anemias. There is no scientific support, either experimental or clinical, for this use. *Zinc phosphide* has been suggested as a therapeutic substitute (Vigier, 1876); there is little scientific information about it.

Phosphorus occurs as a translucent waxy substance of distinctive odor. Melts at about 44° C. Oxidizes (ignites!) on exposure to air. Practically insol. in water, but slightly sol. in alc. (1:400). Sparingly sol. in oils. Sol. in fat solvent. Dose, 0.6 mg., $\frac{1}{100}$ grain, as pill or oily solution. These must be recently prepared. Maximum dose, 2.5 mg., $\frac{1}{25}$ grain.

Phosphuretted Hydrogen.—This gas (Phosphine—PH_3, not to be confused with Phosgene, $COCl_2$!) is a violent poison; 0.025 per cent in air is harmful after a time; and 0.2 per cent is quickly fatal, producing dyspnea, fainting, lowered blood pressure, slowed heart; nausea and vomiting; convulsions and paralyses; coma and asphyxia. The symptoms have been confused with those of food poisoning. Slight cases recover without aftereffects. Postmortem examination shows pulmonary congestion and exudation. The blood is not changed (in contrast to AsH_3, arsine). Industrial poisoning occurs from its presence in acetylene and ferrosilicon. Prolonged exposure may produce the ordinary phenomena of chronic phosphorus poisoning (review, S. H. Webster, 1946).

Phosphorus pentachloride poisoning is described by Roch, 1914.

SODIUM CHLORIDE

Sodium chloride constitutes the greater part of the electrolytes of the tissues (with some exceptions), and especially of the fluids, of vertebrates. Its ions are essential for the functionation of most cells. Since the ions are constantly excreted, especially by the urine, they must be constantly replenished, leading to the instinctive use of salt in food. Its administration to mammals, even by intravenous injection, produces practically only osmotic effects; but marked ion actions may be observed by exposing excised tissues to solutions with or without the sodium and chloride ions. The therapeutic uses of salt depend largely on its osmotic effects. These result in stimulation of the gastric mucous membrane, leading to its use as condiment and in some indigestions; under suitable conditions, a laxative action; irritation of the skin, with attending reflex stimulation, utilized as salt-water baths. After absorption, it leads to diuresis and slight metabolic changes. Isotonic solution is used as vehicle or for cleansing sensitive mucous membranes, *f.i.*, the nose; and for hypodermic and intravenous injections. These saline infusions are employed in hemorrhage, collapse, and for the dilution or removal of systemic poisons. The intravenous injection of strongly hypertonic solutions is fatal, with stimulation and paralysis of the central nervous system.

Retention of chloride occurs in certain pathologic conditions, especially pneumonia and other fevers, nephritis, cancer, and so forth. It may favor the formation of edemas, against which salt-poor diet is sometimes efficient. NaCl depletion in pernicious vomiting, excessive sweating and Addison's disease accounts partly for the phenomena of these conditions.

NaCl Capital, Income and Turnover.—The total NaCl of a human adult amounts to 150 to 300 Gm. (Magnus-Levy, 1906), 5 to 10 ounces, averaging perhaps half a pound. The daily turnover depends on the income, and this on the dietary and culinary taste of the individual; 10 to 15 Gm. is a fair approximation for most persons, so that the daily turnover is about a twentieth of the total stock. Reabsorption in the kidneys protects the organism against excessive loss that would lower the plasma chloride below the 0.562 per cent of NaCl, or 0.38 per cent of Cl.

The *daily salt consumption* of a thousand residents of the city of New York was appraised by B. I. Ashe and Mosenthal, 1937, from the urinary excretion, as: less than 4 Gm. in 5 per cent of the individuals; 4 to 8 Gm. in 37 per cent; over 8 Gm. in 57 per cent; over 20 Gm. in 1.6 per cent. A similar distribution obtains for patients with hypertension, with or without nitrogen retention. Reduction of the income to 5 Gm., or even 1 to 2 Gm., causes no disturbance. For *parenteral nutrition*, 5 Gm. should be supplied daily, more for febrile and perspiring patients; that lost by vomiting should be replaced in addition. Verhage, 1940, reports that a *minimal daily increase* of 200 to 300 mg. of sodium, about a fifteenth of the normal, suffices to maintain the normal sodium level of the blood plasma, the excretion being reduced in proportion. Carnivorous animals obtain a sufficient supply in their food; but since K predominates over Na in the ash of plants, herbivora and animals feeding on a mixed diet require additional NaCl. This need has led to the *instinctive use* of this salt: in regions remote from salt deposits, ashes of plants rich in Na have been used by peoples as ignorant as the Negroes of Soudan; the taste is an effective indication of its presence and incentive to its use. It contrasts sharply with the taste of KCl. A table of the salt content of food is given by Leva, Arch. f. Verdauungskr., *16:* 267.

Absorption.—Sodium chloride is readily absorbed, chiefly from the duodenum; but it serves to keep the intestinal contents isotonic, so that its absorption extends to the rectum.

Studies with *radioactive isotopes* show that Na, Cl, Br and I can be detected in the hand within three to six minutes after ingestion; their absorption is complete in three hours. The absorption of K is about half as fast; it appears in the hand in six to fifteen minutes, and its absorption is completed in five hours (J. G. Hamilton, 1938). The isotopic sodium is rapidly distributed into all the regions where it is normally present. Its urinary excretion followed an exponential curve (D. M. Greenberg, Campbell and Murayama, 1940).

The epithelium of the small intestines, like that of the renal tubules, can move chloride from lower to higher concentrations, against osmotic pressure. If an isotonic mixture of NaCl and some relatively indiffusible salt is placed in an intestinal loop of a living dog or cat, it becomes practically chloride free in one and one-half hours. This is not explainable on physical grounds, and is abolished by protoplasmic poisons, such as sodium cyanide, arsenite or fluoride, hydrogen sulfide or mercuric chloride (Ingraham and Visscher, 1936). *Adrenalectomy* in rats decreases the absorption of sodium chloride from the intestines, but not that of dextrose (W. G. Clark, 1939).

The **distribution of salt in the body** is not identical for the Na and Cl ions; but it is convenient to express Cl also as NaCl and this is generally a fair approximation, since Na is the most abundant of the soluble cations. The chloride ion is confined chiefly to the extracellular fluids, as are also the other haloid and related anions (Br, I, NO_3 and SCN).

The *extracellular fluid*, including the blood plasma and lymph, amounting to about 20 or 30 per cent of the body weight, contains practically all the sodium and chloride. A small amount is *intracellular*, for instance in the red blood corpuscles; about a tenth in the skin (Eichelberger *et al.*, 1943), and very little in muscle and liver cells. This does not diffuse readily in either direction (J. P. Peters, 1944). The *distribution of chloride* in different organs and tissues is relatively constant in different individuals of the same species, and remarkably similar in different species (K. A. Winters, 1934). Comprehensive determinations were made by Wahlgren, 1909, and Padtberg, 1920, on dogs. Similar relations probably hold for man and other animsls: the entire body contains about 0.17 per cent, expressed as Cl (0.11 per cent, Rosemann, 1910). Of this about a third is in the skin, the remainder chiefly in the blood, muscles, bones and intestines. Muscle cells contain little or no Cl (Hastings and Eichelberger, 1937). The highest percentage of Cl exists in the skin (0.38 per cent); then the blood (0.31 per cent); kidneys (0.26 per cent); and lungs (0.24 per cent). The brain, bones and intestines contain 0.17 to 0.18 per cent; the liver, 0.13 per cent; the muscles, only 0.07 per cent. According to other determinations, blood serum contains 0.36 to 0.42 per cent (equivalent to 0.60 to 0.64 per cent NaCl); saliva, 0.16 to 0.24 per cent Cl; the human intestinal juice, 0.58 to 0.67 per cent NaCl; sweat, 0.285 per cent (Kovesi); human gastric "appetite" juice, 0.49 to 0.56 per cent Cl (Carlson, 1915). The red corpuscles contain 0.12 to 0.18 per cent of Cl. The chloride content of the entire body is considerably higher in newborn rats than in adults. It decreases markedly in the first two weeks after birth (K. A. Winter, 1934).

The *ionic content of human blood serum*, at its normal reaction of *p*H 7.4, expressed in milliequivalents per liter, is essentially Na (142) + K (5) + Ca (5) + Mg (2) = Cl (105) + HCO_3 (25) + protein (17) + PO_4 (2) + R (5). Hald and Eisenman, 1937, give somewhat lower values for Na, ranging from 129 to 139. *Human erythrocytes* contain much less Na, averaging 16.5 m. equ. l. Their Cl averages 50; the Cl relation to the serum accords with the Gibbs-Donnan equilibrium, so that the corpuscles are permeable to Cl ions. In diseased conditions the Cl' and HCO_3' tend to vary reciprocally (review, V. C. Myers and Muntwyler, 1940).

Artificial Variations of Chloride Content.—Padtberg studied the changes following the *intravenous injection of NaCl.* Here, also, the skin maintains the highest percentage; but because of their greater mass, the muscles and intestines take up the greater absolute amount. Rosemann, 1911, found the entire Cl content increased by 100 per cent when dogs were given *highly salted food.* With the return to normal diet, the Cl content returned to one and one-half times the ordinary level within five days; the further fall to normal occurred much more slowly. *With Cl-poor food*, the total Cl content sinks to 0.137 per cent, the loss being greatest from the skin. The skin therefore acts as a chloride depot, storing and giving off most of the excessive or deficient Cl. Fasting lowers the total blood chloride by 10 per cent, due almost entirely to loss of plasma volume, for the Cl concentration in the plasma and blood cells is almost unchanged (Austin and Jonas, 1918; Bottin, 1934). *By feeding nitrate* with chloride-poor food, the total chloride may be reduced by more than half in a week, the tissues losing chloride generally in direct proportion to the loss of serum chloride (Hiatt, 1939, 1940).

Chloride Content in Disease.—Biernacki, 1894, found the Cl of the blood constant in numerous diseases. Javal and Adler, 1906, determined the percentage of Cl and water in the organs after death from various diseases, with a special reference to edema, but the results were not decisive. Leva, 1915, stated that human organs in renal, cardiac and vascular disease may contain twice, the skin even three times, the normal amount of Cl, without material increase of their fluid. Similar results were obtained on uranium rabbits. *Decreased Cl concentrations of the serum* occur especially with profuse vomiting, diabetic acidosis, acute mercuric chloride poisoning, adrenal cortex deficiency, lobar pneumonia and other fevers (review, V. C. Myers and Muntwyler, 1940). F. C. McLean 1915, found the chloride of the plasma increased, clinically, in cardiac and renal disturbances, and in pneumonia; diminished in diabetes and with diuretics. The chloride and urea content of the plasma do not go parallel. In uremia, the diminution of blood chloride is concomitant with increased hydrogen ion concentration (McLean, 1916).

The **distribution of Na and of K** differs for various tissues, and also for the same tissue in different animals; especially in the *red blood corpuscles* (see potassium). The concentration of Na ranges from 0.16 to 0.22 per cent in most animals, 0.036 to 0.041 in man, and practically none in the horse, pig and rabbit (Streef, 1938), the quantity being practically reciprocal with that of potassium. Intravenous injection of radioactive sodium into dogs showed that their corpuscles are permeable to Na ions (W. E. Cohn and Cohn, 1939). Muscle cells contain but little Na or K (Hastings and Eichelberger, 1937).

The **excretion of chloride** occurs mainly by the urine, only a small part being lost by the feces and perspiration. The normal kidneys can excrete 15 to 20 Gm. of NaCl per day. The excretion varies quantitatively with the salt income, but generally lags somewhat behind in time. The administration of salt therefore produces a temporary accumulation in the tissues. With a steady income of salt and water, equilibrium is reached, in normal man, in three or four days (Borelli and Girardi, 1915). If the supply of salt is stopped, as in fasting, the urinary and fecal Cl excretion falls to a low level within three days, the tissues retaining their normal salt content with great avidity. A small excretion (0.6 to 0.9 Gm. daily in man) continues, however, so that the tissues finally lose salt.

Diurnal Variations.—In man, the urinary chloride excretion is always greater in the forenoon than in the night, independently of meals. The midday meal has an influence, the excretion being decreased half an hour after eating, owing to the gastric excretion of HCl. This lasts an hour, and is followed by marked increase (Herrmannsdorfer, 1912).

Feces.—The fecal chloride excretion is normally insignificant, but in nephritis it may reach 3 to 5 Gm. of NaCl per day (Javal, 1903; Halpern, 1905).

Time of Excretion.—Giving 10 Gm. by mouth, the additional chloride should be excreted within twenty-four to forty-eight hours, either by diuresis or by increased salt concentration. A longer delay indicates impaired permeability of the kidney.

The observations of Vallery-Radot, 1918, may be taken as an example of the normal course: an individual on a so-called "salt-free" diet, which actually corresponded to 1.5 Gm. of NaCl per day, was excreting 2 Gm. per day. When changed to a normal diet, containing 11.5 Gm. of NaCl per day, and kept on this, he excreted, on the first day, 3 Gm.; second day, 5 Gm.; third day, 11 Gm.; fourth day to the ninth day, 11.5 Gm. daily. On changing to a salt-free diet, the reduction of the excretion followed a similar (inverted) course.

The *diuretic action* of sodium chloride is greatest if this is administered as 0.5 per cent solution; the least change of NaCl balance occurs with 0.2 per cent (J. M. Coon *et al.*, 1941; dogs).

Influence of Other Salts and Diuretics.—The excretion of Cl can be hastened by the administration of related salts (bromides, iodides, nitrates, thiocyanates). Conversely, the administration of Cl hastens the elimination of these salts, and may be useful against iodism and bromism. Diuretics have little effect; the drinking of large quantities of water reduces the percentage of Cl in the urine; the absolute quantity may be unchanged or moderately increased (Rulon and Hawk, 1911).

With dogs, theobromine and caffeine diminish the Cl, both absolute and percentage, independently of any diuretic effect (Saccone, 1911). In rabbits, these and other diuretics tend to increase the Cl excretion proportional to the diuresis (Bonnamour and Imbert, 1912). In patients with *diabetes insipidus* the daily urinary chloride is only normal, notwithstanding the enormous urine volume. The serum chloride level is also normal. Pituitrin therapy does not alter the chloride economy materially (H. Blotner, 1941).

Mechanism of Chloride Regulation.—The blood maintains its chloride concentration remarkably constant, and even the tissues undergo only temporary changes. The regulation is accomplished through the adjustment of the urinary excretion, or rather, by the degree of chloride reabsorption in the tubules. In this, the kidneys do not differentiate sharply between chloride and related ions (bromide, iodide, nitrate and thiocyanate), so that the injection of any of these increases the chloride concentration in the urine, while less related ions (sulfate, acetate, and so forth) do not have this effect (Sollmann, 1902). The mechanism by which this is controlled is not understood, but the hormone of the suprarenal cortex plays an essential part in the sodium retention. *Oral or intravenous administration* of sodium chloride releases a large amount of *pituitrin* (G. H. Chambers, 1945).

Chloride Retention.—The chloride excretion is greatly diminished in some cases of nephritis; in fevers, particularly in pneumonia (where much salt is retained in the effusion); and during the rapid development of new tissue (cancer). Salt is necessarily retained during the formation of edemas, to maintain osmotic equilibrium. Conversely, the retention of salt retains water to isotonicity, increasing the volume of extracellular fluid, and therefore disposing to effusions.

Retention in fever was first described by Redtenbacher, 1850, and has been extensively investigated, especially by Roehmann, 1889, but the subject is still controversial even as to facts. Austin and Sanderman, 1929, *f. i.*, raised doubt whether there is retention in *pneumonia*, in which it was supposed to be prominent. They attributed the low chloride excretion to the low salt content of the ordinary pneumonia diet, for with this low Cl income, the Cl balance is negative before and for several days after the crisis; and when 8 to 20 Gm. of salt were added, this was excreted quite well.

Retention in Cancer.—The diminished excretion is probably explainable by the deficient Cl income, and its need for the formation of new tissues and transudations (Gaertig, 1890; Laudenheimer, 1892).

Retention in nephritis is most likely to occur in acute glomerular nephritis (Borchardt, 1912). However, in chronic parenchymatous nephritis the ability to excrete chloride is generally impaired before the nitrogen excretion (O'Hare, 1916), and the impairment keeps step with the severity of the lesion. Chronic interstitial nephritis is not generally characterized by defective chloride excretion. The Cl excretion is increased in the early diuretic stage of uranium and cantharides nephritis; it is usually diminished with large doses of uranium or chromate. The Cl excretion bears no simple relation to the anatomic changes (Austin and Eisenbrey, 1911).

Salt Test for Nephritis.—Schlayer, 1911, kept a patient on a constant diet for several days, then added 10 Gm. of NaCl in one dose. This excess is normally excreted within twenty-four hours or at most forty-eight hours. A delay beyond this indicates diminished permeability of the kidneys to chlorides. Frothingham, 1915, classified the excess excretion within forty-eight hours of 8.5 Gm. as no retention; 4.5 Gm. as slight retention; less than 4.5 Gm. as considerable retention.

In *cardiac edema*, administration of NaCl to 75 Gm. per day causes some diuresis, with simultaneous increase of edema (Goldring, 1929).

Diabetes.—The literature contains contradictory statements as to the chloride metabolism in human diabetes (Lebensohn, 1915). The "chloride threshold" of the blood is unchanged or lowered (McLean, 1915). Sodium chloride administration to *diabetic rats* tends to restore the glucose tolerance to normal (Orten and Devlin, 1940).

Effects of Excessive Consumption of Salt.—Excess of the Na or Cl ions is ordinarily eliminated promptly; but even when they are retained, these ions *produce only slight effects*, for the amounts normally present are so large that the artificial introduction of ordinary amounts will not increase their ratio to a considerable extent. In this sense Na and Cl are the most indifferent of the ions, and their salts are used when the effects of other ions are to be tested. However, they are essential to life, and the absence of effects is due only to the fact that the variations which are introduced are relatively small.

Salt-poor diet has been used against *hypertension*, but the evidence for its usefulness is not satisfactory. Drastic reduction of sodium income by dialyzed milk appears effective in some patients, not in others. In rats with experimental renal hypertension, such dialyzed milk reduces the blood pressure and apparently prolongs life (A. Grollman *et al.*, 1945). Cl-poor diet has also been employed to enhance the retention of the bromide ion in *epilepsy* (Toulouse and Richet, 1900). Indeed the efficiency of the bromide treatment has been referred to dechloruration, but this is erroneous (see Bromides; Januschke, 1913). Restriction of chloride income greatly diminishes the polyuria of diabetes insipidus (Swann, 1939). Tables of the content of the various salts in foods are given by Albu and Neuberg, "Mineralstoffwechsel."

Limited Salt Income.—The maintenance of a certain sodium and chloride content is indispensable to the body. Animal food contains a sufficiency of this salt; herbivorous and omnivorous diets are insufficient in this respect. Under ordinary conditions, the excretion of salt keeps so nearly parallel with the salt income (Falk, 1848) that a moderate excess of salt income is practically without effect, except on the urine. A *greatly restricted salt income* (as by an excessive milk diet) *can be borne for a considerable time*, being met by a corresponding decrease of chloride excretion, so that the percentage of the salt in the blood is scarcely altered, and no general symptoms result. Dogs on a Cl-poor diet retain Cl or I more efficiently than on ordinary food (Sarvonat and Cremien, 1911). The diminished income of salt in fever seems to have no deleterious effect. Even when the excretion is further increased by liberal water diuresis, the patients show no particular craving for salt. Complete abstention from food does not produce any effects referable to the absence of salt. After a ten day fast, the total quantity of Cl in the body is reduced by only 2 per cent; and the percentage of Cl is even above the normal, because the tissues disappear more rapidly in starvation than does the Cl (Rosemann, 1912). D'Errico, 1910, found no change in the freezing point or conductivity of the blood in inanition. The inorganic metabolism in starvation was also studied by Cathcart and Fawsitt, 1907. Even *when the starvation is reinforced by active loss of chloride*, there may be no symptoms referable to salt deprivation. Hiatt, 1939, 1940, reduced the total Cl of dogs to less than half, in a week, by feeding nitrate with a chloride-poor diet. The animals were apparently normal in their actions, although there must have been considerable dehydration. Ambard, Stahl and Kuhlmann, 1934, produced severe chloride deficiency in dogs, first reducing the plasma chloride to 0.39 per cent by salt-poor food; then to 0.25 to 0.225 per cent by administering histamine to provoke gastric secretion, and evacuating this with apomorphine two or three times daily, for two weeks (Rosemann, 1912, found that the ordinary secretion of gastric hydrochloric acid stops when the chloride stock of the body has fallen by 20 per cent). This reduced level was maintained for as long as eight months. It resulted in dehydration, doubling of the alkali reserve, and diminished excretion of urea, so that the plasma concentration rose to three times the normal. This probably supplied some of the osmotic functions of the missing salt. The appetite and general conditions of the animals did not appear materially disturbed. *Chloride deficiency with normal sodium income* (by substituting $NaHCO_3$ for the NACl of a synthetic diet of rats) results in decreased appetite, increased thirst, increased heat production and diminished growth (Voris and Thacker, 1942). Hypochloremia is reported to render rabbits and cats more susceptible to convulsions (E. Spiegel and Wycis, 1939).

Excessive salt depletion results promptly in severe and fatal symptoms, owing largely to dehydration. This may occur by excessive sweating in "heat cramps"; by the loss of gastric juice in the persistent vomiting of pyloric and high intestinal obstruction; by the profuse diarrhea of cholera; and by deficiency of the suprarenal cortical hormone, and exceptionally by mere restriction of salt income. In hot climates, the capacity for work is impaired if the daily salt income is less than 15 Gm.; higher income has no advantage (H. L. Taylor, Henschel *et al.*, 1943).

Low Salt Income.—J. Forster, 1873, described severe and fatal symptoms in dogs fed on food deprived entirely of salts. But the earlier observations probably involved severe vitamin deficiencies. There have been a few similar reports recently, relating specifically to *sodium deficiency*. Himwich, Fazekas and Spiers, 1936, subjecting dogs to four to seven days of sodium deprivation, observed phenomena resembling those of adrenal deficiency, with increased total concentration of the blood and of blood urea, creatinuria, and decrease of serum chloride. Orent-Keiles *et al.*, 1937, 1940, subjected young rats for nineteen weeks to a diet containing about 0.002 per cent of Na, but adequate in other respects, and observed a fatal symptom complex, including retarded growth, ocular lesions, and disturbances of the estrus rhythms and of reproduction. There was marked retention of K, but no effect on the metabolism of Ca, Mg, P and Cl.

Prolonged emesis, as in pyloric and high intestinal obstruction, deprives the body of salt directly and by preventing absorption of food. The direct loss may be large, as the gastric juice contains about 0.5 per cent of chloride, about one and a half times the plasma concentration. The normal daily output of gastric juice, estimated as 5 liters in man, would therefore contain 25 Gm. of chloride, about three times the normal daily income. In dogs, the gastric juice amounts to 1000 to 2600 cc. per day (Dragstedt and Ellis, 1929), corresponding to 5 to 13 Gm. of Cl. However, the output would be automatically decreased by chloride deficiency. The loss of gastric juice lowers the chloride of the plasma and raises the bicarbonate, producing alkalosis (W. G. MacCallum *et al.*, 1920; Hastings *et al.*, 1921; Haden and Orr, 1923). The water content of the body and especially of the blood is diminished (dehydration) by osmotic adjustment to the lower salt content; the decreased volume and the increased viscosity of the blood diminish blood flow and oxygen supply (W. M. Marriott, 1923; Haden and Orr, 1927), resulting in shock, with death after four to eight days of complete obstruction. Intravenous injection of large quantities of sodium chloride solution may preserve life for several weeks (Hartwell and Hoguet, 1912; McIver and Gamble, 1928, references). In pyloric obstruction the alkalosis may reach the degree of severe tetany. Loss of pancreatic juice and bile, on the contrary, results in loss of alkali, and therefore in diminished plasma bicarbonate (Gamble and McIver, 1925). **Drainage of the gastric juice by a fistula** may also produce these effects (Rosemann, 1912).

Normal Cl Secretion by the Gastric Juice.—Human "appetite" juice contains 0.49 to 0.56 per cent Cl (Carlson, 1915), partly as free HCl, partly balanced by fixed bases, chiefly Na. *Salt depletion, as by drainage of the gastric juice*, markedly decreases the chloride of the gastric juice, and may suppress it entirely when the chloride stock of the body has been lowered by 20 per cent. This also produces complete anorexia (Rosemann, 1912). However, gastric juice of high acidity (about $\frac{1}{3}$ per cent HCl) may be secreted when continued total drainage of the gastric juice has lowered the blood chloride to a third (Dragstedt and Ellis, 1929).

Excessive Perspiration, Heat Cramps.—The twitchings and convulsions that occur on exposure to excessive heat, especially in confined spaces, appear to be due to the loss of salt and water by the profuse perspiration. It may be treated by intravenous injection of normal saline, and prevented by salting the drinking water, so as to maintain the urinary chloride excretion well above 3 Gm. per day (K. N. Moss, 1924; Talbott and Michelsen, 1933), adding about 2 Gm. (half a teaspoonful) of sodium chloride per quart. This is not necessary unless the daily water intake exceeds 4 liters. The *phenomena of excessive NaCl depletion*, as induced in man by a salt-poor diet, together with forced sweating and unlimited water intake, resemble those of heat stroke and Addison's disease: impairment of the sense of taste; cramps, weakness, cardiorespiratory distress on exertion; initial loss of weight; eventually increased viscosity of the blood by dehydration (McCance, 1936).

Chloride Loss by Sweat.—Moss, 1924, observed a maximal sweat loss of 5.8 pounds an hour, containing 2 to 3 Gm. of NaCl. W. M. Simpson, Kislig and Sittler, 1933, found that in a six hour hyperthermia treatment a patient may put out 3 to 5 liters of sweat, containing up to 20 or 25 Gm. of NaCl. The *chloride content of the sweat* varies with conditions and with individuals. It increases with the rate of sweating, but diminishes with acclimatization. Heat cramps are accordingly most common in the first hot spell and in men returning to work after a lay-off (D. B. Gill *et al.*, 1938). Men fully acclimatized to hard work in humid heat, producing 5 to 10 liters of sweat per day, respond to restricted salt income by reducing the salt concentration of the sweat, and so manage to preserve a salt balance with low salt income (J. W. Conn *et al.*, 1946).

Prophylaxis and Treatment of Heat Cramps.—K. N. Moss, 1924, showed that the cramps, fatigue and depression of high-temperature workers are relieved by drinking saline solution, while drinking of water may further lower the Cl concentration of the blood. Chaussin, 1933, observed that food could be salted to the extent of 10 Gm per day under ordinary conditions, but to 25 Gm. if severe labor was performed at high temperature. He also notes that the natives in hot climates use more salt than where the climate is cooler. Danielson, 1936, found that drinking of 0.6 per cent NaCl during therapeutic hyperthermia not only prevented the fall of serum Cl concentration, but actually produced a rise. It did not, however, prevent the fall of base, probably because of relatively greater loss of Cl and organic salts in the sweat. It did not materially alter the other electrolytes of the serum.

Sodium Depletion in Addison's Disease.—In experimental and clinical adrenal cortex deficiency the concentration of sodium in the plasma is markedly decreased, especially in the acute exacerbations, and this seems largely responsible for the symptoms and course; for withholding salt from the diet precipitates the attacks, and administration of salt (10 to 20 Gm. per day) improves them, as the plasma sodium is restored. The capacity of the body to retain sodium is impaired, presumably by a renal action. This appears to be specific, for there is no increase in the excretion of potassium, ammonium or acid; indeed, administration of potassium makes the symptoms worse, or precipitates an attack (R. F. Loeb and associates, 1933; H. H. Anderson and Reed, 1934). The Cl′ concentration is also decreased, more so in the corpuscles than in the plasma (Karaty *et al.*, 1939). The intestinal absorption of NaCl is decreased by adrenalectomy, that of dextrose is unimpaired (W. G. Clark, 1939).

Miscellaneous Systemic Actions of Sodium Chloride.—The ingestion of salt, without sufficient water to render it isotonic, tends to *increase the salt concentration of the body.* This affects mainly the tissues, the molecular concentration of the blood remaining practically unaltered. The increased salt concentration is counteracted by the stimulation of two mechanisms: a desire for water (*thirst*), and the elimination of highly *hypertonic urine.* If water is given freely, the salt is *diuretic.* If the water income is restricted, the poor urine flow decreases the N excretion temporarily (Degrez and Guende, 1912). *Respiratory metabolism* is increased by saline injections, especially if hypertonic (Raeder, 1915).

Saline Diuresis.—When extra salt is administered by mouth, it may increase the urine flow or the percentage of urinary chloride, or both. This probably depends on the state of the tissues more than on the kidneys. Sodium chloride diuresis does not increase the oxygen consumption of excised kidneys perfused by Starling's method (H. Gremels, 1929).

Dermatoses.—Chronic urticaria, eczema, and the like, are often aggravated by the administration of sodium chloride (to 20 Gm. per day) or other sodium salts, but not by other chlorides (Keining and Hopf, 1935).

Salt Glycosuria.—Bock and Hoffmann, 1871, observed that intravenous injection of NaCl solution into rabbits produces glycosuria. This was confirmed by Kuelz, 1872 (who also found that it does not seem to occur in dogs). The glycosuria is greater with rapid injection or higher concentrations, and may be abolished by the addition of Ca ions. The *mechanism* of the salt glycosuria is in dispute. Willenko, 1911, stated that it does not occur after section of the splanchnics and refers it to stimulation of the central nervous system. E. Hirsch, 1915, reported hyperglycemia from intravenous injection of 10 per cent NaCl. This action is central, presumably on the glycosuric center. Solutions of 2.5 per cent or more dilute, even in larger quantities, do not increase the blood sugar; nor does sodium carbonate or acetate, nor calcium chloride. Sodium sulfate also does not produce hyperglycemia (Kleimer and Meltzer, 1916). Magnesium sulfate, however, does so. Diabetic puncture and puncture of the funiculus teres in rabbits increases the urine and the percentage of chloride ("*salt puncture*"). The urinary effect is independent of the glycemia, but depends on nervous impulses carried by the splanchnics (Jungmann, 1914).

Saline Diuresis on Milk Flow.—In lactating goats, with limited water income, diuretic doses of salt or urea decrease the yield of milk and increase its fat content, presumably by diminishing the available amount of water. The nitrogen of the milk is not increased (Steenbock, 1915).

Salt Fever.—Finkelstein, 1908, and Schaps observed that the administration of salt to infants by mouth or hypodermically may produce fever. A slight rise of temperature is also observed in adults, if at least 1 liter of 0.9 per cent NaCl is injected hypodermically (Bingl, 1910), but is prevented if Ca is added, as in Ringer's solution (Bock, 1912; Burnett and Martin, 1916). The rise is accompanied by increased N metabolism and heat production (Freund and Grafe, 1911). Hypertonic salt solution (3 per cent NaCl) is much more effective (Rolly and Christjansen, 1914). A similar rise is produced by the injection of isotonic dextrose or lactose, and by indifferent particles (paraffin, colloid metals, and so on; Bock), but may have a different origin. The salt fever occurs with absolutely sterile solutions and with oral administration (Bingl; Freund, 1913). It is therefore not due to pyrogens. An apparently different type of salt fever is produced by the injection of *hypertonic solutions* of salt, glucose, and the like. This can be prevented by the administration of water and is attributed by Balcar *et al.*, 1919, to the dryness of the tissues, limiting perspiration and therefore reducing heat dissipation.

The **coronary vessels** are dilated by moderate increase of NaCl in the Locke perfusing solution (L. N. Katz and Lindner, 1939).

The **central nervous system** of frogs is inhibited if hypertonic NaCl solution is injected into the dorsal lymph sac. This "*Richet inhibition*" is abolished by section of the medulla, not by removal of the cerebrum. It is attributed to local action on the sensory nerves (Ozorio de Almeida *et al.*, 1938).

Local Actions of Salts.—Salts in isotonic or hypotonic solutions have little local action; in substance or in hypertonic solutions they act as rather mild irritants. Sodium chloride and other neutral salts, in the form of *sea baths*, produce mild but extensive stimulation of the skin, and thereby reflex tonic effects. The mechanical irritation of the dried salt crystals contributes to the result. They do not injure the epidermis. The *parasiticidal action* of fairly concentrated salt solutions is used by irrigation of the rectum against oxyuris, and of the vagina against trichomonas. They are quite effective (L. Rosenthal *et al.*, 1935).

Wright's Surgical Solutions.—A. Wright, 1917, recommended the saturation of wounds with a hypertonic saline solution, aiming to keep the surface irrigated with lymph. He employed 4 per cent of sodium chloride and 1 per cent of sodium citrate in distilled water, sterilized by boiling for half an hour. Fackenheim, 1915, had used the same principle by dressing the wound daily with granulated sugar.

Alimentary Canal.—Salt stimulates the mucosa of the alimentary canal, especially in the stomach before the salt is diluted. Hypertonic solutions produce emesis; if they reach the duodenum, they tend to evoke a "peristaltic rush" that sweeps them onward; if they remain for any time they depress peristalsis (Baur, 1926; v. Oettingen and Sollmann, 1926).

Since the salt is quickly removed by absorption, it does not cause a permanent change. The stimulation by salts may therefore be continued for a considerable time in the treatment of "atomic" *dyspepsia.* Salt may aid the digestion of otherwise difficultly digestible articles. It would be undesirable in hyperchlorhydria and especially in gastric ulcer, and the salt income should be limited in these conditions. Rosenblat, 1907, observed markedly increased secretion in the Pavlov miniature stomach, depending on the concentration; 1 per cent was indifferent; greater dilutions were slightly stimulant. Increase of gastric secretion occurs also if chloride (Na, Ca or Mg) is injected intravenously; this enjoins caution in the surgical use of saline injections, in conditions in which gastric rest is desirable (Frouin, 1922).

Laxative Action.—A teaspoonful of salt in 1 pint of water, taken before breakfast, is often laxative.

Pepsin.—W. W. Hamburger, 1915, found that neutral solutions of NaCl, even in the concentration of serum, rapidly destroy pepsin. The inhibition is complete with 2.5 per cent NaCl; scarcely perceptible with 0.25 per cent. Other inorganic salts act similarly, probably by liberation of OH ions (Hamburger and Halpern, 1915). The destruction does not occur in the presence of free acid; but once destroyed, the ferment can not be reactivated by acidulation.

The *taste of salt* is recognized by humans (and by rats) with concentrations averaging about 0.075 per cent. The difference from water is perceptible even with 0.013 per cent (C. P. Richter and MacLean, 1939).

Toxic Action.—If salt is given in large amounts and concentrated form, the irritation may lead to severe and fatal *gastro-enteritis. Poisoning by enema* was reported by Brooks, 1910. A pint of saturated solution had been injected and repeated twice at hour intervals. The symptoms were restlessness, thirst, rapid pulse, coma, fever (109° F.), frequent micturition, dyspnea. Death occurred eight hours after the first injection, preceded by convulsions and bloody discharge from the rectum.

PREPARATIONS.—***Sodium Chloride,** U.S.P. (Common Salt); NaCl; is freely sol. in water (1:2.8); nearly insol. in alc.; sol. in glyc. (1:10). Chlorides are *incompatible* with salts of silver and lead. ***Isotonic Sodium Chloride Solution,** U.S.P. (Physiological or Normal Saline Solution); contains 0.9 per cent of Sodium Chloride.

SALINE INFUSIONS AND TRANSFUSION

The injection of saline solutions, of blood serum or plasma or noncoagulable blood, and direct transfusion of blood produce similar results and are merely modifications of the same general procedure. The effects of hypodermic or intravenous injections of saline solutions on the quantity of blood, lymph and urine, and the fate of these solutions were discussed under "Salt Action." The temporary increase of plasma volume produces a moderate rise of blood pressure; this, perhaps with some direct salt action, results in increased excitability of the respiratory vagus (H. C. Jackson and Ewing, 1914) and vasomotor centers. With *normal animals*, the rise of capillary pressure is large and lasting; the rise of arterial pressure and the medullary stimulations pass off quickly, without noticeable fatigue. In *animals whose blood pressure is low*, particularly if this is due to hemorrhage, saline infusions bring the pressure toward normal, and maintain it better. Excessive injections of saline solutions may cause death from *pulmonary edema*, or from overdistention of the heart. Therapeutic injections may produce glycosuria, slight fever, and rarely albuminuria.

Factors Involved.—The effects produced by injections of sodium salts depend on the interaction of a number of factors, especially: hydremic plethora; osmotic changes; changes in the alkali reserve, by selective retention of the cation; altered ion ratio in the blood. The nature of the anion probably acts mainly by altering the permeability of the cells to sodium (Gruenwald, 1918).

Quantitative Relations.—The *volume effects* are produced by all salts the ions of which are not specifically toxic, such as most sodium salts; and by glucose, sucrose and urea. These must be used in rather large amounts, from 25 to 50 cc. of the eighth-molecular solution per kilogram of body weight. Isotonic solution of three chlorides or Locke's fluid, are somewhat better than isotonic (0.9 per cent) sodium chloride solution, but the latter suffices for all practical purposes. However, even small injections of isotonic NaCl may produce changes in blood pressure, while Ringer's solution or glucose has much less effect (Selig, 1911); so that the action is probably not wholly osmotic. Frogs' vessels are dilated by perfusion with NaCl (Hooker, 1911). Rapid massive injection of fluid under pressure of 300 mm. Hg into the cranial end of the *carotid artery* of dogs regularly results in pulmonary edema (A. A. Luisada and Sarnoff, 1944).

Vasomotor Center.—In normal animals, injections of 10 to 40 cc. per kilogram produce only slight stimulation or no change. Occasionally, when there is maintained rise of blood pressure, the vasoconstriction is marked (Pilcher and Sollmann, 1914).

"*Velocity Shock.*"—Rapid injection of practically any solution, including isotonic NaCl, may produce prompt and usually brief fall of blood pressure, together with changes in the blood, especially rapid sedimentation of the corpuscles and diminished coagulation. The mechanism is not clear, but it is probably due to alterations of the colloid state, analogous to flocculation shock. It depends on the speed of the injection, not on its bulk or temperature; but it is likely to be greater with hypertonic solutions than with isotonic or hypotonic (Hirschfeld *et al.*, 1931).

Restoration of Normal Blood Volume.—The circulation rapidly disposes of injected solutions by exchange with the tissues. As explained more fully under *General Salt Action*, the total molecular concentration, the ratio of ions, and the total volume of blood are restored to nearly normal within half an hour.

Conditions Delaying the Restoration of the Blood Volume.—In normal dogs and rabbits, the blood volume returns to normal within half an hour after the intravenous injection of warm Ringer's fluid equivalent to the total blood volume. This is delayed by morphine, and by nephritis (uranium, chromate or tartrate), but not by ligation of the kidney vessels. The restoration is not affected by the addition of 0.4 per cent sodium carbonate, either in normal or in nephritic animals (Bogert *et al.*, 1916). The restoration of the blood volume is also delayed by choline and by pilocarpine. Atropine has no effect. In peptone shock, the saline leaves the blood volume rapidly, but not completely (Underhill and Epstein, 1923). With sotonic solutions of sodium bromide, nitrate, acetate and thiocyanate the restoration occurs at about the same rate as with chloride; with sodium sulfate, the return of the old volume is less complete (A. H. Smith and Mendel, 1920).

Special Effects of Anisotonic Solutions.—*Hypotonic* solutions are somewhat more injurious and may lake the blood. *Hypertonic solutions*, by abstracting water from the tissues, produce much more violent stimulation of the central nervous system, and convulsions, always followed by depression. Small intravenous injections raise the blood pressure partly by direct stimulation of the heart (Retzlaff, 1915). With larger injections, the blood pressure shows a progressive fall, with temporary rise during the spasms. The respiration is at first quickened, but becomes slow and shallow as the blood pressure fails. The heart is quickened, feeble, and arrhythmic. In the later stages it may be slowed by stimulation of the vagus center. The temperature rises. The diuretic effect and the local irritation are also much greater. *Compensatory oliguria* follows by mobilization of posterior pituitary antidiuretic hormone (G. H. Chambers, 1945; diminution of store in rats).

Dehydration by Hypertonic Injections of Glucose or Saccharose.—In dogs, the diuresis produced by prolonged intravenous injections may diminish the body weight by 10 to 11 per cent, the plasma volume by 20 per cent, in two hours. The chloride concentration of the blood rises proportionately to the concentration of the plasma; the urea concentration of the blood also increases, although the excretion of urea is increased by the diuresis (Keith, 1924). For the use of hypertonic solutions for lowering the *cerebrospinal pressure*, see under "Salt Actions."

Toxic Doses of Different Cations.—Joseph and Meltzer, 1907, found $MgCl_2$ fatal for mammals with 0.223 Gm. per kilogram (1 cc. m/5 per kilogram per minute); Ca and K required about double, Na twenty times as much.

Balanced Solutions.—Isotonic sodium chloride solution is injurious to isolated tissues; their function requires "balanced" solutions, of the type of Ringer's or Locke's solution. This is negligible in the intact animals, because the regulating mechanisms of the body rapidly restore the normal concentration and ion ratio of the blood. Solutions of sodium chloride of 0.6 to 1 per cent may therefore be used for hypodermic, and even for intravenous, injections, although balanced solutions are somewhat more desirable, such as the "Isotonic Solution of three Chlorides," possibly with the addition of 0.1 per cent of dextrose or buffered with 0.31 per cent of sodium lactate (A. F. Hartman, 1934), or various hydrophilic colloids.

Buffering with sodium bicarbonate, 0.05 to 5 per cent, has the disadvantage of precipitating calcium carbonate, if the finished solution is heated for sterilization. This may be remedied by passing CO_2 through the sterilized solution until the *p*H of 7.35 is reached (neutrality to phenol-red); or it may be prevented by the sealing of the flask during sterilization; or the solution may be heated without the bicarbonate, which is added when the solution has cooled. Phosphate precipitates calcium on aeration, and citrate inactivates calcium temporarily. A variety of minor modifications and special formulas has been proposed, but it is not clear that these deserve preference.

PREPARATIONS OF SALINE SOLUTIONS FOR TRANSFUSION.—The U.S.P. provides three media: (1) nonsterile; (2) sterile, not for parenteral injection; (3) in water for injection for parenteral use. This last should be dispensed unless the others are specified.

Isotonic Sodium Chloride Solution, U.S.P.; 0.9 per cent. *Ringer's Solution,* U.S.P. (Isotonic Solution of Three Chlorides); contains, per cent: NaCl, 0.86; KCl, 0.03; $CaCl_2 . 2H_2O$, 0.03. *Lactated Ringer's Solution,* U.S.P.; per cent: $NaC_3H_5O_3$, 0.31; NaCl, 0.6; KCl, 0.03; $CaCl_2 . 2H_2O$, 0.02.

Colloids leave the vessels slowly, and by their osmotic or orcotic pressure they tend to retain the injected fluid, and so to diminish diuresis, lymph filtration and edemas. They therefore maintain the blood volume materially longer than do noncolloid saline injections, and so are more effective in maintaining the blood pressure in hemorrhage and shock. Gelatin, isinglass, pectin, acacia and dextran have been employed for this purpose. Their superiority, however, over ordinary saline solution is not striking, and there are some disadvantages. They tend to agglutinate the red corpuscles; and if large quantities are retained they may interfere with regeneration of the plasma proteins (W. Locke, 1944). Transfusion of blood is much more effective in serious hemorrhage; and human plasma or human albumin in other shock.

Gelatin was proposed by Hogan, 1913, but ordinary gelatin is a variable product, somewhat antigenic. It is now used as 6 per cent solution after partial degradation by *autoclaving,* which lowers its gelation temperature, and renders it nonantigenic and not liable to febrile reactions (A. Cournand *et al.,* 1944). *Isinglass* is similar. Intravenous injection of gelatin solutions produces *pseudo-agglutination* of erythrocytes, but the cells separate when they come to the small vessels and do not interfere with blood flow (R. G. Abell and Parkins, 1944). There is no immediate toxic or anaphylactoid reaction; but when the injections are repeated several times, some dogs develop serious and sometimes fatal disturbances, chiefly by *derangement of blood production* (F. S. Robscheit-Robbins *et al.,* 1944). About two-thirds of the injected gelatin *disappears from the circulation* within six hours, five-sixths in twenty-four hours. From 20 to 29 per cent of this gelatin is found in the urine (J. M. Little and Dameron, 1944). In a group of human subjects in whom a liter of 5 per cent gelatin was injected, the plasma content averaged 0.78 per cent at the end of the injection, 0.3 per cent in twenty-four hours, and considerable levels in seventy-two hours. The urinary excretion averaged 14.7 Gm. for heavy gelatin of high molecular weight, and 22.7 Gm. for light. After seventy-two hours, 80 per cent of all gelatins had been excreted (W. S. Hoffman and Kozoll, 1946).

The *diuretic effect* is considerably greater than corresponds to the injected fluid (C. E. Bridger *et al.,* 1944).

Acacia ("Gum Arabic") solution was introduced by Bayliss, 1916, 1920, adding 6 to 7 per cent to 0.9 per cent sodium chloride solution, and buffering to *p*H of 7.2. The immediate response is better and more lasting than with plain saline; but the improvement in the ultimate mortality of hemorrhage is so small that the benefit is rather doubtful, and there is some risk of serious and occasionally fatal reactions, cyanosis, dyspnea, tachycardia, pulmonary edema, and extensive necroses in the liver (Studdiford, 1937; Ohta, 1939). Some of the accidents may be due to faulty technic, but some at least are probably due to special susceptibility to the acacia itself. This produces alterations in colloidal equilibrium of the blood, which tend to sedimentation and agglutination of the corpuscles and to other anaphylactoid phenomena (Hanzlik and Karsner, 1919; A. Christie *et al.,* 1935). The susceptibility to these varies in different animals, and recognizable reactions are exceptional in man. There appears also to be considerable difference in different specimens of acacia (De Kruif, 1919). Some samples, especially pure sodium arabinate, may adsorb the calcium of the blood. Pure calcium arabinate avoids this particular danger (J. A. Maas, 1938).

The *acacia leaves the blood stream* slowly, beginning soon after injection. The progress is variable: considerable may have disappeared in six hours, most is gone in ninety-six hours, but some persists for two weeks (Emerson and Phatak, 1936). Andersch and Gibson, 1933, found 60 per cent retained in the liver, smaller amounts in the spleen, kidneys and muscle; the liver storage increases with repeated injections. Acacia was present in the liver of a dog twenty-six months after eight times the therapeutic dosage had been injected (R. E. Smalley *et al.,* 1945). The liver and spleen contained the highest concentration in a patient who died fifty days after the intravenous acacia injection (J. B. Johnson, 1945). The *plasma protein* decreases in the attempt to maintain the normal colloidal pressure, or perhaps by interference with liver function (Kendrick *et al.,* 1938; Heckel *et al.,* 1938).

Pectin is a carbohydrate derived commercially from the white peelings of citrous fruits. When autoclaved with saline at suitable *p*H, it gives a homogeneous solution of predictable viscosity and oncotic pressure (about 68 mm. Hg for the 1.5 per cent solution; S. Middleton and Wiggers, 1943). It usually requires 1000 to 1500 cc. of the 1 per cent solution intravenously to keep up the blood pressure in shock. It leaves the blood stream more rapidly than gelatin. It is nonantigenic and does not alter blood coagulability, but it hastens sedimentation and pseudo-agglutination *in vitro,* similarly to gelatin. It is partly retained in the liver, kidneys, bone marrow and spleen, and there produces foreign body reactions and cellular degeneration (W. C. Hueper, 1945), probably more injurious than with gelatin (H. Popper *et al.,* 1945; A. Cournand *et al.,* 1944).

In human subjects in whom 1 to 3 liters of 1.5 per cent pectin in saline solution was injected, the increased blood volume was maintained much longer than the pectin level, probably by mobilization of labile tissue protein. Urinary excretion of pectin started promptly, and decreased after the first day. It accounted for less than half of the injected quantity. The remainder was probably deposited in the organs (D. D. Kozoll *et al.,* 1946).

Dextran, a water-soluble, high molecular polysaccharide formed in solutions of sugar infected with a special bacterium, appears to be suitable for infusion fluids (A. Grönwall and Ingelman, 1945).

Polyvinyl alcohol of low molecular weight ("RH 623") is being tried, as 4 per cent colloidal solution, with good results in experimental shock and hemorrhages. It maintains the blood pressure about as well as does blood transfusion. It is not retained in the organs, and is reported to leave the circulation about as fast as the plasma proteins are regenerated (W. Locke, 1944; N. W. Roome *et al.*, 1944)

Particulate matter, carbon or erythrocytes, are reported to improve the flow of perfusing solutions through the capillaries by creating eddies, and to delay edema by plugging leaks in vessel walls (B. W. Zweifach, 1940).

Hemoglobin-Saline Solutions.—The addition of 5 to 7 per cent of hemoglobin to normal saline or Ringer solution endows it with about 50 per cent of the oxygen capacity of normal blood, and with sufficient oncotic pressure to prevent edema on perfusion of organs (Salaskin and Kriwsky, 1931; W. R. Amberson and Höber, 1932). The solution may be prepared by hemolyzing beef blood with water, centrifuging to remove the stromata, and adding sodium chloride to restore the molecular concentration. Dogs with half of the blood replaced by the 7 per cent hemoglobin solution are practically normal for a time, but die after five or six hours because the hemoglobin filters out of the blood vessels into the urine and feces (Amberson *et al.*, 1934; Lamson *et al.*, 1945). Clinical injection of laked blood may produce severe reactions, probably by the stroma. Aubertin, Wangermez and Sappey, 1936, claimed that a hemoglobin concentration of 14 per cent is toxic.

Administration of dextrose (glucose) may have advantages, especially in impending acidosis, and in cardiac collapse, where it acts as a nutrient (1 Gm. of glucose yields about 4 calories); in nephritis, when diminished salt permeability of the kidneys may render saline injection inadvisable; or in fever, because the oxidation of the sugar leaves the water at the disposal of the tissues. It is generally used in strongly hypertonic solutions, since these are reported less liable than the isotonic (5 per cent) solution to produce unfavorable reactions. The hypertonic solutions are also used to lower cerebrospinal pressure. Dextrose is used to protect the liver in anesthesia and hepatitis (J. P. Simonds, 1918), often with insulin; and against the hyperemesis of pregnancy (200 to 300 cc. of 25 per cent, intravenously; Titus, 1925). The injections should be graduated, so as to avoid persistent and marked hyperglycemia. Dextrose normally appears in human urine when the intravenous injection rate corresponds to 0.8 to 0.9 Gm. per Kg. per hour (Woodyatt *et al.*, 1915); and for a 70 Kg. individual this corresponds to about 63 Gm. per hour, equivalent to 252 calories or fully twice the food requirement for this time. For parenteral nutrition, at least 100 Gm. daily are necessary to prevent ketonuria. It is best given in two doses, to secure continuous utilization.

Dextrose injection in fever has distinct antipyretic action, by diluting the concentrated blood (Barbour, 1919). It is especially important against circulatory collapse, which is due largely to increased blood concentration, and especially in pulmonary edema (Underhill). Its use in *pneumonia*, especially after the third day, generally causes marked clinical improvement, with stronger and slower pulse, and apparently considerable diminution of mortality (by two-thirds, McCracken *et al.*). It probably acts partly as a food. The dosage should be at least 200 Gm. per day. Part of this may be given by mouth, so far as it is easily tolerated, the remainder by intravenous injection.

The dextrose is generally injected *intravenously*, using a very small needle, in the dosage of 50 to 75 Gm., as sterile 25 to 50 per cent solution in freshly distilled water. It is sometimes buffered with phosphate or citrate (0.25 per cent), but the reason is not clear. It is not advisable to add sodium chloride, unless there is definite salt deficiency. The rate of injection should not exceed 6 cc. of the 25 per cent solution per minute, or corresponding quantities of stronger solutions, and it is advisable to interrupt the injection for some time after each 25 Gm. of dextrose have been injected. Dextrose should not be injected *hypodermically* in large quantities, as it becomes irritating if it is not absorbed. *Intraperitoneal* injections of 5 per cent dextrose have been used in infants against dehydration (Sanford and Heitmeyer, 1928). Care must be used to avoid the neighborhood of large nerves in intravenous injections, as nerve injury has been reported (Hassin, 1938).

Dextrose, U.S.P., contains a molecule of water. *Dextrose Injection*, U.S.P., and *Dextrose Injection* in *Isotonic Solution of Sodium Chloride*, U.S.P., concentrations refer to this hydrous dextrose, which is about 10 per cent weaker than the anhydrous.

Sucrose, injected intravenously, maintains the blood volume longer than dextrose, since it is not removed as glycogen. Its hypertonic solution therefore withdraws fluid from the tissues more effectively, and it is excreted in the urine almost quantitatively in man, 70 to 80 per cent in dogs, causing considerable diuresis (N. M. Keith *et al.*, 1934). It has an advantage over sodium chloride when the kidneys do not excrete this salt effectively; but marked renal lesions from intravenous injection of hypertonic sucrose have been reported in rabbits, and also in man (W. A. D. Anderson and Bethea, 1940).

Therapeutic Uses of Saline Injections.—These are employed, intravenously or subcutaneously, to restore diminished blood volume to tide the patient over acute anemia from hemorrhage; in traumatic shock, burns and dehydration, and for parenteral alimentation.

Hypodermoclysis, subcutaneous infusion of large quantities (800 to 1200 cc.) of saline solution, should be done slowly, one-quarter to one-half hour for each half liter.

Normal saline of 0.9 per cent NaCl is usually employed, but 0.5 per cent quenches thirst more effectively.

Use in Hemorrhage.—Saline injections replace the fluid needed for effective work of the heart. The restoration of the blood pressure succeeds temporarily unless the hemorrhage has reduced the pressure to the level of shock (Pilcher and Sollmann, 1914; Downs, 1916). Short of this, the temporary benefits are often striking; but since the solution does not stay long in the vessels, the final fatality is not greatly influenced even when colloids are added. Blood plasma gives much better results, and whole blood has the advantage of replacing the blood cells as well as the fluid. *In severe but nonfatal hemorrhage,* saline infusions are more helpful for maintaining a better blood pressure and volume, and for diminishing thirst; but if the patient can take water by mouth, the result is generally quite as good as for intravenous injection of salines.

Extremes of Hemorrhage.—Dogs can usually withstand a blood loss of 2 per cent of body weight without physiological disturbance; 3 per cent produces cardiovascular reactions; 4 to 5 per cent is usually fatal (Wiggers). The greater share in the acute injury is by the loss of fluid. Richet, 1918, found that the minimum of blood compatible with survival (in dogs) is 4 per cent of the normal number of corpuscles, and 27 per cent of the normal blood mass. This survival, however, applies only to very acute experiments; the animals die in a few hours from anoxemia. Hydremic edema occurs when the plasma protein is diluted to half. Hoitink, 1935, found that the results in acutely fatal hemorrhage in dogs were no better with various balanced solutions (Ringer, Locke, Tyrode, and so forth) than with sodium chloride. In standardized hemorrhage from a large artery which gave 84 per cent mortality of untreated dogs, this was reduced to 58 per cent by saline injection, to 26 per cent by serum or citrated plasma (Ivy, Greengard *et al.*, 1943).

H. C. Wiggers and Ingraham, 1946, found the addition of sodium bicarbonate in continuous infusion fairly effective against acidosis in impending hemorrhagic shock; but lactate was not successful.

Dehydration shock, critical inadequacy of fluid and salt in the circulation, occurs as *traumatic shock* in severe wounds, especially when combined with hemorrhage. Similar dehydration shock develops in burns; and as *toxic shock* in arsenic poisoning and cholera; and in the pulmonary edema of irritant gas and pneumonia. Various mechanisms may be involved to bring about the dehydration, but the results are similar, involving loss of fluid, electrolytes and protein from the blood plasma, chiefly through increased permeability of the capillary endothelium; leading to hemo-concentration and diminished blood volumes, progressive fall of blood pressure below the critical level, soon becoming irremediable and tending to a fatal ending. Injection of saline or colloidal solutions, which are useful in hemorrhage, and in temporary cardiovascular depression as in phenol poisoning, has only limited and temporary success in replacing the fluid of dehydration shock, since the increased capillary permeability causes them to leave the circulation even more rapidly than in health. Colloidal solutions are not materially better. Frequent repetition of the injection is likely to overload the heart. When the dehydration develops more slowly, as in burns, oral administration of sodium chloride or lactate solution appears distinctly useful.

Standardized shock, as by injuring tissue with a tourniquet (F. M. Allen, 1929), has been used to compare the effects of treatment. E. Mylon *et al.*, 1943, found that intravenous injection of saline did not materially lower the mortality rate, although it doubled the time of survival. The results were not materially better when dextrose or plasma albumin or plasma globulin was added to the saline, but citrated plasma saved most of the animals. Sodium succinate also increased the recovery rate significantly. Methylene blue raised the blood pressure, but did not diminish the mortality.

Shock following unilateral occlusion of the hind limbs of dogs tends to be prevented by intravenous injection of saline solution, the Na, Cl, Ca and K ions being especially important, in decreasing order. Dextrose is relatively ineffective (L. N. Katz *et al.*, 1943; L. Friedberg and Katz, 1945; J. Meyer *et al.*, 1945).

Extensive burns produce marked hemoconcentration, so that the hemoglobin percentage may be doubled. This loss extends to electrolytes, especially sodium, as well as fluid; a third of the extracellular electrolytes may be lost in severe anhydremia. This is more serious than the loss of fluid, since fluid cannot be retained unless there is sufficient salt to keep it isotonic. In standardized burns of mice, S. M. Rosenthal, 1943, found oral or parenteral sodium chloride more effective than plasma injection. In human burns, also, serum and plasma do not prevent hemoconcentration (R. Elman and Brown, 1943). C. L. Fox, 1944, recommends sodium lactate by mouth (75 Gm. of the commercial lactate in 4 liters of water consumed freely).

Use in Uremia and Other Intoxications.—Saline solutions were extensively employed as diuretics; but it is now recognized that simple injection does not increase the elimination of the toxic substances sufficiently to be of much value.

A limited disintoxication occurs with strychnine (Hatcher and Smith, 1917; Kleiner and Meltzer, 1917). The recognition of the impermeability of the kidney to chloride in nephritis enjoins special caution. Mosenthal and Schlayer, 1913, claimed that the kidneys of experimental nephritis do not respond well to NaCl. In any case, saline injections must be used cautiously in anuria, and must not be persisted in if a moderate injection does not cause diuresis.

Plasmaphaeresis (vividialysis).—This term was introduced by Abel to designate the replacement of the plasma with saline solution. The blood is withdrawn, the corpuscles are separated and washed by centrifugation, suspended in 0.6 per cent NaCl, and reinjected. In this way much larger amounts of plasma may be withdrawn without damage, especially if the process is several times repeated. The number of red corpuscles rises at first (*i. e.*, the volume of liquid in the vessels is reduced); but ultimately they decline slowly. The plasma proteins may be reduced to a third. The urea and nonprotein nitrogen of the blood are increased. The temperature rises slightly (Abel, Rowntree and Turner, 1914; Turner, Marshall and Lamson, 1915). Amberson, Stanbury and Warweg, 1936, by using 6 per cent gum saline for replacement, reduced the plasma proteins to 0.1 or 0.2 per cent, without serious disturbance of blood pressure or production of edema. The animals recovered consciousness, regenerated the plasma proteins (in 100 hours with cats, 200 hours with dogs) and lived indefinitely. *Hepatic degeneration* (phosphorus or chloroform) delays regeneration of the blood proteins after plasmaphaeresis (Herr *et al.*, 1918).

I. Snapper, 1946, reports two clinical cases in which vividiffusion was practiced for ten to fourteen hours, removing up to 260 Gm. of urea.

● **Transfusion of blood** or plasma gives much better results than any of the substitutes; the plasma proteins remain much better in the blood stream and serve to retain fluid and salt: they tend to prevent edema; they do not overload the reticulo-endothelial cells; and they obviate the need of regenerating the plasma proteins from body stores. In hemorrhage, whole blood replaces the corpuscles, restoring the oxygen conveyance and relieving the load on hematoproteins.

Transfusion of whole blood was tried clinically in early times, with disastrous results, since foreign species were generally used. L. Panum, 1863, showed that the blood of foreign species can not be utilized for transfusion, since the corpuscles are destroyed. L. Landois, 1875, showed that foreign blood is also agglutinated, "clumped." Blood-group identity is necessary for successful injection. Worms-Mueller, 1875, investigated the acute and late effects of the transfusion of the blood of the same species, the fate of the blood, the therapeutic field, and so forth, and practically stated our modern knowledge of the subject, except some technical details (Sollmann, 1915). These observations have been confirmed by modern investigators. For instance, Weinberger, 1908, found in dogs that the water leaves the blood vessels rapidly, causing diuresis, but not nearly so great as with NaCl solution. The red corpuscles can thus be raised temporarily to over 13,000,000; but they gradually decline during the succeeding days. The specific gravity rises still more. The transferred corpuscles persist over thirty days, as judged by the agglutination reaction (Ashby, 1919). Addition of sodium bicarbonate or lactate to reinjected blood in hemorrhagic shock does not improve the chances of recovery (Ingraham and Wiggers, 1945).

Transfusion of citrated blood is discussed under Sodium Citrate. The use of *cadaver blood* is described by Yudin, 1936.

Indications for transfusion were stated by Mueller as excessive hemorrhage; carbon monoxide poisoning; and some chronic anemias, for instance, leukemia. These are practically the modern indications. Transfusion is also used to overcome the hemorrhagic tendencies of purpura and similar diseases.

Citrated human blood plasma is the best substitute for whole blood in wound shock, and has the advantage that it need not be typed and can be preserved for two or three months, or indefinitely if dried. It is better than whole blood even in hemorrhage during the stage of acute hemoconcentration; but in the later stages whole blood has the advantage of hemoglobin. The injected proteins leave the blood stream rapidly, regardless of the blood volume or concentration (W. Metcalf, 1944). Reactions are rare, and may be guarded against by negative skin tests (M. Levine and State, 1942). Pooling of the plasma inactivates the harmful substances (W. Thalheimer, 1942). Its use in *burns* was introduced by D. O. Weiner *et al.*, 1936. The dosage should be proportioned to the extent of the burn. *Bacterial contamination of plasma* may be prevented by adding 0.2 per cent of sodium sulfathiazole. This concentration is harmless when injected (M Novak, 1942).

Concentrated or dried human blood albumin has the advantage of convenience and compactness, economizing space and weight, important especially in the Navy; it does not require refrigeration for preservation, and reactions are practically absent. Plasma albumin differs from globulins in the smaller size and greater electric charge of its molecules, giving higher oncotic pressures. Their lower viscosity, owing to their more symmetrical shape, permits the injection of more concentrated solutions. Each gram of albumin holds 18 cc. of fluid in the blood stream. It is largely retained in the blood even after six hours (A. Cournand *et al.*, 1944). It is useful especially in shock and low plasma protein. The usual dose of a "unit" of 25 Gm. in 100 cc. of buffered saline solution, equivalent to 500 cc. of plasma, may be repeated in fifteen to thirty minutes. In severe dehydration it must be supplemented by fluid (C. A. Janeway, 1944). *Blood serum* is safe when properly prepared, but some serious reactions have occurred with ordinary preparation (Report, Council on Pharmacy and Chemistry, 1941, J.A.M.A., *117*).

Bovine serum "despeciated" by heating to 72° C. in the presence of formaldehyde and ammonia is reported to lose its toxicity for man, so that it may be used instead of human plasma (F. R. Edwards, 1944). Further reports may be awaited.

PREPARATIONS OF HUMAN PLASMA AND SERUM FOR TRANSFUSION.—These are obtained aseptically from eight or more humans free from transmissible disease, and pooled according to the requirements of the National Institute of Health. The average dose by vein is 500 cc.

Citrated Normal Human Plasma, U.S.P.; 10 per cent of 4 per cent sodium citrate solution is added to the fresh blood before the cells are separated by centrifugation. It may be conserved as (*a*) *Liquid plasma,* with 5 per cent of dextrose for stabilization, and with a preservative; (*b*) *Frozen plasma,* also with 5 per cent of dextrose; (*c*) *Dried plasma,* without dextrose, to be restored to the original volume by solution in 0.1 per cent citric acid.

Human Serum; coagulated for twelve to twenty-four hours, separated by centrifugation through bacteria-retaining filters, aged in refrigerator for at least twenty-eight days. Packaged *liquid* or *dried.*

◆

POTASSIUM SALTS

Potassium is widely distributed through the body and is essential to the vital functions,

but its significance is not fully understood. It acts especially on the receptive mechanism, with excitation by low and inhibition by high concentrations. The augmentory effects are usually inhibited by calcium, and potassium serves to balance the toxicity of sodium and calcium. Under suitable conditions it produces contracture of skeletal muscle and increased tonus of cardiac and smooth muscle (Fenn, 1940); but ordinarily it stimulates smooth muscle and depresses striped muscle; its effects on cardiac muscle are more complex, but generally depressant, restraining the pace-making tissue and suppressing automatic rhythmicity at lower levels of the heart; it depresses nerve fibers so that it may serve as local anesthetic; it also depresses the central nervous system. To produce these effects, however, its concentration or its ratio to the other ions must be increased considerably above the normal. With intravenous or hypodermic injections, the ion actions manifest themselves by depression of the heart and other muscles, and of the central nervous system. These effects may also be secured from toxic doses by mouth; but not by ordinary doses, since the rapid excretion prevents the accumulation of excessive potassium in the tissues, even though their absorption is somewhat more rapid than that of the sodium salt. The therapeutic use of potassium orally as cardiac and nervous depressant was a faulty deduction from the laboratory experiments. The oral administration of moderate quantities of potassium has practically only osmotic effects—diuresis, slight changes in metabolism, and so forth. The therapeutic actions of potassium salts therefore are attributable to their anions, and are practically equivalent to the corresponding sodium salts. The potassium salts perhaps produce somewhat more local irritation, and their taste is more disagreeable. They are contraindicated in renal insufficiency, since the deficient excretion could lead to the development of toxic potassium effects.

Income of Potassium.—The daily diet of man in the United States averages 3.4 Gm. (1.4 to 6.6) of potassium (H. C. Sherman, "Chemistry of Food and Nutrition," Macmillan Co., 1937). This is about a third of the income of sodium. A vegetable diet contains relatively more K. The *absorption* of potassium ingested as chloride (isotope) occurs rapidly, 90 per cent within half an hour, chiefly from the small intestines (M. Joseph *et al.*, 1939).

The distribution of potassium is in many respects converse to that of sodium. Potassium is generally more abundant in the cells, sodium in the extracellular fluids, the serum and lymph. When additional potassium is administered, it diffuses into the cells, as well as into the fluids (Bourdillon, 1937). The potassium content amounts to about a fourth per cent of the body weight, about 175 Gm. for an adult man. Of this the blood contains about 8 Gm.; the blood plasma, 0.3 Gm.; the total extracellular space, 3 Gm. About 98 per cent of the total potassium is intracellular. The mobility of K is greater than that of Na even in aqueous solution, and the difference is intensified through colloidal membranes. With cell membrane this created differences of electric potential excitability and conductivity (L. Michaelis, 1925). The body cells in general appear to be more freely permeable to K than to Na.

The *serum* of all mammals contains about 0.021 per cent of K (21 mg. per 100 cc.) and 0.33 per cent of Na. In man, the serum K ranges normally between 0.018 and 0.022 per cent, and generally the same in disease, but may rise to 0.029 per cent in nephritis and in tetany (Wilkins and Kramer, 1923; W. S. Hoffman and Jacobs, 1934; H. Unger, 1934). It is also high in deficiency of adrenal cortical secretion, and in high intestinal obstruction. In *milliequivalents* of K per liter, normal human serum ranges between 3.0 to 7.0, averaging 4.5. The corpuscles range from 72 to 102, average 82.5 (review, V. C. Myers and Muntwyler, 1940).

The potassium in *red blood corpuscles* varies greatly in different animals, generally inverse to the percentage of Na. In beef, goat and sheep, the K is about 0.055 per cent and Na 0.24 per cent; in man, pig, rabbit, horse, dog and cat, K is between 0.25 and 0.4 per cent; Na, none to 0.2 per cent. In human erythrocytes the K averages 0.423 per cent, or twenty-times its concentration in the serum (Hoffman and Jacobs, 1934). With this ratio, the sudden dissolution of a fifth of the corpuscles would liberate a fatal quantity of potassium. The potassium content of the corpuscles is reported to increase progressively in acute hemorrhage in cats, from 0.01 per cent to 0.03 per cent (J. S. Thaler, 1935). The *rate of penetration* has been studied with radioactive potassium. It requires about twenty-four hours, in life or in the test-tube, to reach equilibrium, so that the ratio of radioactive to ordinary potassium is the same in the corpuscles and in the plasma. Thirty per cent penetration requires, in life, an hour for cats, six and a half hours for man, seven and a half hours for rabbits, eight hours for guinea pigs (Mullins *et al.*, 1941).

Human cerebrospinal fluid contains 0.0126 to 0.0127 per cent, about a third less than serum (H. Unger, 1934). *Human saliva* contains 0.031 to 0.131 per cent, from one and one-half to six times as much as serum (Vladesco and Bellea, 1938).

Muscle fibers contain potassium without sodium (Fahr, 1912), but the amount is small (Hastings and Eichelberger, 1937), about 0.28 per cent of the wet mammalian muscle, 0.98 per cent of the dry weight (J. N. Cumings, 1939). The potassium in the muscle cells is all ionized (E. Bozler and Cole, 1935). The greater part of the K is not diffusible if fresh muscle is hashed cold, but it becomes diffusible if the muscle has been fatigued or heated (E. Ernst, 1932). Muscle is permeable to K ions, but not to anions (Fenn and Cobb, 1935). *When muscle is stimulated* under certain conditions it loses up to 30 per cent of its potassium. Considerable of this is taken up by the liver, and released during recovery (W. O. Fenn, 1939; review, 1936). *Nerve*, at least nonmedullated, also loses potassium during stimulation. The central nervous system and smooth muscle have not been sufficiently investigated (Fenn). *Heart muscle* loses potassium during vagus stimulation (Howell and Duke).

In the skin, the potassium and calcium are much more abundant in the epidermis than in the cuticle (Bohnstedt, 1931; Kooyeman, 1935).

After intravenous injection of potassium salts, the K leaves the plasma rapidly, the concentration returning to nearly normal in fifteen to twenty-five minutes (W. S. Wilde, 1939; Fenn, 1939), by a parabolic curve. After injection of radioactive potassium K_{42} to rats, the uptake is most rapid in the liver, heart, kidneys and lungs, slowest in skeletal muscle, brain, nerve trunks and erythrocytes. The liver attains temporarily a higher concentration (double) than the plasma; other tissues contain less than the plasma concentration. Within six hours, however, all organs have nearly the same concentration. The largest total amount by far is in the muscles (M. Joseph *et al.*, 1939; Noonan *et al.*, 1940, 1941).

Depletion of potassium, by restricted income in rats, diminished the muscle potassium by almost half, with concomitant rise of sodium, which may rise above the K. The Na in the K-deficient was intracellular, while the normal muscle Na is extracellular. The serum K was also reduced to half. The electrolytes of the liver were not materially changed (L. A. Heppel, 1939). Rats on diets extremely deficient in potassium develop necrotic changes in the heart and in the renal tubules (R. H. Follis *et al.*, 1942). *Optimal growth* of rats occurs when the diet contains five times as much Na as K (L. Redina, 1926).

Translocation of Potassium.—Potassium moves about the body rather freely, according to need. It increases in cells during their active growth, and decreases in disintegration. It goes from the cells to plasma when there is excessive loss of NaCl and water from the body, as in hemorrhage, shock, adrenalectomy. Its concentration in the blood rises during muscular activity, and falls during rest and anesthesia. It often rises and falls with the lactic acid and sugar level (review, W. O. Fenn, 1940). It rises in asphyxiation, most of the increase being from the liver, some probably from all organs, very little from muscle (W. O. Fenn, Wilde *et al.*, 1939). The liver is also the chief source of the increased blood plasma potassium in hemorrhage and shock. Traumatized muscle loses potassium and phosphate to the blood (A. P. W. Clarke and Cleghorn, 1942).

Excretion.—A considerable part of the potassium, 15 to 25 per cent, is reexcreted in the feces. The urine contains generally Na:K::2:1 to 5:3. In starvation, the ratio is reversed to 1:3. Potassium is excreted more rapidly than sodium, and is therefore more diuretic. The administration of KCl results promptly in considerable increase of the urinary excretion of both K and Na, and in increased alkalinity of the urine. These effects are more marked than with corresponding doses of NaCl (Glatzel, 1934), although the excretion of K is also hastened by the addition of Na (Biernacki, 1911). Intravenous injection of KCl or KBr, but not of K_2SO_4, renders the urine highly alkaline, with increase of bicarbonate (A. W. Winkler and Smith, 1942). A few experiments by Blumenfeldt, 1913, indicate that the excretion of administered potassium is delayed by aortic insufficiency, arteriosclerosis and interstitial nephritis. Radioactive potassium is excreted at the rate of 6 to 7 per cent per day (M. Joseph *et al.*, 1939).

Systemic Actions.—The *central nervous system* is paralyzed by excess of potassium. The reflexes suffer, then the medulla. Depression of the respiratory center leads to asphyxial convulsions. Absence or increase of K is depressant to the perfused respiratory center of the frog (Hooker, 1913). With intravenous injection, the most important effect is the cardiac paralysis.

Cardiac Actions.—Small concentrations of potassium depress and high concentrations paralyze the heart, the contractility being considerably more resistant than the rhythmicity, so that the arrested heart may contract strongly to electric stimulation. The resistance of the rhythm varies widely for the different portions of the heart, in the direction of the gradient; *i.e.*, it requires much higher concentrations to arrest the rhythm of the sinus than that of the sinus-free ventricle, which is more resistant than the sinus-free auricle. The normal plasma concentration of potassium is distinctly detrimental to the rhythm (not to the contractility) of the ventricle and auricle, and this helps to subject these to the pace-making rhythm of the nodal tissue, which is not depressed by these concentrations (Kolm and Pick, 1920; Sollmann and Chu, 1926). The tonus waves of the turtle's auricle are increased. The rhythmic depression of moderate concentrations of potassium may be more or less antagonized by calcium. Absence of potassium from the perfusion fluid abolishes the inhibitory power of the vagus on the heart (Howell, 1906).

For rabbit's heart perfused with Locke's solutions, the optimal concentration of KCl is about 0.045 per cent. Increase to 0.068 per cent (*i. e.*, one and one-half times the optimal) produces changes in the electrocardiogram which indicate depression of the intrinsic conducting system, with partial bundle-branch block. With 0.09 per cent (*i. e.*, twice the optimal concentration) these changes increase, often to ventricular fibrillation, while the auricles may continue regular. Cardiac arrest occurs at about three times the optimal concentration. All the changes are reversible when the normal K concentration is restored (McLean, Bay and Hastings, 1933). When the perfused heart of various animals has nearly stopped from potassium deficiency, and normal Ringer's solution is admitted, the heart is completely arrested for a time, before resuming rhythmic contractions ("potassium paradox," W. Libbrecht, 1921). The coronary vessels of the perfused dog heart are dilated by increasing the potassium concentration up to 1¾ of the normal, but they are constricted above this concentration (L. N. Katz and Lindner, 1939). *Pericardial application* of concentrated KCl (injected into the pericardial sac of dogs) produces electrocardiographic changes similar to those of coronary occlusion (Wiggers, 1930).

Mechanism of the Potassium Action.—The depressant action of potassium occurs in the nerve-free heart of the chick's embryo, and is therefore muscular. Howell and Duke, 1908, found that stimulation of the vagus increases the output of K in the perfused heart, especially the auricles. They attributed the vagus stoppage to the K which the stimulation of the nerve is assumed to convert from a nondiffusible into a diffusible form. Injection of potassium also liberates acetylcholine in the heart (A. B. L. Beznak, 1934), in the adrenal glands (G. Katz and Katz, 1937), and in other organs (reference: W. O. Fenn, 1940). It mobilizes adrenal epinephrine, as does also calcium chloride (G. Katz and Katz, 1937).

Replacement of potassium in Ringer's solution by other alkali metals, in perfusion of frog and turtle heart, modifies the functions: *Ammonium* increases the rate and contractility, but retards conduction; *rubidium* increases the pacemaker activity, but inhibits the contractility as well as the conduction; *lithium* has no effect on the pacemaker or contractility, but depresses conductivity slightly; *cesium* depresses all the functions (Jentgens, 1937).

Rapid intravenous injection of relatively small quantities of KCl, 2.5 to 15 cc. of isotonic solution, in dogs, produces transient hyperpnea, fall of blood pressure and slowing of the heart, by moderate stimulation of the carotid sinus, together with some direct central inhibition of the vasomotor center and stimulation of the vagus center (Winder, 1939). These effects do not occur with slow injection, and are rather slight, till the dosage exceeds a certain point, when marked cardiac disturbances develop suddenly, with decreased output, marked slowing, block, fibrillation, cardiac arrest, usually before the respiration stops (Mathison, 1911). The *ventricular fibrillation* may result either from increased excitability or by local increase of the refractory period (Wiggers, 1930). These recover spontaneously and promptly, unless the circulation was arrested by the fibrillation. *Slow continuous injections* into dogs or cats produce only minor changes of blood pressure until the final cardiac failure occurs (H. B. Hoff *et al.*, 1939). Larger doses depress the heart muscle directly, even when the vagi are divided. Fatal doses produce ventricular and eventually auricular fibrillation (Hering, 1915). With plasma concentration of 12 to 20 m. eq. per liter, the intravenous toxicity of KCl is diminished by the addition of $CaCl_2$ (A. Winkler *et al.*, 1939) and of NaCl (Amberg and Helmholz, 1916). Skeletal muscle continues to contract after the cardiac muscle is paralyzed. *Arterial injection* causes immediate rise of blood pressure, by stimulation of the vasomotor center, and of the vessels directly (it occurs even when the central nervous system is destroyed, Mathison, 1911).

Ventricular fibrillation is arrested by adequate doses of potassium, and a regular rhythm of the heart may then be started by suitable stimulation. This may be effective, for instance, in electrocution (Wiggers, 1939). In dogs, intravascular injection of 50 mg. of KCl, as 5 per cent solution, per Kg. of body weight, to arrest the fibrillation, then 5 per cent $CaCl_2$, 1 cc. per Kg., with cardiac massage, was successful in less than half of the animals. Better results were obtained by arresting the fibrillation by alternating current, according to Hooker *et al.*, 1933.

Skeletal muscle of frogs is weakened by excess of potassium, the height of contraction is diminished, the latent period lengthened and excitability and conductivity decreased (Fahr, 1910). Veratrine contracture is abolished, but on the other hand, hypertonic KCl produces contracture by itself (F. Buchthal and Lindhard, 1939). In mammals, intra-arterial injection of KCl temporarily increases the response to stimulation, also after curarization, similar to stimulation of the sympathetic nerve supply (A. M. Baetjer, 1935; T. P. Feng, Lee *et al.*, 1938). Somewhat larger doses depress the neuromuscular transmission and then block it, with marked contracture. The response to direct stimulation is not impaired (S. M. Walker, 1947). Intravenous injection counteracts the decreased tension after repeated stimulation, perhaps by replacing the potassium lost in contraction (H. E. Hoff *et al.*, 1941).

Deficiency of potassium has no effect upon the contraction range of a toad gastrocnemius muscle; or upon its ability to pass into a state of tetanus; but the ability of the muscle to maintain a condition of tonus is impaired (Neuschloz, 1923). Potassium is essential for the transfer of PO_4 from phosphopyruvate and phosphoglycerate to creatine in homogenized muscle. It is not replaceable by Na, and is inhibited by Ca (Boyer *et al.*, 1942).

Sensitization of excised muscle to potassium is produced by veratrine, aconitine and delphinine; by thiocyanate, thiosulfate and colchicine; by chloropicrin and bromopicrin; and by guanidine. Susceptibility to acetylcholine is not raised materially. The thiocyanate acts chiefly at the level of the muscle cell; the guanidine at the myoneural junction; the veratrine on both (G. Coppée, 1942).

Clinical myasthenia is reported to be improved by the oral administration of large doses of KCl (Laurent and Walther, 1935), and the symptoms of *myotonia* increased, similarly to prostigmine (Russel and Stedman, 1936). The attacks of *familial periodic paralysis* are reported to be associated with marked fall of the serum K, and to be improved by administration of potassium salts. The paralysis is central and does not occur in normal persons when their serum potassium is reduced to the same level (Allott and McArdle, 1938; Pudenz *et al.*, 1938; G. D. Gammon, Austin *et al.*, 1939; references, W. O. Fenn, 1940).

Deficiency of adrenal cortex function, experimental and in the crises of Addison's disease, is associated with high concentration of K in the plasma, as well as low concentration of Na, and both conditions are remedied by the administration of adrenal cortex. As intraperitoneal injection of large doses of KCl produce phenomena similar to those of adrenal deficiency, it is advisable to restrict the K income of such patients (Zwemer and Truszkowski, 1936).

Smooth Muscle.—The tonus and contractions of the intestines, uterus, bronchi and arterioles are stimulated by excess of potassium (Mathison, 1912). However, the vessels of frogs are dilated by perfusion with potassium (Hooker, 1911).

Amebae immersed in isomolecular KCl solution (0.025 M.) show reversible inhibition of locomotion and marked increase of protoplasmic viscosity. Both effects are produced by acidifying the solution to *p*H4 (Corson, 1944).

Ciliary motion is but little affected by potassium (Ishikawa and Ohzono, 1931).

Nerve.—Excess of potassium depresses the oxygen consumption of nerve (T. H. Chang *et al.*, 1935). Injection of K suspends the conductivity of nerve and potentiates the anesthetic effect of cocaine. Na, MH_4 and Mg do not have this effect (Zorn, 1913). Injury and the local application of lipolytic anesthetics increase the concentration of K ions in medullated nerve fibers. This may play a part in the anesthetic effect (Menten, 1912). Under clinical conditions the local anesthetic action of potassium salts is almost insignificant, since the potassium is rapidly absorbed or "neutralized" by other ions in the tissues (Sollmann, 1917). However, 1 per cent potassium chloride may be used in place of normal saline for the dilution of the more active anesthetics.

The *excitability of the sympathetic cervical ganglion* to stimulation of the preganglionic nerve or by acetylcholine is increased by potassium (Feldberg and Vertiainen, 1934).

Potassium Therapy of Allergic Disorders.—B. Bloom, 1938, reported prompt and striking improvement, often within a few minutes, in hay fever patients from oral administration of potassium chloride, 0.3 to 0.65 Gm., 5 to 10 grains, three times daily. Most other clinicians have not obtained a definite response (H. Miller and Piness, 1940; G. F. Harsh and Donovan, 1940; S. S. Rubin *et al.*, 1940).

Location of Potassium Action.—Excised tissues respond to potassium excess, deficiency and restoration much more rapidly than the ion can pass into or out of the muscle cells (Urano, Fabr). It must therefore act on the cell surface or membrane. It has been suggested that the high migration speed of the K ions would upset the surface potential.

The **effects of oral administration** of an ordinary dose of potassium salts are chiefly, if not exclusively, those of the anions, since the potassium is so readily excreted that its concentration in the blood or tissues does not rise materially unless very large doses are given, or if the excretion is seriously checked by renal disease.

In man, oral ingestion of 12 Gm. of KCl is generally not toxic, although the plasma potassium is raised by about two-thirds in two hours (M. Norn, 1929); 0.1 Gm. of potassium salt per Kg. of body weight generally does not produce demonstrable harmful effects; but in some individuals 0.08 Gm. per Kg. is harmful to the kidneys, reducing the inulin and urea clearance. The electrocardiogram frequently shows increased T wave even with 35 mg. per Kg., also changes of renal function (N. M. Keith and Osterberg, 1946). Paresthesias sometimes occur if the serum level reaches 30 mg. per cent. Rats suffered no harmful effects when the potassium of the diet was four times that of the sodium (H. G. Miller, 1923). Rapid intravenous injection of 1 per cent solution may cause intense pain along the vein; this does not occur with slow injection (N. M. Keith *et al.*, 1941). The intravenous toxicity of KCl is diminished by simultaneous injection of calcium salts (Winkler, Hoff and Smith, 1939) or of hypertonic sodium chloride or dextrose (G. Amberg and Helmholz, 1918). Administration of *desoxycorticosterone* or of *thyroid* increased the tolerance of rats for intraperitoneal injection of potassium chloride (B. E. Lowenstein and Zwemer, 1943).

Potassium Poisoning in Nephritis.—The administration of 5 to 10 Gm. of KCl (diluted) usually produces no symptoms, even when the permeability to NaCl is impaired, as in chronic nephritis, and it is doubtful whether oral administration of potassium salts can lead to the accumulation of a fatal concentration unless there is complete anuria. Occasionally a nephritic patient may develop severe potassium poisoning, as in a case described by Smillie, 1915. The symptoms started after seven hours and reached their maximum in twenty-one hours. They consisted in cyanosis, weak pulse and vomiting. Cardiac arrest preceded by progressive electrocardiogram changes characteristic of potassium poisoning were recorded in several deaths of uremic patients with fatal serum potassium concentration (J. F. Marchand and Finch, 1944; N. M. Keith *et al.*, 1944). *Removal of the kidneys or ligation of the ureter* in dogs raises the serum potassium progressively, with electrocardiogram changes characteristic of potassium until cardiac arrest occurs, chiefly by potassium accumulation (H. E. Hoff, Smith and Winkler, 1941). Direct introduction of potassium salts into the stomach or duodenum after ligation of the ureters hastens death (A. W. Winkler *et al.*, 1941).

Potassium in the Toxicity of Urine.—Intravenous injection of urine produces a variety of effects, differing qualitatively as well as quantitatively according to the origin of the urine, and the animal into which it is injected. (Hatcher and Smith, 1916, found that intravenous injection of urine is not toxic for cats.) Various theories and methods of diagnosis have been built around the differences of toxicity, but too many factors are involved. A part of the effects is due to potassium, but unidentified organic constituents also play an important part (Kuizumi). These are apparently formed largely in the kidney, for death occurs much earlier if the urine is continuously reinjected (by implanting a ureter in a vein) than if the kidneys are excised (Galehr and Tadashi, 1927).

B. Zondek and Black, 1946, report that dialyzed human urine, adjusted to isotonic, is not toxic for rabbits and rats by intravenous injection, nor for the frog heart.

Potassium-deficient diet causes the death of rats in about twenty-three days, preceded by loss of weight, shortening of hair, cyanosis, cardiac slowing and irregularities, abdominal distention, lethargy and coma. Marked ascites is common, and the viscera, especially the heart muscle and kidneys, show degenerative changes (Schrader, Prickett and Salmon, 1937; Keiles and McCollum, 1941). The minimal requirement appears to be 0.17 per cent of the diet (Kornberg and Endicott, 1946).

Administration of Potassium.—Potassium salts are used chiefly for the anion, but sodium salts generally deserve preference. The taste of potassium is less salty but more disagreeable. It is more easily excreted, and is therefore less liable to cause salt edema. If large quantities of salts are administered over long periods, as with bromide in epilepsy, it would be theoretically desirable to balance the sodium with potassium, perhaps in the serum ratio of 15 to 1. Practically, however, this does not appear to be material. If potassium is used for its own sake (as in myasthenia), it is administered as *Potassium Chloride,* U.S.P., which is readily soluble in water, but which should be diluted to at least 1 per cent. The dosage is stated as 1 to 2 Gm. (15 to 30 grains). *It must not be confused with the toxic chlorate. Potassium Chloride Tablets,* U.S.P.; usual sizes 0.3 and 0.5 Gm.

LITHIUM SALTS

Lithium urate is relatively soluble. By a misinterpretation of this chemical fact, the lithium salts were introduced as solvents for uric acid, and hence as remedies against gout, rheumatic conditions, and the like (lithium carbonate, 0.12 to 0.3 Gm.; citrate, 0.3 to 0.6 Gm.; both soluble in water). Since the soluble urate can not be formed in the presence of sodium or potassium ions, it can not exist in the body or in the urine. The uses of lithium salts therefore have no rational foundation, and larger doses are somewhat dangerous.

The actions of lithium resemble those of potassium, but it is less toxic to the heart, and causes a vagus stimulation. These effects are seen only on intravenous injection. It may be used to replace Na in frog heart perfusion, requiring only a slight increase of K and some decrease of Ca (Dulière, 1927). An important difference from potassium consists in a *specific gastro-enteritis* which is produced even when the salts are given subcutaneously, or if the administration of moderate doses is continued for some time (1 Gm. of the carbonate in man). The lithium is largely excreted by this channel. It is also excreted by the kidneys, but does not cause nephritis (Krumhoff, 1884; Good, 1902), and also in the milk (Koldewijn, 1910). *Acute poisoning from larger doses* in man (four doses of 2 Gm. of LiCl) is described by Cleveland, 1913. There were no gastro-intestinal symptoms; but marked muscular and general prostration; vertigo, and eye and ear symptoms resembling those of cinchonism.

Action on Urates.—Lipowitz, 1841, found that lithium carbonate is a better solvent for uric acid (about four times) than sodium carbonate. He suggested its therapeutic use, and this was introduced by Ure, 1844, and Binswanger, 1847. Garrod, 1861, found that gouty tophi were dissolved in lithium solution. The solvent action, however, occurs only when strong solutions of lithium carbonate act on uric acid. In the presence of NH_4, Na or K, the less soluble urates of these cations are formed. The solution can not therefore occur under the conditions of the body or urine. Lithium salts have diuretic actions (Husemann), but no greater than the Na salts. The slight superiority of lithium could exist only with very large doses, and these are unsafe (Haskins, 1916). The popular "Lithia waters" have been shown to be practically devoid of lithium. The best contain only 0.01 to 0.02 per cent. "Buffalo Lithia Water" contains only a fifth as much lithium as Potomac River water; 200,000 gallons would be needed to supply the ordinary therapeutic dose of lithium.

◆

CESIUM AND RUBIDIUM

These also resemble potassium and may replace it in the excised frog heart (Zwaardemaker, 1918). Potassium deficiency in the diet of rats may be largely replaced by cesium and more effectively by rubidium. These prevent the myocardial necrosis and the damage to the renal tubular epithelium. Convulsive seizures were noted (R H. Follis, 1943).

Cesium exists normally in the retinal layers of the eyes of pigs, sheep and oxen (G. H. Scott and Canaga, 1939). Its excretion was studied by C. F. Graham and Wright, 1933.

Rubidium iodide and bromide were introduced into therapeutics, with the improbable claim that they produce less iodism and bromism. The doses are the same as those of the potassium salts.

◆

AMMONIUM SALTS

Ammonium is formed in normal metabolism as a precursor to urea. Through this it plays an important role in neutrality regulation. It produces the "salt actions" of indifferent salts, and penetrates readily into cells, as ion and especially as ammonia gas, which is formed from it in alkaline solutions. Its actions per se are not pronounced or important. Ammonium salts are used chiefly as carriers of acid actions (chloride) or alkali actions (hydroxide or carbonate locally, acetate systemically).

Absorption and Excretion.—Ammonium salts are absorbed from the digestive tract, and what is not converted into urea is excreted by the urine, probably more readily than other cathions. Absorption and excretion of *gaseous ammonia* by the lungs is doubtful, or slight at most. It was denied by Magnus, 1902, and Brucini, 1907. Hoeber, 1912, and McGuigan, 1913, claimed that the inhalation increases the percentage of ammonium in the blood. However, this insignificant absorption occurs from the trachea and bronchi, and also from injured alveoli (Magnus *et al.*, 1914). W. Coleman, 1916, stated that traces of ammonium can be discerned in the *sputum* (not in the saliva) twelve hours after discontinuing small doses of the salts.

Penetration of Cells.—The ammonium ion, like other cations, diffuses very little into cells, including erythrocytes. Ammonia, NH_3, which is formed by the hydrolysis of ammonium salts of weak acids, enters cells readily. In erythrocytes, this results in *hemolysis* (Jacobs and Parpart, 1938).

Disintoxication of Ammonium.—Ammonium is partly excreted as such by the urine; but the greater proportion is rapidly converted into urea by splitting off two molecules of water. This liberates the acid ion with which the NH_4 was combined, and this seizes upon the free fixed alkali of the body, and so diminishes the alkali stock of the tissues. In this way any excess of ammonium introduced into the body is soon eliminated, or at least ceases to act as ammonium.

There is similarly a fairly definite relation between the ammonium excretion, the reaction of the urine and acidosis conditions (Hasselbalch, 1916). Ingested ammonium disappears rapidly from the circulation, even if the kidneys are ligated (Jacobson, 1914). The conversion of ammonium carbonate into urea is practically complete in all mammals. Ammonium chloride is destroyed more efficiently by herbivorous animals than by carnivores or man. In man, after the administration of 5 Gm. of ammonium chloride, 52.5 per cent was recovered from the urine in two days (Wolf and Osterberg, 1912).

Ammonium in Metabolism.—Arterial blood contains normally about 1.5 mg. of NH_4 per 100 cc. Portal blood contains from 3.5 to 8.5 mg. (Carlson and Jacobson, 1910). Folin and Denis, 1912, believed that the excess in the portal blood comes mainly from bacterial changes in the large intestines. The ammonium is probably a normal forerunner of urea. This is formed from ammonium carbamate by the subtraction of H_2O. *The source of the endogenous ammonium* of the urine is chiefly glutamine; other amino acids may add a minor quantity. This conversion is increased by acid, decreased by alkali. It diminishes the amount of urea that can be formed. *Urea* is not transformed into ammonium, but is excreted as such (D. D. Van Slyke, Phillips *et al.*, 1943).

Function of Ammonium in Neutrality Regulation.—The transformation of ammonium into urea is utilized for the control of the reaction of the body: when there is excessive formation of acid (acidosis), the transformation is less complete, the acid being neutralized by the ammonium and excreted in the urine. If alkalis are administered, the ammonium is displaced from its salts, and converted more completely, so that none may appear in the urine (Janney, 1912). The ammonium-urea relation of the urine is thus an index of the acid production or alkali income. The ammonium excretion is high in diabetes (Boussignault, 1850), where a tendency to acidosis is present.

Place of Urea Formation.—The transformation of ammonium into urea occurs in perfused *liver* (v. Schroeder, 1892; Fiske and Karsner, 1913); the urea may also be considerably higher in the hepatic than in the portal blood (Van Slyke, Cullen and McLean, 1915). No urea is formed in dogs after excision of the liver, so that this appears to be the sole place of urea formation (J. L. Bollman and Mann, 1933), although it was believed that all organs participate, especially in its formation from amino acids (Folin, 1914; S. Bliss, 1929). However, the *ammonium formation* for protection against acidosis appears to occur exclusively in the kidneys (S. R. Benedict and Nash, 1926).

Utilization of Ammonium Nitrogen.—Grafe and Schupfer, 1912, claimed that ammonium may replace the protein food. This was confirmed by Knoop, 1913, Grafe, 1914, and others. It does not prove that ammonium is converted into tissue nitrogen. It is more probable that it is utilized by the intestinal bacteria, which are then digested and their nitrogen absorbed. Accordingly, Henriques and Anderson, 1914, found no retention of nitrogen after the intravenous injection of ammonium or urea. Taylor and Ringer, 1913, observed considerable N retention after oral administration of ammonium carbonate, but the associated changes in metabolism indicate that the retention is due to a toxic action of the ammonium, rather than to its utilization (Underhill and Goldschmidt, 1913).

The ammonium content of the blood has not been found increased in uremia or in acute yellow atrophy of the liver. An increase of 50 per cent above the normal has been reported after complete excision of the thyroids and parathyroids (MacCallum and Voegtlin, 1909; Berkeley and Beebe, 1909); and the ammonium production is increased (Underhill and Saiki, 1908), or its destruction diminished (Carlson and Jacobson, 1910). A similar increase was reported in clinical tetany (Musser and Goodman, 1909). However, Carlson and Jacobson, 1911, showed that the increase of ammonium is not constant and falls within the variation of normal animals, so that even these conditions can not be classed as ammonium intoxications. McNeil and Levy, 1917, concluded that increase of blood ammonium above 1 mg. per 100 cc. which occurs in various diseases, is not connected with acidosis, but rather with hepatic disturbance, especially of the acute functional type.

Ammonium chloride acidosis has a twofold basis: the direct acidity of the salt of a strong acid and a weak base; and the conversion of part of the ammonium into urea, leaving an excess of chloride anions, which neutralize a corresponding amount of the alkali reserve of the body (Haldane, 1920). The direct acidity is responsible chiefly for the immediate effects on the circulation and respiration when ammonium chloride is injected intravenously. The acidification of the urine is due entirely to the second mechanism, since the ammonium concentration of the urine is insignificant. The change in the acid-base equilibrium is also chiefly due to the second mechanism, for it becomes marked only when the ammonium is converted into urea, and is still apparent after six weeks (as low oxygen and carbon dioxide content of the blood), when the ammonium has completely disappeared (Haldane, Linder *et al.*, 1928).

Therapeutic use is made of this acidosis to acidify the urine so as to render it bactericidal and as an aid to hexamethylenamine and to mandelic acid; to combat alkalosis; to mobilize and remove lead in chronic lead poisoning; to diminish convulsions, as those of epilepsy or camphor, the rationale being obscure; and to reinforce the action of organic mercurial diuretics. The *dosage* for these purposes is 1 to 2 Gm., 15 to 30 grains, four times daily, freely diluted with water, or as enteric capsules. Excessive acidosis should be avoided.

Diuresis may be produced by ammonium chloride alone, but is not practical, as it requires very large doses, at least 15 Gm., or even 40 Gm. per day (N. Keith, 1931), which tend to cause too much acidosis and disturbance of the salt equilibrium. *Ammonium acetate solution,* which tends to render the urine alkaline, has been employed as a mild diaphoretic and diuretic in fevers, but is presumably useless.

Intravenous injection of ammonium chloride produces immediate increase of respiration, fall of blood pressure and slowing of the heart, partly the results of the acid reaction of the salt; but injection of ammonium carbonate and hydroxide produces similar respiratory stimulation (Brassfield *et al.*, 1946).

With large doses, Marfori, 1893, described prompt tremors and twitchings, progressing to tetany, violent convulsions and opisthotonos; irregular respiration; salivation and emesis; somnolence and lassitude. If the injection is not promptly fatal, the functions recover rapidly (Meneguizzi, 1912). The *respiratory activity* produced by intravenous injection of ammonium chloride has been investigated by C. R. Brassfield *et al.*, 1945. *Acetoacetic acid production* from pyruvic acid in the liver is increased by ammonium chloride, *in vivo* (Annau) and in liver sections (Edson, 1935).

A *curare-like effect* on skeletal muscle is demonstrable with ammonium, but it is much weaker than with the organic ammonium bases. This is presumably the explanation of the relief of toxin tetanus which was reported by Dixon and Ranson, 1930, for large doses of ammonium chloride in rats.

Plant Tumors.—The injection of ammonium salts and a number of other substances produce tumor-like cell proliferations in plants (E. F. Smith, 1917). They are probably due to removal of growth-restraining factors

Ammonia as Stimulant.—Ammonium carbonate and hydroxide, which liberate gaseous ammonia, are used for reflex stimulation by inhalation (especially as ammonium carbonate, "smelling salts," "sal volatile"), or by oral administration of "aromatic spirit of ammonia." This is also used as alkaline carminative in dyspepsia. It contains 4 per cent of ammonium carbonate, 0.2 per cent of ammonium hydroxide, with aromatic oils and alcohol, which renders the ammonia less irritant (Robert Boyle), by reacting with it to form aldehydes. Half a teaspoonful to a teaspoonful is taken in water. The freshly made spiritus turns milky, but the aged forms a clear solution with water. *Inhalation of ammonia vapor* stimulates the medullary centers through the sensory trigeminal endings, producing momentary standstill, then increase of respiration; stimulation of the vasomotor center (rise of blood pressure); and vagus slowing of the pulse (in rabbits, vagus standstill). It is used for stimulating the medulla reflexly in headache, fainting, collapse, excessive anesthesia, and so on. Care must be used so that the unconscious patient is not made to inhale too concentrated a vapor, which may cause laryngitis, bronchitis and pneumonia.

Applied to the skin, ammonia produces rubefaction, and if concentrated and confined, vesication, usually without corrosion. It is used in combination with oil (ammonia liniment) for counterirritation in rheumatism, and so forth. Ammonia also is applied to insect bites.

Expectorant Action.—Ammonium chloride is said to make the sputum subjectively "looser," easier to raise, and perhaps more abundant. The increased secretion of mucus and saliva is mainly a reflex from the local irritant action, although there may be some direct central stimulation (V. E. Henderson, 1910). The liquefaction of the mucus may be due partly to the excretion of the alkaline ammonium carbonate by the saliva. This excretion, however, is small, since most of the ammonium is destroyed in the body. Ammonium chloride is also said to have a primary astringent effect on the mucous membrane. Ammonium chloride is used in acute and chronic bronchitis in the dose of 0.3 Gm., 5 grains, repeated as needed; either as troches (0.1 Gm., 1½ grain) or in solution. Its disagreeable taste is less noticeable in acid mixtures (*syrup of citric acid*).

The *expectorant actions of ammonium carbonate* are more definite, as its alkalinity liquefies the mucus, and the irritation and nausea are more marked. The saliva, however, is rendered more acid (Brassfield *et al.*, 1946). It is used, 0.1 to 0.3 Gm. in solution, when the mucus is thick and purulent. Its taste is disagreeable. Syrups of Glycyrrhiza, Wild Cherry and Tolu are used as flavors, not very successfully. It is *incompatible* with Syrups of Citric Acid or Orange.

Toxicology.—The neutral ammonium salts may cause gastritis. This would be treated by dilution and evacuation. Ammonia and the carbonate produce more violent irritation, and also inflammation of the respiratory passages. The mortality of ammonia poisoning is therefore high. If the patient recovers from the acute effects, pneumonia may set in; or the hoarseness or aphonia may last for months. The *treatment* consists in artificial respiration, weak acids and oils.

Preparations.—***Ammonium Chloride,** U.S.P. (Sal. Ammoniac; Salmiac; Muriate of Ammonia), NH_4Cl, is a white crystalline, odorless powder, of cooling saline taste. Freely sol. in water (1:2.6); sol. in alc. (1:100); freely sol. in glyc. (1:8). Neutral or slightly acid to litmus. *Incompatible* with alkaline hydroxides or carbonates (liberation of ammonia). Dose, as expectorant, 0.3 Gm., 5 grains, every three or four hours; as diuretic, 3 to 6 Gm. daily. *Ammonium Chloride Capsules,* U.S.P.; usual sizes, 0.3 and 0.5 Gm. *Ammonium Acetate Solution,* U.S.P. (Spirit of Mindererus), is 7 per cent $NH_4C_2H_3O_2$, with small amounts of acetic and carbonic acids. Should be slightly acid. Must be recently prepared. Dose, 15 cc., 4 drachms.

***Ammonium Carbonate,** U.S.P. (Sal Volatile, Hartshorn, Bakers' Ammonia), is a mixture of varying proportions of acid ammonium carbonate (NH_4HCO_3) and ammonium carbamate ($NH_4NH_2CO_2$). For medicinal purposes, only the translucent pieces are used. On exposure to air, it becomes a powder, losing NH_3 and CO_2; and changing to ammonium bicarbonate, NH_4HCO_3. White, hard, translucent, striated masses; strong odor of ammonia, without empyreuma; sharp, saline taste. It dissolves slowly in four parts of water, the carbamate changing to normal ammonium carbonate. It is decomposed by hot water. Alcohol dissolves the carbamate and leaves the carbonate. Incompatible with acids and the salts of most metals and alkaloids. Dose, 0.3 Gm., 5 grains. ***Aromatic Spirit of Ammonia,** U.S.P. (Spiritus Ammoniae Aromaticus; Aromatic Ammonia), is a solution of ammonium carbonate (4 per cent), ammonia water (2 per cent) and aromatic oils (1.2 per cent) in 70 per cent alcohol. A nearly colorless liquid when freshly prepared, but gradually acquires a yellowish color. Dose, 1 to 4 cc., 15 to 60 minims, in a glass of water.

Diluted Solution of Ammonia, U.S.P. (Ammonia Water), contains about 9.3 Gm. of NH_3 in 100 cc. It loses strength on standing. Colorless liquid of pungent ammonia odor and caustic soapy taste. Freely miscible with water and alc. Incompatible with most metals and alkaloids. Dose, 1 cc., 15 minims, largely diluted. *Strong Solution of Ammonia,* U.S.P., contains 28 per cent ammonia. *Ammonia Liniment* (Household Liniment) is a mixture of 1 part ammonia water, 1 part almond oil and 2 parts olive oil.

◆

EXPECTORANTS

This term, literally "out of the chest," has been extended to all remedies that quiet cough. This comprises the following approaches: *Anodyne expectorants,* especially opiates, which dull the appreciation of the cough reflex. They give the most effective symptomatic relief, and may be justified to secure rest; but they do not remove the pathologic condition. *Local anesthetics,* such as orthoform lozenges, are no more desirable and are less effective. *Demulcent expectorants,* acacia, licorice, sugar or syrup, glycerin diminish the cough sensation by protecting the inflamed mucosa of the pharynx; and are therefore directly beneficial, especially against "rawness" or "nervous tickling." *Astringents* (lozenges of tannin or catechu) furnish a protective coating and contract the inflamed vessels, but their action does not extend below the larynx. *Nauseants,* by increasing the secretion of mucus, furnish the protection of demulcents, but extend also into the bronchioles. They liquefy the mucus, and therefore render expectoration easier, as has been confirmed by roentgenoscopy (Gordonoff, 1938; the ciliary movement contributes little to the transport of viscid mucus; Gordonoff and Mauderli, 1936). The nauseants which act centrally (ipecac and antimony) are called *sedative expectorants,* because they depress the patient. Those which act by local irritation (senega, squill) are termed *stimulant expectorants,* because they stimulate the mucosae directly.

Liquefying expectorants promote expectoration by decreasing the viscosity of the mucus. *Alkaline expectorants,* sodium bicarbonate or ammonium carbonate, may be used for this purpose above the larynx, as lozenges; their action may be extended into the larger bronchi by spraying. *Saline expectorants,* ammonium chloride and potassium iodide, extend the action to the entire bronchial tree. *Aromatic expectorants,* terpene hydrate, various volatile oils, tar, are used especially in chronic bronchitis, to promote a reaction toward healing; they are also employed if the secretion is thin and abundant.

E. M. Boyd, 1946, reports that the *output of fluid from the respiratory tract* is increased by acid ammonium salts, guaiacol, ipecac and iodides when absorbed; and by syrups when given by mouth, but not by stomach tube.

The great number of expectorants is not generally needed. The following suffice to meet conditions in the most effective manner: *Against dry congestion:* Syrup Ipecac, 1 cc., or Tartar Emetic, 5 mg. *Against thick secretion:* Ammon. Chloride, 0.3 Gm.; KI, 0.25

Gm. *Against excessive thin secretion:* Terpene Hydrate, 0.15 Gm. in capsules. *Against irritation:* Codeine, 5 mg.; alkaline gargles.

Cough Mixtures.—These polypharmacal preparations usually contain morphine and therefore give relief; but since they can not meet the special indications of the different stages, they should be avoided. They are illustrated by the "Brown Mixture," whose activity depends on antimony and opium; and by *Compound Syrup of White Pine*, N.F.

◆

UREA

Urea, $CO(NH_2)_2$, produces the physical "salt actions," as it is easily absorbed and diffused, and its toxicity is low.

Fate and Excretion.—Urea is not utilized in nutrition (Henriquez and Anderson, 1914). When additional urea is administered, it is excreted promptly and completely, mainly by the kidneys. The excretion is impaired in chronic interstitial nephritis (v. Monakow), but not in chronic parenchymatous nephritis, so that urea has been recommended as a diuretic in the latter condition (McLean). The sweat also excretes a small amount of urea (0.21 per cent, Kovesi). The urea content of the milk is not increased by urea administration (Steenbock, 1915).

Diuretic Action.—As urea is a nonthreshold substance, it is effective as a diuretic and may be used for this purpose provided that the glomerular function is not impaired, so that it does not raise the blood urea nitrogen materially. Urea inhibits water absorption in the loops of Henle until the urea level of the plasma exceeds 100 mg. per 100 cc.; above 200 mg. it diminishes diuresis and edema results (Gremels, 1938).

Toxic Actions.—No effects are perceptible if the urea nitrogen of the blood is below 45 mg. per 100 cc. Loss of appetite, nausea and vomiting develop about 70 mg. (J. H. Crawford and McIntosh, 1925). Hewlett *et al.*, 1916, found that the administration of 100 Gm. of urea by mouth to man increases the blood urea to 160 to 245 mg. per 100 cc. in a few hours. This is accompanied by prostration, apathy and somnolence, symptoms resembling those that occur in pure retention uremia, when the blood urea rises to 100 to 200 mg. per 100 cc. However, nephritis may not show any uremic symptoms with 255 mg. (McLean, 1917). *Intravenous injection* of urea, 0.1 to 3.2 Gm. per Kg., in dogs causes immediate marked fall of blood pressure with cardiac slowing, followed by prolonged moderate rise of pressure, increase of heart rate and polyuria. These effects are attributed to direct stimulation of the medullary vasomotor and cardiac centers (Popesco, 1939).

Urea in the Treatment of Infected Wounds.—The strongly proteolytic action of urea, described by K. Spiro, 1900, and W. Ransdem, 1902, suggested the liberal application of urea crystals, or a saturated aqueous solution, against the foul odor of cancer (W. M. Millar, 1932), and then to other septic wounds. It deodorizes, hastens healing and does not irritate the surrounding tissue (Holder and McKay, 1937). Urea delays or hinders the clotting of blood by a solvent effect on fibrin (Foulger and Mills). It accelerates peptic and tryptic digestion *in vitro* (optimal concentration about 15 per cent), probably by an action on the protein substrate (McCawley and Gurchot, 1940).

Urea, U.S.P. (*Carbamide*), $CO(NH_2)_2$; freely soluble in water (1 Gm. in 1.5 cc.). Dose, 0.5 to 8 Gm. in solution or cachets, to a total of 15 to 60 Gm. per day for three to five days, when it should be omitted for a few days, and then repeated if necessary (H. R. Miller and Feldman, 1932). It should be taken in water, after meals, when it is not likely to cause nausea. Fantus recommends Syrup of Acacia to disguise the taste.

◆

CALCIUM SALTS

The insoluble calcium phosphate and carbonate serve to give hardness to the bones and teeth. Their deficiency is one of the important phenomena of rickets and osteomalacia. Pathologic calcifications of arteries and other tissues are phenomena of degeneration; their mechansim is not understood.

The soluble Ca ions are present in all tissues, and appear to be essential to the proper permeability of the plasma membrane. Excess of Ca is depressant to most nervous and muscular functions, and is antagonistic to Mg and Na. These systemic actions are produced only on excised tissue or with intravenous injection, since the absorption of Ca is slow. It has been tried, with only partial success, in various spasmodic conditions. Acute deficiency of Ca produces stimulation of these structures, most conspicuously of the central nervous system. This is seen in poisoning by oxalates, which precipitate Ca. It may also be produced by the intravenous injection of citrates or tartrates which decrease the ionization of Ca. Calcium is necessary for the coagulation of blood and for the typical clotting of milk. Calcium salts have therefore been administered in hemorrhagic conditions; but since these are not due to deficiency of Ca, the additional Ca has no effect. Calcium seems to decrease the permeability of blood and lymph vessels, and thereby to lessen exudation. It has been used against serum rashes and urticaria with variable success. Calcium chloride renders the urine acid. Calcium carbonate (chalk) is employed in diarrheas, mainly as antacid and protective. Lime water (solution of calcium hydroxide) is added to milk to increase its alkalinity. Calcium oxide, quicklime, is a slowly acting caustic, and is used as disinfectant, as is also the hydroxide or slaked lime. Calcium sulfate, plaster of

Paris, is important for its mechanical properties. The calcium salts are also used for the actions of their anions (bromide, and so forth).

The **calcium content of the body** averages about 3.8 pounds in human adults, about 99 per cent of this in the skeleton, $99\frac{1}{3}$ per cent in adult rats, and not below 98.9 per cent in immature rats raised on calcium-poor food (Bessey, King *et al.*, 1935).

The **daily requirement of calcium** for man is estimated as 0.5 to 1.5 Gm. It varies with growth and age, pregnancy and lactation; but 0.9 Gm. may be accepted as fully meeting the usual requirements of adults. The optimum probably lies above this, but is difficult to judge, as effects on growth, longevity and fertility extend over long periods, even over several generations (Sherman, Campbell and Lanford, 1938).

Adults require the daily consumption of 450 to 900 mg., averaging 750 mg., to maintain calcium equilibrium. About 300 mg. of this are not absorbed, so that the actual "stream" is about 450 mg. per day (J. Outhouse *et al.*, 1941). Childhood requires retention of Ca and of P for bone growth. The required *retention* has been estimated as 0.3 Gm. per day of Ca at one year, rising gradually to 0.5 Gm. at adolescence (Leitsch, 1937); the required *income* of children as 1.2 Gm. per day, of adults as 0.5 Gm. Older men require 0.5 Gm. of Ca and 1.2 Gm. of P per day for equilibrium (E. C. Owen, 1939). The urinary excretion of Ca of adults is remarkably constant, about 0.5 Gm., although the income varies widely (Buttner, 1939).

The **daily income of calcium,** with ordinary American diets, ranges from 0.08 to 1.7 Gm., averaging 0.85. The average is barely adequate for ordinary requirements, and would be inadequate in pregnancy and lactation. It is easily increased by drinking milk, or by diluting the table salt with an equal amount of chalk (McCollum, 1919). The entire daily requirement of 0.9 Gm. is supplied by 1 quart of milk, but would need pounds of meat or cereals. It is not generally realized that milk usually contains more calcium than does lime water (Sherman *et al.*, 1918).

A quart of milk furnishes 1.2 Gm. of calcium and 0.9 Gm. of phosphorus. The phosphate content in cow's milk is considerably higher than in human milk, both absolutely and in relation to calcium (G. Stearns, 1939). The calcium of milk seems to be more favorably retained than calcium lactate (Givens and Mendel, 1917). The utilization of the calcium of milk products averages about 29 per cent (F. R. Steggerda and Mitchell, 1941). Meat ranks next to milk in the diet as a Ca source (Krane, 1927). H. N. Green and Mellanby, 1928, reported that *wheat and other cereals* have a decalcifying effect on animals fed with a diet deficient in vitamin D; but their results may be explained by the Ca and P content of their diet. The calcium of refined flour is utilized better by man than that of whole wheat flour; the phytic acid of the bran appears to interfere with the absorption (R. A. McCance and Widdowson, 1942). Inorganic calcium salts supply the calcium needs as well as do natural foods (Osborne and Mendel, 1918).

The *appetite for calcium* (when rats are given access to calcium lactate solutions) is a sensitive index of substances that affect the calcium concentration of the blood: It increases greatly when the level is lowered by parathyroidectomy, and is decreased by dihydrotachysterol, within twenty-four hours (C. P. Richter and Birmingham, 1941).

The availability of the ingested calcium and phosphate is decreased by substances which tend to precipitate either, and is favored by those that keep them in solution. The proportion of total ingested calcium which is absorbed varies with individuals and in species (review, M. A. Logan, 1940).

For *foods*, it is said to vary directly with the Ca:P ratio, and is better for meats than for vegetables (Orr *et al.*, 1928). The calcium of carrots and spinach is poorly utilized (by growing rats), and the calcium oxalate of vegetables is completely unutilizable (McClugage and Mendel, 1918; Fairbanks and Mitchell, 1938). Feeding with cabbage tends to raise the blood calcium, and bran and oats lower it (Orr *et al.*, 1928).

The *solubility and absorbability of the chemical compounds of calcium in the gastro-intestinal tract* vary with the reaction: those that contain ionized calcium, including the bicarbonate and acid phosphate, are soluble when the reaction is acid, and are precipitated as basic salts when the reaction turns toward alkaline. They therefore tend to dissolve in the acid stomach and then remain in solution, or are precipitated at various levels of the small intestines, and are absorbed or not, accordingly. Organic calcium compounds are less subject to alkali precipitation.

Practically, the form and solubility of calcium employed make little difference in their availability, except at critical levels of vitamin D income, when calcium lactate gave better results than the difficultly soluble calcium silicate (Deobald, Elvehjem *et al.*, 1936). Rats on slightly low Ca and P income generally utilized *dicalcium phosphate* somewhat better than the tricalcic, but the difference is so small that it could only be detected under marginal conditions (Rottenstein and Maynard, 1934). In *achylia gastrica*, the absorption curve of calcium lactate or gluconate runs practically normal, and is but slightly increased by administering hydrochloric acid (J. P. Quigley, Einsel and Mull, 1936).

The excretion of calcium varies with the diet (Kochmann, 1919). Nelson and Williams, 1916, found the average daily excretion by urine and feces in man to total 0.31 to 0.73 Gm. of Ca (all ages, unrestricted diet); 0.11 to 0.36 Gm. per day is excreted by the urine, mainly as phosphate; the remainder leaves by the feces, also as phosphate, representing chiefly unabsorbed calcium. It is believed (E. Voit, 1880) that a part of the fecal Ca is absorbed by the small intestines and reexcreted by the large; but no substantial amount is excreted by the human colon (C. S. Welch *et al.*, 1936).

The amount of calcium circulated daily from the blood into the intestinal lumen and then reabsorbed into the blood may be as large as the amount absorbed from the food. The effect of acid on the excretion of calcium is appreciable but minor (it is more important in rabbits). *Ketosis* increases the urinary calcium excretion (review, M. A. Logan, 1940).

With *hypodermic injection* of calcium salts, a large part is excreted promptly by the urine, a small proportion being temporarily retained. The intestines do not always participate in the excretion. The output of Mg is also increased (Mendel and Benedict, 1909). *Intravenously injected* calcium disappears promptly from the blood, and is rapidly, but not quantitatively, excreted, chiefly by the intestines.

Calcium retention and depletion depend not only on the income, but chiefly on absorption from the intestinal tract as influenced by various conditions, including the calcium store, acid-base balance, lactation, magnesium income and various hormones, especially the parathyroid and thyroid.

Growth requires calcium retention. In preschool children, this is usually at the rate of 6 to 10 mg. per day, regardless of the ingested amount within wide limits (A. L. Daniels, Hutton *et al.*, 1935). Mendel and Osborne, 1917, found that rats require considerable calcium and phosphate for growth. The *administration of Ca* (chloride or lactate, several grams per day) increases the Ca stock of the tissues and blood, even in well fed adults (Voorhoeve, 1911 and 1913); but for a given income of Ca, the rate of Ca retention is determined by the degree to which the skeleton is already saturated with Ca; low saturation tends to favor retention (Fairbanks and Mitchell, 1936). *Acidosis* depletes the calcium of the bones and causes increased excretion (Underhill, 1916). This holds also for acid-ash food (bran and oats), while basic-ash food (cabbage) tends to retention and increase of the plasma Ca level (Orr *et al.*, 1928). Oral administration of hydrochloric acid increases the urinary excretion of Ca and Mg (Stehle, 1917). Alkalis do not decrease the urinary Ca output in human diabetes (Givens and Mendel, 1917).

The *relations of magnesium and calcium excretion* appear complex. In human urine, either Ca or Mg may predominate, this being fairly constant for the individual, and largely independent of the food (Nelson and Burns, 1916). The administration of soluble Mg salts increases the urinary excretion of Ca, but not if phosphates are present in the alimentary canal (Hart and Steenbock, 1912). Becka, 1929, reported that $MgCl_2$ caused primary retention of Ca, followed by increased urinary excretion; that $MgSO_4$ caused loss of Ca by the feces; and $Mg(OH)_2$ caused retention. *Lactation* depletes the Ca stock, in cows, even when Ca is added to the food (Forbes *et al.*, 1917). *Hyperthyroidism* increases Ca excretion, by feces and urine, more than any other condition, so that the output may be four or five times the normal; it is lowered in thyroid deficiency. The serum calcium level is normal in both conditions (Aub, 1937), but Graves' disease causes a marked negative calcium balance, with decalcification of the bones, especially the spine. The *parathyroid relation* will be discussed in a separate section.

Calcium Content of Blood.—The corpuscles contain little calcium, so that there is a marked difference between the calcium content of the whole blood and that of the serum. The calcium concentration of human erythrocytes is 0.1 to 1.4, average 0.2 milliequivalents per liter (Hald and Eisenman, 1937); that of the serum or plasma, on the other hand, is remarkably uniform, 4.5 to 5.7, average 5.2 milliequivalents per liter (E. Kirk *et al.*, 1935), between 9 and 11 mg. of Ca per 100 cc. even in most pathological conditions (Halverson *et al.*, 1917). It is not easily altered, except temporarily, because the plasma is saturated with calcium, for normal conditions, and is kept so by the precipitation of any excess as phosphate; and by the replenishment of any deficiency through solution of the calcium of trabecular bone, which acts as reservoir. The solubility of calcium in the plasma is determined by the ratio of carbonate and phosphate, and by the *p*H, increase of carbonate and acidity being solvent, excess phosphate and alkalinity being precipitant. Brief alterations of these conditions may be produced by the injection of calcium salts, more lasting alterations by viosterol and parathyroid hormone, and by their deficiency.

Calcium gluconate, administered by mouth in the clinical dosage of 2 Gm. in 20 cc. of water, raises the Ca level of the serum to a peak level of 15 mg. per 100 cc. in about four hours, returning to normal in about the twelfth hour. With intramuscular injection, the same dose reaches a peak of 19 mg. in an hour, and the normal in the eighth hour (Lieberman, 1931).

The Condition of Calcium in the Blood Plasma.—Of the normal 9 to 11 mg. per 100 cc., about half to two-thirds (5 to 6 mg.) is *diffusible; i. e.*, it is in diffusion equilibrium with solutions of ionizable calcium salts of this concentration (Rona and Takahashi, 1911). The ultrafiltrate of serum also contains about half of the calcium. Determination of the calcium ion content of serum and other fluids by the effect on the isolated frog heart also corresponds to about 5 mg. per 100 cc., so that this part of the calcium may be considered as ionized (McLean and Hastings, 1935). The remaining third to half, which is *not diffusible* or ultrafiltrable, exists almost entirely as protein salts and is ordinarliy proportional to the protein concentration (Salveson and Linder, 1923).

An insignificant part of the calcium exists as diffusible nonionized compounds, similar to the calcium-sodium citrate. None of the indiffusible calcium appears to be in lipid combination, for none is extracted by ether; nor in combination with phosphate, for all the serum phosphate is filtrable (Grollman, 1927). The distinction between diffusible and nondiffusible calcium is not sharp, for the protein salts furnish ionized calcium, and vice versa, if the equilibrium is disturbed by lowering or increasing the total calcium content.

The entire calcium of serum diffuses into isotonic sodium chloride solution, and 90 per cent is precipitated by m/320 oxalate. About 5 per cent of the calcium of the plasma is in nonionized but diffusible form (Logan, 1940). Moderate increase of serum calcium by intravenous injection of small amounts of calcium salts, or by parathyroid administration, is almost exclusively in the diffusible fraction; but larger increases extend also to the nondiffusible (Greenberg and Tufts, 1934). The normal ratio is restored in one or two days (Moritz, 1926). In the protein-poor *cerebrospinal fluid*, the calcium (5 mg. per 100 cc.) is practically entirely diffusible (Salveson and Linder) and corresponds to the ionized calcium of the serum (McLean and Hastings). The calcium of *milk*, which is about ten times as high as in blood plasma, exists about a fourth as undissociated calcium caseinate, and three-fourths as colloidal calcium phosphate (N. C. Wright, 1928).

Organic Calcium Complexes.—Ca, Ba and Sr form reversible nonionized molecules with many organic acids, such as citric, tartaric, succinic, lactic, acetic, phthalic, benzoic and salicylic. These do not produce the calcium ion effects, for instance on frog heart (N. R. Jacobs, 1946).

Effects of Phosphate on Calcium Solubility.—The ionized calcium of the plasma is balanced by Cl′, HCO'_3 and HPO''_4 anions. The solubility of the bicarbonate, which is probably the chief form (Halverson *et al.*, 1917), is limited, and the phosphate is even less soluble. The solubility, that of the phosphate especially, decreases by the formation of basic carbonate and phosphate, if the H ion concentration is lowered. The plasma is ordinarily fairly saturated with calcium for the existing conditions. In Ringer's solutions buffered with bicarbonate and phosphate in imitation of the plasma, calcium phosphate is precipitated by aeration, which removes CO_2 and tends to render the solution more alkaline; or by increasing the proportion of phosphate ions (Sollmann, von Oettingen and Ishikawa, 1928). Corresponding conditions tend to lower the calcium concentration of the plasma and vice versa. The calcium changes of parathyroid hormone, *f. i.*, seem to be secondary to changes in the plasma phosphate level.

Detailed studies of the reactions of alkali carbonates with calcium phosphates have been made by H. J. Wichmann, 1943. PO_4 increases the solubility of $CaCO_3$; HCO_3 increases the solubility of calcium phosphates (I. Greenwald, 1945).

Addition of sodium phosphate to serum *in vitro* lowers the calcium in solution by the formation of a colloidal complex of Ca and PO_4. This occurs also on intravenous injection and even on oral administration of soluble phosphates (F. C. McLean and Hinricks, 1938). The colloidal calcium phosphate is quickly removed from the circulation by phagocytosis in the liver and spleen (Gersh, 1938). Even tertiary calcium phosphate, $Ca_3(PO_4)_2$, which is practically insoluble in water, precipitates calcium carbonate from serum (Sendroy and Hastings, 1927). On the other hand, unsaturation of calcium, *f. i.*, by acidosis or by decrease of phosphate, would be made good by solution of the calcium stores of the bone trabeculae. *Calcification*, on the other hand, is probably due to local increase of phosphate ions, liberated from lecithin by phosphatase at the site of calcification (Robison). Sodium hexametaphosphate disionizes calcium without precipitation. The addition of *citrates* disionizes calcium, as shown by conductivity measurements, as well as by the masking of the ordinary calcium reactions. Acetates and lactates do not have this effect (Shear, Kramer and Resnikoff, 1929). *Naphuride* (Germanin) also disionizes calcium by forming a complex, and so prevents blood coagulation (Mulli *et al.*, 1933).

Disturbances of the plasma calcium level are characteristic for several pathologic conditions. In *rickets* there is a slight but distinct decrease (Howland and Marriott, 1917). In *tetany*, the plasma calcium falls to 3 to 5 mg. per 100 cc. This is counteracted by measures that increase the acid-alkali balance of the body, *i. e.*, by the administration of acids, ammonium chloride or calcium chloride. The calcium level of the blood may be materially raised by the injection of the parathyroid hormone; the level falls if the parathyroids are excised. *Hyperglycemia*, diabetic or by dextrose injection, tends to raise the plasma Ca by decreasing the inorganic phosphate of the plasma (by synthesis of phosphate ester).

Calcium chloride injections prevent the glycosuria and fever of NaCl injections, but large doses of $CaCl_2$ may themselves produce glycosuria (Underhill and Kleiner, 1908). In *phlorhizin glycosuria,* Jacoby and Rosenbloom, 1915, found that large doses of calcium diminish the excretion of sugar, nitrogen and acetone. The blood sugar is also lowered, so that presumably the production of sugar is diminished. *Calcium therapy in phthisis* was recommended by Fourcroy, 1783. It has been tried repeatedly, on the assumption that phthisis is accompanied by excessive excretion of calcium. This has been affirmed by some competent observers, but does not appear to be an invariable phenomenon (Kahn, 1914). Mohler and Bergeim, 1917, found no characteristic changes. The clinical reports are too discordant to justify faith in this treatment. The intravenous injection of 5 cc. of 5 per cent calcium chloride against *intestinal tuberculosis* was introduced by Saxtorph, 1918. According to Fishberg, 1919, it relieves the diarrhea and pain in minor grades. It is ineffective in the severer grades, and is at best only palliative. The plasma phosphate is reported normal in *asthmatic conditions* (Criep and McElroy, 1928, 167 patients) and after *splenectomy* or injection of spleen extract (Underhill and Gross, 1929; contradicting Hall and Abderhalden). Moraczewski, 1900, claimed considerable loss of Ca in *pernicious anemia.*

Functional Variations in the Plasma-Calcium Level.—*Age,* between twenty and ninety years, does not show any correlations (Kirk, Lewis and Thompson, 1935). *Pregnant women* show a slight decline of the plasma Ca level from 10.4 to 9.9 mg. at eight weeks before term, with recovery to 10.0 mg. by term. This is maintained even with nursing, to dismissal at six weeks post partum. The plasma phosphate shows nearly parallel changes during gestation, with a marked rise after delivery. The phosphatase is generally within the normal range to the seventh month, then increases progressively to 80 per cent above the normal in the last month. The *fetal blood* has distinctly higher levels of Ca and P than the maternal blood drawn at the same time. The serum Ca at birth is usually 11 to 13 mg. per cent (G. Stearns, 1939) and drops distinctly during the first four days after delivery, then rises slightly above the average of later infancy (Mull and Bill, 1934; Mull, 1936; Bodansky, 1939; Denzer *et al.,* 1939). In *cows,* Meigs, Blatherwick and Cary, 1919, found the plasma calcium between 8.6 and 11 mg. per 100 Gm., practically unaffected by pregnancy, lactation or considerable changes of diet (in very young calves, however, it is higher, up to 13.7 mg. per cent). Emmerich and Loew, 1915, observed that administration of calcium to female mice, guinea pigs and rabbits was followed by increased *fertility,* a greater number of pregnancies and higher averages of the feti. The *depletion* of the mother's body during pregnancy amounts to 6 per cent of the total calcium, in rats (Mull, 1936). Lactation causes 2 to 28 per cent decrease of the body calcium, practically all derived from the skeleton (H. C. Sherman and McLeod, 1925). The Ca and PO_4 of the fetus do not come from the *teeth,* and these show no more change than in parallel observations of nonpregnant women (Mull, Bill and Kinney, 1934).

Egg shell formation in birds requires large amounts of calcium carbonate, about a kilogram per hen in the laying season. About 5 Gm. of $CaCO_3$ are deposited in the shell by the cells in direct contact with the egg. The deposition begins as soon as the egg reaches the uterus, and continues during most of the twenty to twenty-four hours' sojourn of the hen egg, the shell being quite rigid about thirteen hours before laying. Phosphatase does not appear involved in the deposition, as the alkaline phosphatase content of these shell glands is low (M. S. Gutowska *et al.,* 1943). Carbonic anhydrase appears essential, for egg shell formation is arrested by sulfanilamide, which inhibits carbonic anhydrase (Keilin and Mann, 1944), and not by sulfapyridine, which lacks this effect (Benesh, Barron and Mawson, 1944); but R. Bernard and Genest, 1945, consider the evidence inconclusive. The blood serum calcium level of laying hens is two or three times higher than that of nonlaying hens or of males (review, R. M. Conrad and Scott, 1938). A similar rise occurs in ovulating pigeons, beginning some days before egg shell secretion starts. The calcium is supplied both from the food and from the skeleton. The addition of calcium salts to the ordinary feed of pigeons does not materially influence the amount of calcium in the egg shells, but egg laying ceases if the food calcium is deficient (review, W. U. Gardner and Pfeiffer, 1943). Abrupt withdrawal of calcium from the diet of laying hens lowered their bone ash by 10 per cent, and the shells had only 25 per cent of the normal ash content (Deobald *et al.,* 1936). Injection of *estrogenic hormones* into birds raises their serum calcium level and accelerates formation of endosteal bone, probably by stimulation of the osteoblasts and not by calcium increase (review, W. U. Gardner and Pfeiffer, 1943).

Distribution of Ca in Cells.—Calcium is present in practically all cells and tissues. Only a few of the lower fungi are able to live without it. The calcium (also magnesium) is concentrated in the nucleus, the cell membrane, the anisotropic discs of striated muscles, the zymogen granules of the pancreas, and definite locations of some epithelial cells. It appears to be nondiffusible, presumably bound to proteins (G. H. Scott, 1943). Animal cells are covered with a protein-like coating which is stiffened by calcium. The essential plasma membrane is within this coating and does not require calcium for its maintenance (R. Chambers, 1942). *Red blood cells* contain calcium in all mammals studied, as well as in man. The content of human corpuscles is about 1.6 mg. per 100 Gm., about a third to a half of their Na content (Streef, 1938). The calcium content of *skeletal muscle,* in animals on normal Ca intake, does not increase when the Ca or vitamin D income is increased. Tetany (in kittens) is not preceded by significant change in the muscle calcium; nor are guanidine convulsions in rabbits. Parathyroid excision gave variable results (Burns, 1933). In mammalian *smooth muscle,* the calcium and magnesium are almost entirely within the muscle cells, little in the tissue spaces (G. H. Scott, 1940; electron microscope). *In the skin,* calcium is more abundant in the epidermis than in the cutis, as is also potassium (Kooyeman, 1935).

Calcium in Bone.—Normal mature bone contains somewhat less than half its weight of water, and fat up to 25 per cent. Of dog fat-free bone, 30 to 40 per cent is organic, the remainder inorganic, consisting practically entirely of $Ca_3(PO_4)_2$ and $CaCO_3$, generally in the ratio of $\frac{1}{2}$–3:1, generally 3:1. This corresponds to the *apatite* group of minerals (Hoppe-Seyler), either $3Ca_3(PO_4)_2 . CaCO_3$; or $3Ca_3(PO_4)_2 . Ca(OH)_2$, with some $CaCO_3$. The evidence is not decisive, but probably both are present- and other ions may take the place of the $(OH)_2$, for instance fluoride, giving "*multiple apatites,*" $nCa_3(PO_4)_2$ CaX'', where X″ may be O, Cl_2, SO_4, CO_3, F_2, and so forth, or mixtures of these (Taylor and Sheard, 1933).

Calcium Phosphates.—Primary calcium phosphate $Ca(H_2PO_4)_2$, is very soluble, but does not exist at the *p*H range of animal fluids. Secondary calcium phosphate, $CaHPO_4$, and the tertiary phosphate, $Ca_3(PO_4)_2$, are difficultly soluble, but hydrolyze readily to form hydroxy apatite $3Ca_3(PO_4)_2 \cdot Ca(OH)_2$ (Bassett), which is a stable solid phase over a wide range of *p*H of biologic significance (Huggins, 1937, review). Blood plasma is practically saturated with calcium bicarbonate and dicalcium phosphate (H. G. Wells, 1906). Serum dissolves 475 per cent more $CaCO_3$ than does water, and 90 per cent more $Ca_3(PO_4)_2$. This relatively high solvent power is due partly to the CO_2 tension, partly to the proteins, which act as protective colloids. Both may be readily altered, for instance by local changes of reaction, or by local autolysis of the proteins. The latter decreases the solubility of the phosphate more than that of the carbonate, so that the phosphate would be precipitated more readily. This agrees with the fact that bone contains about nine times as much of the phosphate as of the carbonate of calcium (Pauli and Samec, 1909). The precipitation of calcium in the presence of colloids was investigated by Sabbatani and Salvioli, 1912.

Bone Calcium.—The *ratio Ca:P::1:0.6* is nearly uniform in all bone, normal or pathological, including the bone of rickets and of phosphate deficiency. The *carbonate fraction* varies much more than the calcium phosphate. It increases with age (in rats and in cattle; Kramer and Shear, 1928; Neal, Palmer *et al.*, 1931). It is decreased in acidosis and increased in alkalosis (Huggins, review, 1937). *X-ray diffraction studies* of normal bone show the micellae arranged longitudinally in the shaft, but it is not certain whether this is due to crystalloids or to the collagen or ossein (J. H. Clark, 1931; Bogert and Hastings, 1931). This orientation is largely destroyed in rickets, probably by the breaking down of the collagen. On healing, inorganic micellae do not regain the regular orientation, and the bone remains weakened (G. L. Clark and Mrgudick, 1934). *Proper deposition of calcium in the formation of bone is* influenced by several factors: (1) endocrine glands, especially the parathyroid, thyroid, pituitary and sex glands; (2) vitamins, especially D and C; (3) the supply of Ca and PO_4; (4) acid-base balance (review, M. A. Logan, 1940). *Renovation of bone* goes on continuously, especially in the trabeculae. By feeding *radioactive P isotope,* Chievitz and Hevesy, 1935, determined that in adults some 30 per cent of the P atoms of the skeleton were removed and replaced in twenty days. The exchange is more lively when extra calcium is mobilized in pregnancy, lactation, acidosis, or by the parathyroid hormone (G. C. Hevesy *et al.*, 1940). On *intravenous injection of radioactive calcium or strontium lactate,* a third to a half is found in the skeleton after twenty-four hours. Their concentration in newformed bone may be a hundred times more than in soft tissues. It is highest in the roots of teeth and in trabecular bone, lowest in liver and fat (C. Pecher *et al.*, 1942). It has been suggested to use such radioactive injections in treating cancerous bone.

Radioactive carbonate, injected into rats as sodium or barium carbonate containing C^{14}, appears primarily in preexisting bone, rather than in the currently deposited bone, showing that the old bone entertains an active exchange. It does not decrease appreciably in the bone within four months, indicating that it may result in radiation bone lesions (W. Bloom *et al.*, 1947).

Feedings *dyes,* as alizarin and related anthraquinones (madder dye), stains new bone by forming calcium lakes, while old bone is but little stained. Lithium carmine and trypan blue stain the organic material of new bone, so that the color persists after decalcification of the specimens (review, C. Huggins, 1937).

Calcium-deficient diets stunt bone growth in young animals, and lead to a form of rickets. The bones contain about the normal percentage of lime; but little bone is laid down, and this is thin, pliable, deformed and fragile (E. Voit, 1889). It contains more water, Na and K, while the Mg is not materially increased. The percentages vary, however, in different parts of the skeleton. The animals are undersized, with poor appetite and defective nutrition (Weiser, 1914). *Low phosphate intake* decreases the ash content of bone; but the Ca:P ratio of bone is not materially altered by either Ca or P deficiency. In rabbits, the Ca content of the bones is increased by green food, diminished by exclusive *oat diet* (Luithlen, 1912). The "*decalcifying effect*" *of cereals* was also emphasized by E. Mellanby, 1926. It is probably due to faulty Ca:P ratio, for cereals are low in available phosphate, since 30 to 70 per cent of the P of grains exists as *phytin,* which is poorly utilized by man and by rats (Report of Committee on Foods, J.A.M.A., 1937, *109:* 30). *Sodium oxalate,* administered for a week, diminishes the Ca content of the soft tissues before it affects the bones (Sarvonat and Roubier, 1911). If this diet is rich in magnesium, the bones may accumulate double the normal Mg content, without improving the skeletal development. *Lactation* causes marked loss of bone calcium (Sherman and McLeod, 1925).

Storage of Other Metals in Bone.—Trabecular bone is the chief storage magazine of elements whose chemical properties resemble those of calcium. This has been demonstrated for lead, radium, thorium, polonium, and holds doubtless for strontium and barium. Bone and tooth are also the chief depositories for fluoride. Lead and the other bases are mobilized by the same agencies that mobilize the bone calcium, such as acidosis (ingestion of H_3PO_4 or NH_4Cl); and by the administration of parathyroid hormone (Hunter and Aub, 1927).

The calcium of teeth is also of the *apatite* model (Brekhus and Armstrong, 1934). That of the enamel is mostly of the calcium hydroxide form, with the Ca:P ratio of about 2:15; that of the dentine with 2.09 ratio, probably containing some $CaHPO_4$, more carbonate, and twice as much Mg as the enamel. Only traces of K, F or Si are found in either (Bowes and Murray, 1935; Armstrong, 1935). *Mature erupted teeth* are not affected in calcium content or in structure by changes of the calcium or phosphate income, of the general calcium metabolism, or by viosterol (Schour, 1938). The *phosphate metabolism* of developed teeth is small, requiring about eight months to exchange 1 per cent for radioactive isotope, and $\frac{1}{8}$ to $\frac{1}{10}$ per cent with the enamel (G. C. Hevesy and Armstrong, 1940). Unlike bone, neither dentine nor enamel functions as storehouses of calcium, and they are not subject to calcium withdrawal, for instance in pregnancy (Kinney, Mull and Bill, 1932), or on parathyroid administration. Tooth decay and caries are in no way connected with calcium metabolism; nor with the chemical solvent action of saliva (Brekhus and Armstrong, 1934). *Immature,* *growing and calcifying teeth* may easily be affected by changes in the calcium metabolism, by diet, vitamins and endocrines; and the changes initiated at this time may influence the resistance of the adult tooth. Most of the evidence is derived from the incisors of rats, which continue to grow throughout life; it is therefore questionable whether they can be transferred directly to the human. Schour, 1938, believed that they correlate well; the Committee on Dental Therapeutics (J. Am. Dent. Ass., 1936, *23:* 139) believes that there is no decisive evidence that the addition of Ca or PO_4 to a normal diet has any definite effect on the incidence of dental decay for adult, child or fetus. Since the calcification of human teeth is entirely postnatal, it would not be affected by the Ca or P income of the mother during gestation (A. F. Hess and Roman, 1932); but I. G. Macey *et al.*, 1930, reported that large doses of Vitamin D during pregnancy tend to promote tooth development and to prevent later caries. The density of enamel and dentine increases with age (review, J. A. Marshall, 1939).

Phosphatase.—The actual deposition of calcium in bones is apparently due to the local activity of phosphatase, which splits off inorganic phosphate from hexose phosphate and other phosphoric esters, such as glycerophosphate (Martland and Robison, 1924), thereby raising the PO_4 to the level where calcium phosphate is precipitated. This occurs *in vitro* when the Ca × P in the serum or Ringer's solution exceeds 30 mg. per 100 cc., practically regardless of the ratio of the two elements to each other. At this level calcium is deposited *in vitro* in ossifying rachitic cartilage (Shipley, Kramer and Howland, 1928). Slices of rachitic bone do not deposit calcium when laid in Tyrode solution with the Ca and PO_4 concentration of plasma, but addition of phosphate esters leads to marked calcification, resembling the normal healing of rickets. Addition of NaCl, KCl and especially of Mg (1 to 2 mg. per 100 cc.) necessitates higher concentrations of PO_4 and Ca in the Ringer solution (Shelling, Kramer and Orent, 1928). Addition of bicarbonate favors Ca deposition, indicating that the deposit is a Ca phosphate-bicarbonate salt. Protein and glucose raise the concentration of Ca necessary, probably by the disionization of Ca.

Phosphatase is widely *distributed* through the tissues in cartilage, kidneys, intestines and blood plasma, but its concentration is especially high in the ossifying centers of actively calcifying bone; for instance, epiphyseal junction contained forty-six times as much as costal cartilage (Robison). It rises rapidly at the site of fracture in broken bone, to eighty times the normal, and remains high till the repair is completed (W. E. Wilkins and Regen, 1935). Viosterol administration tends to lower the phosphatase content of the plasma, coincident with the rise in plasma calcium (Crimm and Strayer, 1936, 1937). The *phosphatase level of the blood serum* is increased in diseases of the bone, especially if osteoblastic activity is increased as in rickets, where it may rise to twenty times the normal. This increase is one of the earliest and most delicate signs of rickets, going fairly parallel with the progress of the disease and regressing with its cure. Increase of phosphatase also occurs in osteitis deformans and in jaundice (H. D. Kay, 1930; A. Bodansky, 1933).

There are *several phosphatases* grouped according to the reaction of their optimal activity, as alkaline about *p*H 9, and acid about *p*H 5. *Alkaline phosphatase* is by far the more widely distributed. It is the form concerned in the formation of osseous tissue and is probably involved in the absorption of dextrose from the intestines and its reabsorption from the renal tubules. Its activity is enhanced twenty- to forty-fold by Mg ions; that of acid phosphatase is not (Bamann and Riedel, 1934). *Acid phosphatase* occurs chiefly in the liver and kidneys, and is involved in glycolysis by acting on hexose phosphates. It is abundant in human prostatic secretion, being formed by normal and cancerous prostatic epithelium, and serves as an index of prostatic activity and therefore of androgen. It is increased in the blood serum of patients with bone metastases of prostatic carcinoma. Castration or administration of estrogens is used to inhibit this condition (Huggins, 1943).

Degenerative calcification is a common pathologic process, especially in connective tissue. The calcified areas are generally dead (except those that have the structure of bone). The lime deposits in the dead tissue have usually the same proportion of lime salts as bone, about 87 per cent of phosphate, and 10 to 15 per cent of carbonate. The mechanism of calcification is not understood. Wells (1906) found that certain substances, including dead cartilage, when introduced into the tissue of rabbits, accumulated rather large quantities of calcium, indicating a direct physical or chemical affinity. MacCordick, 1913, found the rigidity of *calcified arteries* different during life from after death, and therefore suggested that the Ca is in solution during life, and deposits in the plaques after death.

Rickets.—Disorders of the Ca and PO_4 equilibrium of the blood are responsible for rickets and osteomalacia. Clinical rickets is caused by deficiency of vitamin D (ultraviolet irradiation, or its product, viosterol), leading to defective bone calcification and various systemic disturbances, which may include spasmophilia if the plasma-calcium level is low. The percentage of mineral substances, and particularly the calcium phosphate in the abnormal proliferation bony tissue, is materially reduced, sometimes to half of the normal, but the Ca:P ratio remains practically unchanged. The immediate cause of rickets is a low Ca × P product in the plasma. Ordinary human rickets is "low P rickets," due to disturbance of the phosphate metabolism, and not of the calcium. The calcium income may be abundant (Stoelzner, 1899) and the Ca:P ratio of the diet may be normal; the absorption and excretion of calcium are practically normal (Ruedel, 1893); the calcium level of the blood is but little decreased (Howland and Marriott, 1917). The condition is prevented and cured by the antirachitic vitamin, by sunlight and by ultraviolet light. The administration of calcium salts has little effect (M. Klotz, 1915).

Ca × P Product of the Plasma and Body Fluids.—**Disorders of calcium and phosphate metabolism fall into**

three groups (Albright, Bauer *et al.*, 1931): (1) *Low Ca × P* results in failure to deposit calcium phosphate in the osteoid matrix, and produces rickets or osteomalacia. The C × P of human plasma is normally about 50 mg. per 100 cc., made up of about 10 mg. of Ca and 5 mg. of P. Active rickets develops if the product falls below 30; healing sets in when it rises to 40 and becomes complete above 50 (Howland and Kramer, 1922). In incomplete treatment, the P rises before the Ca is accommodated, resulting in lowering of the Ca (by precipitation?), giving "low Ca rickets" and spasmophilia (Gerstenberger). (2) *Ca × P product above normal* occurs in viosterol poisoning. Calcium phosphate is deposited in tissues other than bone. (3) *Normal Ca × P product* with abnormal Ca:P occurs in parathyroid deficiency or excess.

Calcium and Phosphate Excretion.—In clinical rickets, the fecal excretion of calcium is increased, the urinary decreased. The fecal phosphate excretion is markedly increased (Shohl, 1938).

Rat rickets resembles human rickets closely as to the histologic picture, the low P:Ca ratio and the curability by vitamin D or ultraviolet light. They differ in that rickets develops in rats only if there is a great disproportion in the Ca:P income, in addition to the vitamin D deficiency (McCollum *et al.*, 1921). There are some further differences of minor significance (Shohl, review). *Salts of other earths and metals* (Be, Mg, Sr, Fe, Pb, Tl), which hinder adequate utilization of Ca or P (Rehm and Winters, 1940, ferric chloride), cause rickets in rats (McCollum *et al.*, 1921) and in puppies. J. H. Jones, 1935, reported that beryllium rickets of puppies is not prevented by vitamin D. Manganese also produces rickets in rats on low P:high Ca diet, which is cured by vitamin D only if the diet is made optimal in Ca and P (Blumberg, Shelling and Jackson, 1938). *Puppies*, like children and unlike rats, develop rickets on vitamin D deficiency without great distortion of diet; if the vitamin D deficient diet of dogs contains a normal P:Ca ratio, osteoporosis results; if it is alkaline, it gives paradentosis; if it is low in Ca, it gives paradentosis and osteitis fibrosa (A. F. Morgan, 1934). In *osteomalacia*, the bone contains but 20 to 40 per cent, instead of the normal 56 to 60 per cent of inorganic salts, their place being taken by new-formed osteoid tissue. The condition is due to excessive destruction of bone tissue and may occur with high Ca and PO_4 income. Limbeck, 1894, found the excretion of Ca, especially by the intestines, to exceed the income. Neumann, 1896, also found the excretion high, especially in the early stages, when the Ca of the bones is still high. The later stages may show retention. Vitamin D changes the balance of Ca and P to positive, but large doses are necessary (Blumgart *et al.*). *Infantile scurvy* shows a decided decrease of blood calcium, although not so much as in rickets. This is associated with slight acidosis. There is no tendency to tetany (A. F. Hess, 1919).

Systemic Actions.—Calcium ions are important for the irritability of the nervous and muscular systems, somatic and autonomic. Their effects are complex, depending largely on the Ca:K ratio, and are modified by the Na and H ion concentration. In general, predominance of Ca resembles parasympathetic, and of K, sympathetic stimulation, but not always. Ca quiets activity so as to render it more regular and vigorous, with longer survival of excised organs. Excess of Ca ion depresses, deficiency exaggerates, excitability; both modify the responses to stimulation by drugs or other means, but the details vary for different tissues. Intact animals also are depressed by excessive Ca concentration of the plasma, whether it is induced acutely by injecting calcium salts, or more slowly and persistently by parathyroid hormone; conversely, decrease of the Ca ion concentration of the plasma, by parathyroid deficiency, or by the injection of the anions (oxalate, and so forth) that disionize calcium, produces tetany and increased excitability of the autonomic system (vagus, depressor, and so on). Loss of total Ca by acute hemorrhage does not have this effect (Schafir, 1915), since it does not lower the calcium concentration of the plasma. Calcium ions are essential in the *coagulation of blood and of milk.* They appear to mitigate acute inflammation and edema. Calcium chloride renders the urine acid, by converting a large part of the Ca into insoluble basic phosphate in the intestines. Hypodermically, calcium chloride acts as a corrosive irritant. This is avoidable by the use of the less ionized organic salts, such as the gluconate, but even this is likely to lead to abscess formation in infants if it is injected intramuscularly (S. S. Lamm, 1945).

Calcium functions in the *extraneous coat of cells* in animals and plants. It stiffens the surface cytoplasm, and decreases the viscosity of the interior cytoplasm. In its absence the constituents disperse in the surrounding medium (M. E. Reid, 1943).

The *antagonism of Ca and Mg* has been discussed (see Index). It should be remembered that the actions of Ca are conditioned on the ratio of other ions. Thus, the intravenous injection of Ca which is depressant to normal animals, causes recovery of an animal anesthetized with Mg. Strontium does not have this effect (Meltzer, 1909).

Inactivation of Calcium.—The Ca in the body fluids, and presumably in the cells, can be rendered inactive by the introduction of precipitant anions, such as the oxalates or fluorides; or by decreasing its ionization with sodium citrate or tartrate (Sabbatani, 1902), or hexametaphosphate. In the isolated heart, the toxicity is greatest for citrate, then oxalate, then tartrate (Salant and Hecht, 1914). The inactivation produces the opposite effects from Ca, viz., excessive stimulation, convulsions, hypersensitiveness of the autonomic nerves and rhythmic contractions. These effects may be promptly removed by the addition of Ca and less efficiently by Sr and Mg (Starkenstein, 1914); but not by other cations, not even by those (Ba, and so forth) which precipitate the oxalate. The stimulation is therefore not due to the oxalate, and the like, as such, but to the inactivation of the Ca. This is confirmed by the observation that equimolecular solutions of the different inactivators have practically equivalent effects (Starkenstein). However, Salant and Hecht, 1914, found in perfusion of the isolated heart that calcium citrate or tartrate solutions act practically the same as equimolecular calcium chloride.

Toxic effects of calcium salts occur only with parenteral administration. This is used clinically in parathyroid tetany, most safely as the gluconate hypodermically.

Smaller injections, 0.06 to 0.09 Gm. of the chloride or acetate per Kg., in cats or dogs, are followed by characteristic impairment of the equilibrium and postural reflexes of the skeletal muscles. The intravenous "reactions" may be in part colloidal, owing to the formation of colloidal $Ca_3(PO_4)_2$ (Heubner, 1924). *Hypodermic injections* have similar, but much slower, actions. Animals die of central paralysis a few days after the hypodermic injection of 0.3 to 0.4 Gm. of $CaCl_2$ per kilogram. Oral administration does not produce these systemic effects.

Respiration.—Schlick, 1911, described apparent stimulation in anesthetized mammals. Haffner, 1913, found that this is indirect, because of failure of circulation from cardiac depression. The direct action is respiratory depression, which may be the cause of death. The *perfused respiatory center of frogs* is depressed by decrease of Ca, stimulated by absence or excess of Ca (Hooker, 1913). *Excised bronchial muscle* is constricted by Ca or Sr, though less than by Ba (Trendelenburg, 1912). Calcium arrests pituitary asthma (Kayser, 1914).

Circulation.—Slow intravenous injection of calcium chloride solution produces, successively, vagal bradycardia, ventricular arrhythmias, ventricular fibrillation, with only minor changes in the blood pressure, until terminal cardiac failure occurs rather suddenly (H. E. Hoff *et al.*, 1939; A. W. Winkler *et al.*, 1940). Small doses, intravenously, sometimes increase the blood pressure and heart rate slightly, by brief depression of the vagi; larger doses paralyze the vagi, but diminish the heart rate and blood pressure, by a mixed effect on the cardiac muscles and nerves (Cazzola, 1913). The small doses may considerably increase the output of the heart without changing the rate, *i. e.*, by increasing the amplitude (Rothberger and Winterberg, 1912).

Electrocardiograms are altered by the rapid injection of 10 cc. of 20 per cent calcium gluconate into the cubital vein in man. The heart rate is then markedly slowed. The T wave is almost flattened or inverted, also often the P wave. Occasionally subjects respond with premature ventricular beats, sinus arrhythmia and sinus arrest (K. Berliner, 1936). The effects of intravenous therapeutic doses are transitory. The earliest resemble vagus stimulation, but there may also be direct increase of the excitability of the ventricular muscle, foci of idiopathic ventricular contractions, and ventricular extrasystoles (N. E. Clarke, 1941). Slow intravenous injection of dilute calcium chloride into *dogs* produced successively: (1) At concentration of 15 to 65 mg. of Ca per 100 cc. of serum, slowing, often with changes of the T wave and AV conduction. (2) At 25 to 90 mg., acceleration, often ending in ventricular fibrillation. (3) At 70 to 190 mg., second slowing, with cardiac depression ending in arrest without ventricular fibrillation. Animals that survive the acute experiment may die later from unassigned causes (H. E. Hoff *et al.*, 1939). In anesthetized *rabbits*, intravenous injection of 10 per cent $CaCl_2$ at the rate of 2 to 6 cc. per minute, results in AV block, auricular fibrillation, ventricular extrasystoles and cardiac arrest. Atropine prevents the block and auricular fibrillation, but not the other irregularities. Amytal, in narcotic doses, suppresses the arrhythmias (H. E. Hoff and Nahum, 1937). *In complete heart block* injections of calcium (or barium) produce attacks of temporary arrhythmia and ventricular tachycardia, increasing to fibrillation. These attacks may be preceded by groups of powerful and rapid beats. The auricles are affected in the same sense, but not so greatly. The blood pressure rises (Van Egmond, 1913). In perfusion of the isolated fibrillating heart of dogs, increase of calcium dilates the *coronary vessels* (L. N. Katz and Lindner, 1919).

Cardiac Synergisms.—The calcium concentration of the blood modifies the circulatory reactions considerably to atropine, pilocarpine, and so on (Salant, 1924). The most important is a marked synergism with digitalis, which renders it dangerous to inject calcium solutions into digitalized patients.

Digatalis and Calcium Synergism.—O. Loewi, 1917, called attention to this danger. W. D. M. Lloyd, 1928, reported complete cardiac arrest from intravenous injection of 4 cc. of 10 per cent calcium chloride, resuscitated with epinephrine and cardiac massage. Two clinical deaths were reported by Bower and Mengle, 1936, who confirmed that the fatal intravenous dose of calcium gluconate for dogs is lowered 30 to 40 per cent by digitalization. La Barre and van Heerswynghels, 1939, found it lowered by a third in cats. Conversely, disionization of calcium by sodium hexametaphosphate restores chick hearts arrested by digitalis (Paff, 1940). In *perfused frog hearts*, absence of calcium from the perfusing fluid does not appear to interfere with the typical action of epinephrine, agaricin, saponin, strophanthin or veratrine.

Calcium on Heart Muscle.—On excised frog heart, Ca antagonizes both the toxic action of Na and the inhibitory action of K. *Deficiency of Ca* in Ringer's solution below 0.43 millimolar depresses the contractions, and absence of Ca promptly arrests them, through the predominance of the K ions. The effects are so rapid as to suggest that they must be exerted on the plasma membrane. *Other earthy metals*, Ba, Sr, Ca and radium emanations act similarly. Low concentrations increase the diastole, to diastolic standstill. Higher concentrations increase the systole to systolic standstill (Kionka, 1914). *Increase of Ca* above 0.43 millimolar has relatively little effect until the excess becomes large (A. J. Clark *et al.*, 1928). Segments of *turtle ventricle* are not materially affected by deficiency or excess of Ca (Chu and Sollmann). *Perfused cat heart* shows increased coronary flow when the Ca of the Locke solution is doubled. This is much greater than the slight increase in the height of the contractions, indicating dilatation of the coronary vessels (Mancke, 1930).

Cardiac Vagus.—The presence of Ca is necessary for the inhibitory activity of the vagus (Schiff; Busquet and Pachon, 1909), but apparently not for muscarine (O. Loewi, 1912). However, contradictory results are often obtained. With *perfused mammalian hearts, increase* of Ca to two or three times that of Locke's solution generally lowers the threshold of vagus excitability, but occasionally the effect is reversed. *Decrease* of Ca may raise or lower the excitability (Mandelstamm, 1927). With perfused *turtle* heart, deficiency or absence of Ca in the solution does not interfere with vagus excitability (Brine, 1917). With *frogs,* somewhat smaller concentration of Ca suffices in the presence of K (Hagan and Ormond, 1912). A moderate decrease of Ca increases the excitability of the vagus; excess of Ca diminishes the excitability (Cazzola, 1913). Similar phenomena are observed with the *pelvic and chorda tympani nerves* (O. Loewi, 1912). Increase of Ca also restores the irritability of the vagus when this has been *depressed by Mg* (Auer and Meltzer, 1909). The *vagus center* is stimulated by intravenous injection of calcium chloride, for section of the vagi prevents cardiac slowing on intravenous injection of calcium chloride in dogs (de Nito, 1928).

Blood Vessels.—Hooker, 1911, found that Ca perfusion dilates the vessels of the *frog.* Cow, 1911, found the sensitiveness of *mammalian* arterial rings to epinephrine and pituitary increased by absence of Ca; the reaction to barium was unaffected. *With perfused organs,* Hayashi, 1927, found Ca ions indispensable for vasoconstrictor action by digitalis glycosides, favorable for hydrastinine, indifferent for barium, antagonistic for epinephrine. With *perfused frogs,* deficiency of Ca in the fluid causes the *production of edema;* excess of Ca produces capillary constriction and arrests the flow (H. J. Hamburger, 1922). Hamburger advised a solution containing NaCl 0.6 + $CaCl_2$ (anhydrous) 0.0035 per cent. The *carotid sinus vasomotor reflex* is diminished by hypocalcemia (oxalate injection or parathyroid excision) and promptly restored by the injection of calcium (Heymans *et al.,* 1933).

Circulation-Time Test.—Intravenous injection of 3 to 5 cc. of 10 per cent calcium gluconate or chloride solution causes a sensation of heat which travels with the solution in the blood stream. It is first noted in the mouth, beginning normally ten to seventeen seconds after the injection (S. J. Goldberg, 1936).

Nerve Fibers.—The threshold for electric stimulation is raised by increase of Ca ions and lowered by their decrease, until sequences of impulses are discharged in response to the stimulus (Brink, Sjostrand and Bronk, 1939). If a motor nerve is placed in a decalcifying solution, rhythmic twitchings start in the muscle within five minutes, and increase to tetanus (J. Loeb, 1901).

Calcium Precipitants on Brain.—Direct application of calcium precipitants to the cerebrum stimulates the white matter and increases the excitability of the gray matter to electric stimulation (Maxwell, 1906).

Skeletal Muscle.—Excised frog muscle when immersed in NaCl solution develops rhythmical contractions, which are abolished by the addition of Ca (Sidney Ringer, 1883) and increased by sodium citrate or oxalate, which disionize the calcium. The antagonism is mutual. If the rhythmic contractions do not start in the decalcifying solution, they will generally do so when the muscle is removed to air or oil (J. Loeb, 1901). Calcium also abolishes the rhythmic contractions induced by guanidine, barium or physostigmine, and has some *curare action* (Joseph and Meltzer, 1911). S. W. Kuffler, 1944, claims that calcium deficiency first increases the sensitivity, then blocks the motor end plates, and that calcium excess depresses the electrical excitability of the muscle fiber near the end plates. *Rigor mortis* is hastened by the systemic administration of Ca, delayed by Mg (Meltzer and Auer, 1907). *Isolated fibers* of skeletal muscle shorten to a fourth of their length if their cut surface is exposed to dilute calcium chloride solution for two or three minutes. Naked *protoplasm* in general is clotted or jelled by low concentrations of calcium ions (Heilbrunn, 1940).

Use of Calcium in Convulsions.—The depressant action of calcium suggested its use in *strychnine poisoning,* but Fischer (1904) found it ineffective. Zanda (1902) obtained better results by dural injection, but the effective dose was so large as to be itself dangerous. Januschke and Masslow, 1914, concluded that even large doses of calcium have no direct inhibitory effect on experimental convulsions, whether cerebral, medullary or spinal. The apparently successful results of Januschke, 1913, and presumably those of Yogi, 1912, and other workers, are attributed to delayed absorption of the hypodermic injections of the convulsants, which results from previous calcium treatment. Beutner and Wastl, 1939, reported that injection of calcium chloride, 100 mg. per Kg., reduces materially the incidence of procaine convulsions in guinea pigs, but that calcium gluconate is ineffective. Calcium chloride administration controls the *tetany* arising from *parathyroid deficiency* or other causes (Netter, 1907; W. G. McCallum and Voegtlin, 1908; Kinnicutt, 1909). Goeppert advised 8 to 14 Gm. of calcium chloride daily, in doses of 1.5 to 2 Gm. The administration must be continuous, for spasms reappear if it is discontinued for twelve hours (M. Klotz, 1915). Gruenfelder, 1913, reported that *laryngospasm* and tetany are controlled more promptly by calcium bromide (2 Gm. per day) than by sodium bromide.

Smooth Muscle.—Absence of calcium suppresses the rhythmic contractions, which reappear when Ca is added (Buglia, 1911). Large excess of calcium is also depressant. Slight departures from the ordinary concentrations of the blood or Ringer's solution have little effect. The responses to intermediate changes are complex. Deficiency of calcium income is reported to cause hypotonicity of the colon (E. C. Roberston, 1938). For *excised intestine* of cats, Vanysek, 1914, stated that calcium chloride stimulates the circular and relaxes the longitudinal muscle. Auer and Meltzer, 1909, observed that the intravenous injection of Ca produces a maximal *miosis,* in which the pupil is irresponsive to sympathetic stimulation. The simultaneous exhibition of other drugs shows interesting complex phenomena. The miotic action appears to be due mainly to direct stimulation of the sphincter muscle fibers, and probably also of their nerve endings, supported by diminished irritability of the peripheral sympathetic mechanism. *Spasms of the urinary tract,* bladder, ureters, renal pelvis and calyx are often completely relieved clinically by intravenous injection of 10 cc. of 10 per cent calcium gluconate solution; it fails, however, in some patients, especially if the urine is alkaline or excessively acid (H. R. Trattner and Walzak, 1944). **Ciliary movement** in frog's pharynx is depressed by excess of calcium (S. Ishikawa and Ohzono, 1931).

Gastric secretion of dogs, when increased by histamine or vagus stimulation, is checked by intravenous injection of calcium lactate, 4.3 to 13 mg. per Kg. (R. Grant, 1941).

Effect on Effusions.—R. Chiari and Januschke, 1910 and 1911, reported that the hypodermic injection of Ca prevents the pleural effusion which ordinarily occurs after fatal doses of NaI, diphtheria toxin, thiosinamine, and so forth. It also prevented the inflammatory edema of the conjunctiva after oil of mustard or abrin; and the irritation of the skin by croton oil (Luithlen, 1913). It has been found similarly useful in various skin rashes. Some of these results were contradicted by Levy, 1911 and 1914. H. Gold, 1928, found that calcium chloride injection tends to prevent effusion after pleural injection of copper sulfate, but was unsuccessful against severer irritation. The effect of a dose lasts about a day. Fleischer, Hoyt and L. Loeb, 1909, found that $CaCl_2$, intravenously, decreases the elimination of injected saline fluids, not only by the kidneys, but to a lesser extent also by the intestines. It also causes some depression of intestinal absorption. On the other hand, it increases the tendency to peritoneal and pulmonary transudation. This is only partly due to interference with the kidney function, for the ascitic tendency is exaggerated by Ca even after nephrectomy. Yanagawa, 1916, did not obtain any effect on the *lymph flow;* but his observations were restricted to acute changes.

Mechanism of the Antiedemic Action.—Chiari and Januschke suggest that the Ca has a precipitant effect on the cement substance of the endothelium. Deltjen (1904) observed that small traces of calcium, strontium, barium and magnesium lessen the solvent action of distilled water on cells. Herbst found that sea urchin ova swell when Ca is removed, and shrink when it is added. Osterhout, 1911 and 1912, showed that $CaCl_2$ prevents the entrance of NaCl into spirogyra filaments, and that it renders the plasma membrane of kelp (laminaria) impermeable. Pfeffer, 1877, stated that calcium phosphate forms semipermeable membranes. These were investigated in further detail by Meigs, 1915. The changes in the appearance of fluorescein in the anterior chamber of the eye also indicate decreased permeability (G. Rosenow, 1916). *Phagocytosis* may play a part. H. J. Hamburger, 1910, found that therapeutic quantities hypodermically or by mouth, increase the ameboid movements of the leukocytes, and therefore chemotaxis and phagocytosis. This holds true for the leukocytes of rabbits as well as horses (de Haan, 1918); for bacteria as well as carbon. It requires the presence of serum, and the favorable concentration has a narrow range, which varies with conditions and for different organisms (Redden, 1918). On the other hand, Ikeda, 1916, reported that the migration of leukocytes from inflamed frog's mesentery is inhibited by calcium chloride.

Use of Calcium in Skin Rashes, Catarrhs, and Other Conditions.—Wright, 1896, claimed that the administration of calcium chloride tends to prevent the occurrence of serum rashes. Netter, 1907, also believed it useful in urticaria, acute edema, frost bite and pruritus. Other similar conditions said to be relieved by Ca are boils, erythema, lichen planus, hemoglobinuria, and so forth (Luff, 1909); hay fever and iodide coryza (Chiari and Januschke, 1911; Emmerich and Loew, 1915); asthma (Kayser, 1912, 1914). It often fails, even when continued for long periods, and the evidence for its value is not convincing. Large doses must be administered for some time, and even then the clinical benefits are uncertain. The susceptibility to experimental wheals (codeine) does not appear to be influenced by the Ca level of the plasma (Pilcher). Strong solution of $CaCl_2$ (10 per cent), applied to the scarified skin, raises an urticarial wheal (Pilcher and Sollmann, 1916).

Effects of Various Conditions on Skin Reactions.—Luithlen, 1911 to 1913, studying the reaction of the skin of cats to croton oil, found that this may be modified by Ca and oxalates; by different diets (suggesting that eczema may be a constitutional exaggeration of the reaction of the skin to normal irritation); and by the injection of serum, soluble starch and even mineral colloids, *i. e.*, silica.

Calcium in Blood Coagulation.—Ca is necessary for the action of thrombokinase on thrombogen (or for the conversion of prothrombin into thrombin: Howell, 1914) and hence for the coagulation of the blood. The coagulation of shed blood is prevented by the addition of 0.1 per cent of a soluble oxalate, or 0.4 per cent of a citrate or fluoride. The latter, however, also acts otherwise than on the calcium. Strontium and barium have the same effect as calcium, in a less degree (Ringer and Sainsbury, 1890).

The addition of calcium to plasma to a certain point increases its coagulability; an *excess of calcium* interferes with coagulation or inhibits it completely. It can then be restored by the addition of citrate (von Zarday, 1933). The *amount of oxalate or fluoride* required to prevent clotting is three or four times the stoichiometric equivalent of the calcium present in the blood (Thompson and Collip, 1932), and it appears necessary to have an excess of the calcium immobilizer to complete the disionization. *If thrombin is decalcified* by citrate or oxalate soon after its formation, it fails to clot fibrinogen solution; but if the thrombin has first aged for several hours, then decalcification does not prevent clotting; so that there appears to be a "calcium-containing intermediate," which changes to stable thrombin (J. H. Ferguson, 1937). With *hirudin plasma* the coagulation is further delayed by the addition of calcium (Hess, 1915).

Historical.—The influence of calcium on coagulation was not recognized till 1879 (Hammarsten and others); its indispensability was first shown by Arthus and Pagès, 1890. The inhibition of coagulation by plant juices, which is due to disionization of calcium, was described by Archibald Pitcairn, 1717 (Sollmann and von Oettingen, 1926).

Calcium administration has little if any effect on coagulation time, since the normal calcium concentration of the plasma is close to optimal.

Estimations of the coagulation time after administration of Ca have given contradictory results, owing partly to differences of technic, partly to the time when the observations were made. The experiments of Velden, 1913, indicate that the coagulability is indeed increased for a short time. This increase is also produced by equal quantities of NaCl, and is probably due to a local action on the alimentary canal. It does not last beyond twenty or thirty minutes and would therefore be useless. An hour after *intravenous injection of calcium chloride,* Kormos, 1933, found the plasma level of calcium, thrombin and fibrogen increased, and also higher sedimentation rates; the bleeding time, coagulation time and thrombocyte count were decreased. The changes began to regress in three hours and were gone in twenty-four hours. Intramuscular injection produced the same changes in less degree.

Calcium as hemostatic was tried clinically in operations usually attended with considerable or persistent hemorrhage, as in obstructed jaundice (Lee and Vincent, 1915), and in aneurysm purpura (Russel, 1907) and hemophilia (Wright, 1893); but since the calcium level is normal in these conditions, and therefore optimal, it is doubtful whether any good is accomplished. Indeed, the addition of calcium to hemophilic blood *in vitro* delays rather than hastens coagulation (Hess, 1915).

Coagulation of Milk.—Ca is necessary for the precipitation of the casinogen as casein. Its place may be taken by Sr and Ba (Harris, 1896).

Acid: Base Balance.—When calcium chloride is administered by mouth, a part reacts in the intestine with phosphate and carbonate to form insoluble basic salts which are excreted with the feces, leaving the unbalanced chloride ion to be absorbed, and thereby increasing the proportion of fixed acid in the body and the acidity of the urine (Haldane *et al.*, 1923). This acidity tends to dissolve and mobilize the bone calcium, so that the prolonged administration of large doses of calcium chloride to animals may actually produce rarefaction of bony tissue (Etienne, 1912).

Calcium lactate and gluconate have less of this acidifying effect, as their anions form feeble acids. *Calcium carbonate* is alkalizing. *Intravenous injection* of calcium is less effective, as only the part excreted into the intestines participates in the reactions. When calcium chloride is *added to serum in vitro*, it decreases the bicarbonate content by forming $CaCO_3$. This is not precipitated in the presence of the protein colloids, but is removed from the aqueous phase (Lipschitz, 1939). For *acidification of the urine*, 1 to 3 Gm. (15 to 45 grains) of calcium chloride are administered four times daily with meals. It may be prescribed as a 45 per cent solution, to be freely diluted. It is used as a diuretic, especially in cardiac edema if digitalis alone does not suffice (Goldring, 1929). Calcium lactate may be effective.

The *urine flow* tends to be increased, in normal individuals, presumably mainly by the acidosis. In perfusion of excised kidney, calcium decreases the vein and ureter flow (Sollmann), but this involves unphysiological concentrations. *In nephritis* (particularly glomerular), large doses of calcium chloride by mouth sometimes cause marked diuresis, but may be ineffective (Keith and Barrier, 1924). The diuresis may outlast the administration (Blum), so that it may be due to absorption of the nephritic edema, rather than to a renal action. Duenner, 1916, found that intravenous injection of calcium into rabbits converted subacute uranium nephritis into the acute form. In human nephritis, Jacoby and Eisner, 1913, found that calcium administration decreased the excretion of chloride, iodide and nitrogen. Abe, 1913, claimed that it prevents the increase of urate excretion by cinchophen. Hamburger found that the sugar retention of frog kidneys was conditioned on a narrow zone of calcium concentration.

Calcium Carbonate in Digestive Tract.—Precipitated calcium carbonate is used as an *abrasive tooth powder*. It is a sparingly soluble alkali, which neutralizes the gastric juice without rendering it actively alkaline. This is used against *hyperchlorhydria*, and to increase the base:acid balance of the body.

The *pH of saturated $CaCO_3$ solution* is 8.8; of $Ca(HCO_3)_2$, 5.98 to 6.2 (J. W. Williams and Chucka, 1927). *Calcium phosphate* also buffers gastric hyperacidity, but has little or no effect on the acid-base balance (none with basic phosphate, slight increase with acid phosphate). *Calcium chloride intravenously* (10 cc. of 10 per cent for man) increases the gastric acidity. This is inhibited by epinephrine, not by atropine (Petrovic, 1926).

Diarrhea tends to be relieved by calcium carbonate or calcium phosphate, 1 Gm. every two hours. They act chiefly as protective powders, analogous to bismuth, partly as antacid, and possibly by diminishing permeability. If prescribed in suspension, the Prepared Chalk is preferred, as it is more colloidal.

Intestinal Flora.—Rats on salt-poor diet develop diarrhea by the displacement of their normal intestinal flora, predominantly B. acidophilus, by the coli, proteus and streptococcus groups. The addition of Ca and PO_4 tends to restore the normal flora (Eppright, Valley and Smith, 1937).

Saline Cathartics.—Chiari, 1910, called attention to the fact that all the cathartic ions are antagonistic to Ca; this may explain their action, at least partly.

Oral Administration for Systemic Action.—Milk deserves preference for securing adequate calcium income; a pint furnishes 0.45 Gm. of Ca. If it is not feasible, calcium phosphate may take its place. Calcium carbonate and phosphate are absorbed almost as well as any of the calcium salts, since they are largely converted into soluble salts in the digestive tract (O. Loew, 1914). They should therefore serve as well for oral administration as the water-soluble chloride, lactate or gluconate, but as these happened to form the starting point of the modern calcium therapy, they are generally prescribed. The chloride is less costly, but its taste is more disagreeable. Fantus recommends syrup of acacia to disguise the taste. The single *oral dose* of the chloride is 0.5 to 1 Gm., 8 to 15 grains, in solution, with meals. *Calcium gluconate,* which contains 9.3 per cent of Ca, has the advantage of being practically tasteless by mouth, and nonirritant by hypodermic or intramuscular injection; its intravenous toxicity is about a fourth that of calcium chloride (Rothlin, 1927). The adult dose is 5 Gm. three times daily, by mouth; 1 Gm. on alternate days intramuscularly. Its solubility in water at room temperature is about 3 per cent.

Hypodermic administration has no material advantage. The gluconate or lactate is preferred to the more irritant chloride; at least, the chloride should not be used in concentrations above 1 or 2 per cent, or there will be indurations or sloughing (Wright, 1896; Seelig, 1925). The local injection of calcium chloride also breaks down the local resistance against bacterial infection, at the site of injection ("kataphylaxis"). This has been used to induce experimental infections (Bullock and Cramer, 1919; abscesses, Rossides, 1926). The concentration of the lactate should not exceed 5 per cent since stronger solutions solidify (Hugenholtz, 1915). The *hypodermic dose* of the lactate is 0.5 to 2 Gm. in 20 to 50 cc. of water. *Intravenous injections* are employed in spasmodic conditions; 2 to 4 Gm. of the chloride or lactate in a liter of normal saline, injected slowly. The chloride should not be injected intravenously in concentrations above 1 per cent (Seelig, 1925), lest the escape of the solution around the needle cause sloughing. The gluconate may be injected as 10 cc. of 10 per cent. *Calcium should not be injected into digitalized patients.*

The daily dose against serum rash is 0.75 to 1 Gm., beginning on the day of the antitoxin injection, and continuing for three days after the last injection (Netter, 1909). Against hay fever, hemorrhage, and so forth, 1 to 3 Gm. are given daily, commencing as early as possible and continuing for several weeks. This continued use does not seem to cause harm (Emmerich and Loew, 1913, 1915). The lactate may be given in double this dosage. Hypodermic and especially intravenous administration appear inadvisable.

PREPARATIONS.—***Precipitated Calcium Carbonate,** U.S.P. (Precipitated Chalk), $CaCO_3$, is a fine white powder, without odor or taste. Practically insol. in water; decomposed by acids. Dose, 1 Gm., 15 grains, as powder. This neutralizes 0.730 Gm. absolute HCl. Larger doses are harmless. ***Prepared Chalk,** U.S.P. (Creta Praeparata; Drop Chalk), is native *Calcium Carbonate* freed from most of its impurities by elutriation. A very fine, amorphous powder, often formed into cones.

Chalk Mixture, U.S.P. (Mistura Cretae), contains 6 per cent of Prepared Chalk, suspended in water with Bentonite clay, and flavored with saccharin and cinnamon. It must be recently prepared. Dose, 15 cc., 4 drachms. *Calcium Phosphate, Precipitated,* U.S.P. (Tribasic Calcium Phosphate), $Ca_3(PO_4)_2$, is practically insol. in water. Dose, 1 Gm., 15 grains. *Dibasic Calcium Phosphate,* U.S.P., $CaHPO_4.H_2O$, almost insoluble in water. Dose, 1 Gm. *Calcium Hydorxide Solution,* U.S.P. (Liquor Calcis, Lime Water), contains about 0.15 per cent of $Ca(OH)_2$. A clear, colorless liquid of alkaline taste. Dose, 15 cc., 4 drachms.

***Calcium Chloride,** U.S.P. (not to be confused with Chlorinated Lime, miscalled "Chloride of Lime"), $CaCl_2.2H_2O$, contains about 78 per cent of $CaCl_2$; odorless; sharp saline taste. Very deliquescent, and should therefore not be dispensed in powders, but as solution. Freely sol. in water (1:1.2); also in alc. (1:10). *Incompatible* with carbonates, phosphates and sulfates. Dose, by mouth, 0.5 to 2 Gm., 8 to 30 grains, diluted; intravenous, 1 Gm. ***Calcium Gluconate,** U.S.P., $[CH_2OH(CHOH)_4.COO]_2Ca.H_2O$, yielding about 9 per cent of Ca. A white crystalline or granular powder; odorless; tasteless; stable in air. Slowly sol. in water (1:30) with practically neutral reaction. More palatable than the chloride; for hypodermic or intramuscular use is nonirritant. Dose, oral, 5 Gm.; intravenous, 1 Gm. *Calcium Gluconate Injection,* U.S.P., a watery solution. May be stabilized by the addition of other calcium salts up to 5 per cent of the gluconate. Usually available in ampuls of 1 Gm. in 10 cc. *Calcium Levulinate* (dihydrated), N.N.R.; properties similar to those of gluconate; virtually nonirritant. *Calcium Lactate,* $Ca(C_3H_5O_3)_2.5H_2O$, U.S.P., occurs as white, granular, odorless, tasteless powder. Sol. in water (1:20), but very slightly sol. in alc. Dose, 1 to 4 Gm., 15 to 60 grains.

PARATHYROID HORMONE

The hormone of the parathyroid glands, "*parathormone,*" which has not been isolated in pure form, regulates the Ca and PO_4 metabolism. Its deficiency, as by excision of the glands, lowers the Ca level of the plasma and tissues, causing tetany; its injection increases the Ca level and produces sedation, muscular and nervous. The symptoms resulting from excision are relieved by increasing the Ca level, by the injection of calcium salts or of parathyroid extract or by the administration of vitamin D; the chief difference is in the promptness and duration of the relief. The parathyroid glands are not essential to life, if the calcium level is kept up, as by vitamin D. However, while both agents raise the calcium level of the blood, the mechanism of their action is different. Parathyroid hormone lowers the PO_4 level and withdraws calcium from trabecular bone; vitamin D raises the plasma level of both Ca and PO_4, chiefly by better absorption from the intestines. The significant changes in the plasma level and urinary excretion of calcium and phosphate are shown in the following tabulation:

EFFECT OF PARATHYROID

	Administration	*Deficiency*
Renal PO_4 threshold	lowered	raised
Urinary PO_4 excretion	increased	decreased
Serum PO_4 level	lowered	slight absolute rise; marked increase of PO_4:Ca
Serum Ca leve	rises to double normal	falls to ½ or ⅓ normal
Urinary Ca exclretion	tends to rise	tends to fall

The fecal excretion of both elements is not materially changed.

Administration of parathyroid hormone to rats decreases the retention of *radioactive strontium* in the femur, decreases its fecal excretion, increases its urinary excretion, and produces marked retention of strontium in the kidneys (W. R. Tweedy, 1945).

Historical.—The parathyroid glands were discovered by Sandstroem, 1880, and their physiological importance was pointed out by Gley, 1892. The actions of the parathyroid hormone were placed on a definite quantitative basis by the discovery of Collip, 1925, that the calcium content of blood plasma can be markedly raised by the intravenous injection of purified acidulated aqueous extracts of the parathyroid gland (similar to the extracts prepared by A. M. Hanson, 1923). The literature is reviewed by D. L. Thomson and Collip, 1932; A. M. Hanson, 1935; and Aub, 1935.

Calcium Content of the Plasma.—The removal of the parathyroids from dogs lowers the plasma calcium from the normal (about 10 mg. per 100 cc.) to 8, 5 or even 3 mg., in twenty-four hours to ten days. A single injection of the parathyroid extract restores the calcium level to the normal, and as this is approached, the spasmodic phenomena disappear. The calcium level reaches a maximum in nine to eighteen hours, and then declines to the previous level, in twelve to thirty-six hours. By repeating the injections daily, the calcium can be maintained at the normal level, and the tetany kept completely suppressed. Injection of the extract in normal animals raises the plasma calcium in an entirely similar manner; the rise merely starts from a higher level and therefore passes at once into hypercalcemia. A single dose may raise the calcium to 18 mg.

The rise is gradual, reaching its maximum in twelve to eighteen hours after intramuscular injection. It is more rapid on intravenous injection, reaching its maximum in four to eight hours, but this is only about one-half as high as with intramuscular injection. Oral administration is generally ineffective. The recovery of the calcium level is similarly gradual, the duration depending on the rise. With repeated administrations, the response diminishes gradually and disappears entirely after several months. *With the injections repeated* at intervals of four hours, the calcium level rises to a maximum of about 20 mg. in twenty hours, remains there for some time, then begins to decline, about the thirty-sixth hour, in spite of the continued administration.

Differences in Animals.—*Man and dogs* are especially responsive, and run a similar course in every respect. *Rabbits and rats* give variable results, but do not ordinarily respond with marked hypercalcemia, because their renal and intestinal excretion of calcium keeps up with its mobilization from bone (Pugsley, 1932). *Complete excision of the parathyroids in rats* causes a fall of the calcium level comparable with that in dogs. The level begins to ascend spontaneously in about three months and is practically normal in seven to ten months. The operated rats are two or three times more reactive to parathyroid injection than are normal rats (Tweedy and Chandler, 1929). Reports of different workers vary as to *cats*. The rise of serum calcium on injection of parathormone is faster and higher if the external temperature is below 50° F. (T. J. C. Combes, 1942).

The *phosphate level of the plasma* is also altered by the parathyroid hormone, but not so strikingly. *Administration* of the hormone lowers the PO_4 level until the Ca rises above 14 to 15 mg., when it rises (apparently because the renal threshold rises when above this level).

In deficiency, the PO_4 rises slightly, the P:Ca markedly (Albright, Bauer and Ellsworth, 1929).

Urinary Excretion of Phosphate and Calcium.—*Parathyroid deficiency* strikingly decreases the phosphate excretion. The urinary calcium excretion is slightly decreased. The fecal excretion of both elements may be somewhat increased, but not materially so. The phosphate retention precedes the other changes; as it does not materially raise the PO_4 level of the blood, it may be assumed to be precipitated with calcium (Greenwald and Gross, 1925; Albright and Ellsworth, 1929), presumably in bone. Administration of sodium phosphate prevents the rise of serum calcium by parathormone injection (A. H. Neufeld and Collip, 1942). *Administration of parathyroid hormone* promptly increases urinary phosphate excretion, reaching a maximum in two hours (Albright and Ellsworth, 1929). The Ca excretion also tends to rise, but not so promptly, and, with overdosage, the phosphate excretion may be greater than the corresponding calcium (Greenwald). The fecal excretion again is not materially altered. The *mechanism of the parathyroid action* is not clear. A. H. Neufeld and Collip, 1942, reported that the parathormone injection has no effect when anuria is produced as by clamping the renal vessels, indicating that its action is directly renal; but Selye, 1942, found that the bone changes occur after nephrectomy; and E. P. Monahan and Freeman, 1944, found that the serum calcium level of nephrectomized animals is lowered by removing the parathyroids and that the serum phosphate level is not raised, as would be expected if the parathyroid action were renal. The urinary clearance of injected sodium phosphate of normal animals also is not altered either by injection or deficiency of parathyroid hormone (M. Fay *et al.*, 1942). It appears, therefore, that the primary action is not on the kidneys, but presumably on the osteoclastic and osteoblastic processes in the bones.

Simultaneous injection of calcium chloride and parathyroid hormone has been cited as an argument for direct stimulation of osteoclastic activity. The plasma calcium shows the prompt peak of the calcium injection, then a remission, and then the gradual parathyroid peak. *Acute liver injury* by phosphorus also obliterates hypercalcemic response, but carbon tetrachloride, hydrazine and benzene do not (D. M. Greenberg, 1935).

With prolonged administration of sublethal doses of parathyroid hormone (10 units per day for dogs) the urinary calcium excretion at first increases enormously, for instance from 0.3 to 39 mg. This is followed by a gradual decline; when the administration is discontinued, the calcium excretion drops sharply below normal. The urinary phosphate rises about 20 per cent, remains high during the administration, and falls below normal in the after-period. Fecal excretion of Ca and P is changed but little during the administration, and drops after suspension (Greenwald and Gross, 1926). *Continued administration to human adults and normal and rickety children* leads to negative calcium balance, by increased urinary excretion, even when the plasma calcium is not raised. The fecal excretion is slightly increased. On low calcium income, the Ca balance becomes more negative, the urinary phosphate excretion rises and the plasma phosphate falls (Albright, Bauer, Ropes and Aub. 1929). The *loss of potency* when injections are continued for several months is not due to exhaustion of the calcium reserves, for ammonium chloride still produces ionized calcium elimination, and viosterol is still effective (Albright *et al.*, 1929).

Calcium Partition in Serum.—The increase on *parathyroid injection* involves first the more diffusible calcium; but the rise of the less diffusible is more prolonged, so that the normal ratio is eventually restored (Moritz, 1926). With *parathyroid deficiency*, the ratio of diffusible and nondiffusible plasma calcium is either unchanged or the nondiffusible is increased. The *calcium level of cerebrospinal fluid*, which is normally about half that of the serum, is but little changed by parathyroid administration, or at least very slowly. Injected calcium also does not pass readily into this fluid.

The *source of the calcium* for the increased plasma level and the increased excretion comes from the food calcium, and beyond this from trabecular bone. The latter may suffice, for evisceration does not diminish the rise of calcium level. None comes from the liver, spleen, pancreas, pituitary, thyroid or central nervous system (C. P. Stewart and Percival, 1927); the kidneys may show deposits of calcium around and into the tubules (Chown, Lee and Teal, 1936).

The *bone changes with continued parathyroid administration*, as seen in young dogs, consist in marked resorption of bone, both spongy and cortical, with *osteofibrosis*. Guinea pigs show bone resorption even after a single dose (Jaffe and Bodansky, 1930). Analogous changes occur in cats, rabbits and rats. The bone fractures more readily, the trabeculae are fewer, the ash is decreased, but its calcium percentage is higher (Lambie, Kermack and Harvey, 1929; Bauer, Aub and Albright, 1929).

Prolonged parathyroid deficiency causes the *teeth* of rats to become opaque, brittle, distorted, with general disorganization of the enamel, and with exostoses of the alveolar bone (J. Erdheim, 1911). The *bones* are low in ash, Ca and P, relatively high in Mg. Muscles and viscera do not have increased calcium. Cataracts are common. The *teeth and jawbones* of rats are also affected by continued administration, similarly to faulty Ca:PO_4 ratio in the diet, or to viosterol deficiency. The pulpar surface shows congestion, degeneration of the odontoblasts, fibrosis and necrosis; with poor calcification of the dentin and enamel (Backberg and Berke, 1934). Matured teeth, in man, do not show resorption, although the surrounding bone is markedly resorbed (K. H. Thoma, 1933; Albright, Aub and Bauer, 1934).

Clinical osteitis fibrosa cystica is attributable to progressive decalcification by hyperparathyroidism, generally from adenoma (F. Mandl, 1927). Osteitis deformans has no connection with parathyroid function; osteomalacia proper is due to deficiency of calcium income and vitamin D.

Parathyroid Administration on Other Salts.—The plasma chloride is markedly increased. The alkali reserve is somewhat lowered. The total ash and the magnesium content of living tissue are lowered by continued administration, but the magnesium as well as calcium percentage of the ash is raised (Coppo and Pisa, 1935).

The **symptoms following total excision of the parathyroid glands** are most striking when both glands are removed at one operation, in dogs, but they are entirely similar in man and are due solely to the hypocalcemia. They begin with refusal of food and water; then restlessness and hyperexcitability; then persistent emesis, leading to alkalosis; *hyperexcitability of the peripheral motor nerves to electric stimulation*, which is probably the earliest detectable sign: pruritus; diarrhea, often bloody, attributed to hyperexcitability of the innervation of the gastro-intestinal tract with tendency to acute digestive uclers; fibrillary twitchings of the skeletal muscles, saltations, *tetany*, then convulsions, initiated by clonic and tonic contractions. This sequence may terminate in death, after about six major convulsions, either from respiratory spasm or from exhaustion; or the convulsions may become milder, with gradual recovery.

The *ammonium content* of the blood is increased by depressed functionation of the liver (Carlson and Jacobson, 1910). *Guanidine*, histamine and similar *toxic bases* appear in the urine (W. F. Koch, 1913). D. M. Paton *et al.*, 1917, suggested that the parathyroids regulate guanidine metabolism and so control muscular tone.

The *carbohydrate tolerance* is lowered by excision of the parathyroids (Underhill and Hilsditch, 1909).

Destruction of the parathyroids also increases the *vasoconstrictor response* to nicotine, epinephrine and pituitary, involving therefore the most peripheral vasomotor mechanism. This effect is counteracted by calcium (Hoskins and Wheelon, 1914).

Removal of the parathyroids from rats increases their *appetite for calcium*, so that they drink suitable calcium solutions in preference to water. This is also used for the bio-assay of substances that affect the blood calcium (C. P. Richter and Birmingham, 1941).

Variations of susceptibility are marked, according to the amount of accessory parathyroid tissue, and other factors. The mortality of untreated dogs is 95 to 100 per cent; cats, 50 to 80 per cent; rabbits, 13 to 33 per cent (Dragstedt); rats generally survive and are therefore used to study the prolonged course. Rabbits die if all accessory parathyroid tissue is removed. Cats generally show only depressive symptoms. Old animals are less susceptible than young. Pregnancy and rickets, and calcium-poor or phosphate-rich diet accelerate tetany and death. Carnivora are most susceptible, especially when fed on meat alone. Accessory parathyroid tissue is frequent, especially in cats, mainly as inclusions in the thymus gland. It hypertrophies when the chief glands are excised, so that the animals which escape early death generally return to normal. Two stage removal is therefore much less fatal than one stage. This hypertrophy is not the sole element in the recovery, however, for accessory tissue has been demonstrated in only 10 per cent of the rats which survive, although their serum calcium falls low (5 to 8 mg. per cent) and returns slowly to normal values (in three to nine months).

Phenomena of Overdosage.—When the calcium level of the plasma rises above 15 mg., the phenomena of calcium poisoning develop. Their severity depends not only on the extent, but also on the duration of the calcium rise; a single injection is therefore rarely fatal even if the level reaches 20 or 23 mg.; continued administration would invariably be fatal, even at lower levels, 18 to 23 mg. Uncontrolled administration of parathyroid hormone would therefore be dangerous, but there is no danger under proper conditions; *i. e.*, careful dosage, surveillance of the patient and immediate discontinuance when *warning symptoms* of overdosage appear, namely, vomiting and diarrhea. The acute effects are due primarily to the hypercalcemia, but they become complicated as they progress. The acute effects, in dogs, are usually confined to weakness and apathy, sometimes with vomiting, without significant changes of blood pressure. After about twenty-four hours, when the plasma calcium turns downward, the symptoms become more severe, passing through anorexia, diarrhea, vomiting, extreme lassitude, muscular atony, lethargy and coma, to death. There is marked dehydration, the plasma volume diminishes greatly, the blood viscosity rises correspondingly and hinders the circulation (Collip and Clark, 1925). The urine output is greatly diminished; the urea, the phosphate, and the osmotic pressure of the blood plasma increase. Acidosis develops.

Postmortem examination shows intense capillary hyperemia of the stomach and small intestines, culminating in hemorrhages. The lesions are coextensive with the vagal innervation and appear to be due to vagal hyperexcitability. They may be prevented by atropine or by section of the vagi, although these do not prevent the hypercalcemia (N. B. Taylor, Weld and Sykes, 1933). Hemorrhages occur also in the bone marrow.

The *course* of the parathyroid overdosage differs considerably from that of calcium chloride injection, since this does not produce a sufficiently lasting rise of blood calcium; but similar effects follow if sodium biphosphate is injected with the calcium (Collip, 1926). *Susceptibility to parathyroid intoxication* appears low in many animals, such as cats, rabbits, rats, mice, guinea pigs, and fowl.

Perfusion of frogs with parathyroid hormone is reported to increase the height of *muscular contraction* to 400 per cent. This effect is abolished by inactivation of the hormone by acid or alcohol, and by curare, by degeneration of the nerve endings and by calcium deficiency; but the Ca may be replaced by strontium. The response may be used for bio-assay (Gellhorn, 1935). *Exudate formation*, in response to pleural injection of copper sulfate in dogs, is reported to be diminished when the plasma calcium level is markedly raised by parathyroid hormone (H. Gold, 1928).

Moderate but long-continued overdosage may lead to myasthenia, renal damage, rise of blood phosphate, abnormal deposits of calcium in soft tissues, kidney stones of calcium phosphate, rarefaction of trabecular bone and development of osteitis fibrosa cystica, with increased activity of the osteoclasts and usually also of the osteoblasts. Morris, 1915, described *mental symptoms* in a patient, which he was inclined to attribute to the prolonged administration of large doses of parathyroid gland. *High phosphate diet* is beneficial in clinical hyperparathyroidism, but not completely effective. The serum phosphate rises, but is rapidly excreted; the serum calcium falls, but not so much as might be expected. The urinary calcium excretion is lowered (Albright *et al.*). *Dietary production of parathyroid hypertrophy* is produced in fowl by maize and wheat. It is retarded by feeding calcium, accelerated by sulfuric acid or neutral sulfur (Marine, 1914). E. J. Baumann and Sprinson, 1937, produced parathyroid hypertrophy in rabbits fed on carrots and oats, with a P:Ca ratio of 0.5. The plasma phosphate is low, calcium high. The circulatory parathyroid hormone is increased, the serum phosphatase diminished.

Clinical Tetany.—Excision of the parathyroid glands in man is followed by the same phenomena as in animals. Tetany, more or less painful tonic spasms of the muscles, particularly of the extremities, sometimes associated with parasthesias and fibrillary twitching, may appear between sixteen hours and six days after the operation. It is not conditioned on any fixed calcium level of the plasma; it may be present at 8.7 mg. per cent, or absent at 3.5 mg. Thomson and Collip believe that the calcium deficiency causes only twitching, and that the tetany proper and the convulsions are caused by the alkalosis which develops from the hyperpnea when the muscular tremors and the calcium deficiency increase the heat production. Raising the temperature brings on tetany in parathyroidectomized dogs, and cooling diminishes the convulsions (W. R. Bryan and Garrey, 1931).

In harmony with this, the convulsions may be arrested by producing acidosis, by ammonium chloride (T. E. Boyd, Austin and Ducey, 1926) or other acidic agents, by inhaling carbon dioxide (Swingle, Wenner and Stanley, 1928), by uranium nephritic acidosis (Swingle, 1928), and indeed by the acid produced by the convulsions themselves; and of course also by calcium chloride administration which acts both as acid and as calcium; and finally by increasing the calcium-ion concentration by parathyroid hormone or viosterol. This conception *unifies the causes of tetany* (R. Ellsworth, 1933) as alkalosis (1) directly by alkali injection, including alkaline phosphate (Binger, 1917) and the excessive vomiting of gastric tetany; and (2) secondary to calcium deficiency and hyperpnea, in parathyroid deficiency, low-calcium rickets, citrate or oxalate injection (J. Loeb, 1901) and calcium loss by the persistent diarrhea of cholera. In *infantile tetany* the spasmodic symptoms are paralleled by a corresponding fall of the plasma calcium to a mean of about 5 mg. per 100 cc. (Howland and Marriott, 1917). The concentration of the phosphate in the plasma is approximately normal, but the excretion of phosphate in the urine is diminished.

Guanidine tetany resembles parathyroid tetany symptomatically, and increase of the guanidine content of the blood and urine was reported, but the analytical methods proved to be untrustworthy (R. H. Major, Orr and Weber, 1927; Greenwald). Watanabe, 1918, reported that the blood serum contains about the normal amount of calcium, but that the phosphate content is markedly increased. The claim that guanidine lowers the calcium level is not supported by conclusive evidence (G. Bayer, 1932). The blood pressure is generally lowered in parathyroid tetany, and raised with guanidine (Stoland and Bryant, 1926).

Treatment of Parathyroid Deficiency.—Under the stimulus of parathyroid deficiency the accessory parathyroid tissue hypertrophies, and generally becomes quite or nearly adequate after a few weeks. Treatment is indicated to diminish the symptoms during the interim. It comprises the injection of calcium gluconate for immediate relief, which is then sustained for several weeks by parathyroid administration, with abundant calcium income. Viosterol is used if longer treatment is necessary (review, Aub, 1935). Dihydrotachysterol permits material simplification (Albright, 1939). The same treatment is also effective in other tetanies (infantile, gastric) that involve calcium deficiency. Parathyroid therapy is not effective against other spasmodic conditions.

For *immediate relief, calcium salts* may be injected intravenously, preferably the gluconate, 0.15 cc. of 20 per cent per Kg., taking at least four minutes for the injection. A few minutes later, the same quantity of gluconate may be injected intramuscularly (A. L. Lieberman, 1931). The relief is dramatic and may persist over two hours, and the injection may be repeated if the tetany recurs. It is advisable, however, to continue the therapy with *injection of parathyroid hormone*, the full effect of which has a latent period of four hours (although intravenous injection may relieve the tetany in half an hour), but persists for twenty hours after a single injection. A more even effect is obtained, more economically, by administering it twice daily. The dosage and duration must be controlled by frequent determinations of the plasma calcium and phosphate, so that the calcium does not rise above 12 to 13 mg. per 100 cc., for 14 mg. produces hypercalcemic symptoms, loss of appetite, nausea and fatigue. The lower limit is estimated by the continuance or recurrence of tetany, since the individual susceptibility varies. The response to parathyroid injection diminishes gradually and is completely lost after several months. The cause is not understood, as the response to the injection of calcium, to acidosis and to viosterol persists. It is therefore advisable, also for economy, to supplement the hormone with *viosterol* at once, and to omit the hormone injections after two or three weeks, when they would be less effective and less needed. Several days of viosterol administration are required to develop the maximal effect, but it persists for at least two weeks after the administration is discontinued, and can be maintained indefinitely. Even young puppies and pregnant dogs get along without parathyroids if adequate vitamin D is administered (Kozelka, Hart and Bohstedt, 1933). *Dihydrotachysterol*, one of the photochemical derivatives of ergosterol, developed by Holz, is reported especially effective. It is marketed in oil solution, 5 mg. per cubic centimeter, and is administered orally, generally 3 cc. per day until calcium appears in the urine by the Sulkowitch test, and then kept at a maintenance level of about 1 cc. three to five times per week (F. Albright, 1939; Albright, Bloomberg *et al.*, 1938). The *calcium intake* should be liberal during the hormone or viosterol administration, else it would need to be drawn from the bones. The phosphate income should be low. A meat diet is said to be beneficial, perhaps by combating alkalosis; also lactose, perhaps by facilitating calcium absorption and lowering the blood phosphate. Calcium lactate, orally, 1.8 to 4.4 mg. per Kg. per day, prevents the parathyroid tetany in dogs; cow's milk does not; strontium lactate does, perhaps by binding phosphate in the intestines (L. R. Dragstedt and Sudan, 1926). Parathyroidectomized rats exhibit a greatly increased *appetite for calcium* (as lactate or gluconate); their appetite for NaCl, KCl, Na_2HPO_4, NaI or $(NH_4)_2SO_4$ is not greatly changed (J. F. Eckert, 1938).

Other Spasmodic Conditions.—Parathyroid administration and injections have been tried against paralysis agitans (Berkeley, 1909), chorea and eclampsia, apparently without success, for these conditions do not show calcium deficiency. This applies also to gastric tetany, excessive pulmonary ventilation, and other forms of alkalosis. The spasms could probably be allayed by increasing the calcium above the normal, but this would also develop the dangerous effects of hypercalcemia.

Interrelation with Thymus.—Uhlenhuth, 1918, found that mammalian thymus produces convulsions when fed to the larvae of salamanders. This occurs only before their parathyroids have developed. Apparently, thymus contains tetanic poisons, which are antagonized by the parathyroids. Calcium and magnesium also check the thymus convulsions, but much less perfectly.

Other therapeutic uses of parathyroid hormone have been sought, both for the increased calcium level of the plasma, and for the decalcification of bone and other calcium deposits, but with little success (Aub, 1935).

Increasing the plasma calcium level is of little value for healing fractures. Some good results have been reported in persistent edemas, nephritis and cardiac, but they are not convincing; still less convincing are the results in asthma, vasomotor rhinitis, hemorrhage and jaundice. *In experimental oxalate and fluoride* poisoning, of mice, the results are excellent, so that the fluoride toxicity may be used for the bio-assay of parathyroid hormone (Kochmann, 1934). *Decalcification* of various tissues, calcified glands and arteries, myositis ossificans, otosclerosis, and the like, is not successful, as the mobilization of calcium occurs from the organized spongy bone, and not from abnormal deposits.

Removal of abnormal metals stored in the bone trabeculae may be accomplished with parathyroid hormone; for instance, lead (D. Hunter and Aub, 1927), radium, thorium and polonium; but it is not so easily managed clinically as are the acid-producing salts, such as ammonium chloride.

Parathyroid Injection, U.S.P. (Solution of Parathyroid, Parathyroid Extract), is a sterile, watery solution of the calcium-raising principles of fresh parathyroid gland, adjusted by bio-assay so that 1 cc. represents no less than 100 U.S.P. units, each unit being a hundredth of the amount required to raise the calcium content of 100 cc. of the blood serum of normal dogs (of 8 to 16 Kg.) by 1 mg. within sixteen to eighteen hours after subcutaneous administration. The detailed directions of the U.S.P. must be followed. Available in ampuls of 100 units in 1 cc. Average dose, 25 units intramuscularly. The *dosage* should be adjusted according to the effects. The usual range is 10 to 25 units per day, or on alternate days; 10 units in infantile tetany; injected hypodermically, intramuscularly or intravenously, often in fractionated doses. As much as 100 units has been injected in an hour, but this is not advisable, and could not be continued. The extract is somewhat effective by mouth but the absorption is uncertain and difficult to control, and the hypodermic, intramuscular or intravenous injections of the purified extracts are vastly superior.

VITAMIN D, VIOSTEROL, IRRADIATED ERGOSTEROL

Vitamin D is a general name applied to sterols concerned with the proper utilization of calcium and phosphate and the orderly calcification of bone. Their deficiency results in the development of rickets. Vitamin D occurs naturally in foods, especially in egg yolk, milk and in the liver fat of marine fishes, such as cod liver oil. The antirachitic action of sunlight and ultraviolet rays is attributable to the activation of sterols of the skin (A. F. Hess *et al.*, 1925). Ultraviolet therapy is reviewed by E. M. Luce-Clausen, 1938. A series of substances having these properties are obtained from ergosterol by ultraviolet irradiation and by other physicochemical processes. These constitute "Viosterol." Some have been isolated in pure crystalline form. Analogous products of similar properties have been prepared from 7-dehydrocholesterol, and these are probably the forms which exist naturally in the body and in cod liver oil. The relative potency of different products varies for different animals. A "rat unit" of cod liver oil is somewhat more effective against human rickets and especially against the leg weakness of chicks than a rat unit of viosterol (Bills, Massengale and Imboden, 1934). Vitamin D is *stable*, differing in this respect from vitamin A, with which it is associated in cod liver oil. It resists prolonged heating at 100° C., and keeps indefinitely in cold storage.

Historical.—After the existence of antirachitic properties in cod liver oil had been established (by E. Mellanby, 1919), McCollum, Simmons *et al.*, 1922, showed that this vitamin "D" is distinct from the growth vitamin A. Later work confirmed that the "D" does not protect against xerophthalmia and other phenomena of "A" deficiency (Wilkes *et al.*, 1929). About the same time, Huldschinsky, 1919, established analogous antirachitic effects on exposing patients to sunlight or artificial ultraviolet rays. A. F. Hess and H. Steenbock, 1924, independently and almost simultaneously discovered that antirachitic properties can be conferred on many foods and oils, which are not in themselves antirachitic, by short exposure to the ultraviolet rays of the same wave length, about 310 μ, which is effective directly on patients. Starting with the observation that ordinary cholesterol is rendered potently antirachitic by such irradiation, Hess and Weinstock, 1925, showed that this is associated with definite changes in the absorption spectrum of the solution, and that excessive exposure produces further changes in the absorption and destroys the activity.

The *vitamin D content of natural food* is not sufficient for growing children, unless it is supplemented by considerable exposure of the skin to ultraviolet radiation, sunlight or artificial. About the only foods which contain significant but small amounts are milk, liver and egg yolk. Vegetables and vegetable oils contain little; the earlier claims were based on faulty methods (J. Coffin, 1935).

Egg yolk is a good source of vitamin D, so that two yolks a day may cure rickets; but the content is variable. Their activity is not destroyed by hard-boiling, nor by six months of cold storage. *Milk and butter*, which are a good source of vitamin A, contain relatively little D. There is considerable seasonal difference, depending on the rations more than on the sunlight exposure of the cows. It may be increased to sixteen times by feeding irradiated yeast. It is decreased by sterilization or commercial evaporation of the milk (review, Clouse, 1933)

Cod liver oil and the liver fat of other fishes are rich in vitamin D aswell as in A, in varying proportions. Oils from individual fish may differ a thousand times in potency, and the two vitamins do not go parallel (A. F. Hess, Bills and Honeywell, 1929). The body oil of fish is also potent. Fish liver oils contain several D vitamins, distinguished by their relative potency on rats and chicks (Bills, Massengale *et al.*, 1937). All are sterols and therefore pass into the nonsaponifiable lipoid fraction (as does also vitamin A). Such *concentrates* may be used therapeutically, avoiding the excess fat of the oils.

Antirachitic Sterol Derivatives.—At least ten exist, and five of these are well understood. The most important are activation products of ergosterol and of 7-dehydrocholesterol. Most of the others are mainly of theoretical interest. The crystallized "Calciferol" ("D_2") is purified activated ergosterol. It is the active component of viosterol, of irradiated vegetable foods and of "yeast milk," the milk of cattle fed with irradiated yeast. Most of the other antirachitic agents are formed from 7-dehydrocholesterol, the provitamin associated with animal cholesterol. It is the agent activated in the skin by ultraviolet radiation, and the active agent of fish oil, of egg yolk and of directly irradiated milk. At least two forms occur in fish oils, and it is not known whether these are identical with any of those produced artificially (Bills, 1938).

Structural Relations.—The sterols are phenanthrene derivatives, with a "*cholane*" nucleus. This series also includes the bile acids; toad poisons (bufotalin); the estrogenic and androgenic hormones and progesterone; morphine and its derivatives; the carcinogenic compounds; and the aglucones of the digitalis series (Lundgren, 1935; Bills, 1935).

Irradiation Products of Ergosterol.—*Ergosterol* was originally obtained from ergot, but it is widely distributed in plants. At present it is prepared almost exclusively from yeast. Small quantities are present in many vegetable foods. It is insoluble in water, sparingly soluble in oils, freely soluble in most organic solvents. It is levorotatory, unstable, highly unsaturated, with three double bonds (Bills, Honeywell and Cox, 1928). It has a strong absorption band in the ultraviolet spectrum, with three maxima between 260 and 293.5. This disappears with irradiation, and a new band is formed between 240 and 248.

Activation of Ergosterol.—Ergosterol has no antirachitic effects until it is irradiated by specific ultraviolet rays, or by other means which cause an intramolecular rearrangement, involving a shift in the position of a double bond, the atoms remaining the same, $C_{28}H_{43}$-OH. The change is initiated by any wave lengths which are absorbed by the ergosterol (Bills, 1938). These produce progressive changes, as revealed by successive alterations in the spectrum, as well as by successive inintensification and destruction of the antirachitic properties (Hess and Weinstock, 1925; T. A. Webster and Bourdillon, 1929). The means of activation, including electron bombardment, do not alter the nature of the antirachitic substance, but only the rate of production and the amount of by-products. Only some 10 per cent of the ergosterol undergoes activation (Holtz, 1927). The solvent influences the rate of the changes. The pure, dry viosterol soon loses activity; but irradiated foods remain active for at least six months, and oily solutions of viosterol appear to retain their full activity indefinitely.

Time of Irradiation.—The production of the antirachitic substance by irradiation, and its destruction by oxidation go hand in hand. The maximum efficiency is reached in half an hour, so that the activity does not increase by further exposure (Jendrassik and Kemenyffi, 1928; Van Stoek, Dureuil and Hendebert, 1928). Brief exposure is especially important in the *irradiation of food;* even a fraction of a second may suffice in favorable cases, and prolonged treatment develops disagreeable taste and odor and may destroy the A and C vitamins (Clouse, 1933, review). *Wave lengths* of 280 to 302 millimicrons appear most potent for the formation of viosterol; even 230 is effective, but requires much longer. With the quartz mercury lamp, waves shorter than 270 destroy the antirachitic factors (Morton, Heibron and Kamm, 1927). The Sperti patent utilizes longer wave lengths than the ordinary Steenbock patent, claiming a product of higher and more uniform antirachitic activity and lower toxicity (Rider, Sperti *et al.*, 1936). *Activation of ergosterol by other means* has been accomplished with cathode rays, radium emanation, low velocity electrons (McQuarrie *et al.*, 1937), by a clay catalyst and by nitrites (Bills and McDonald, 1926, 1931). These influence the amount of the by-products.

Products of Ergosterol Irradiation.—At least five or six substances are formed in the ordinary irradiation of ergosterol (Windaus, 1930), by overlapping stages as follows:

Ergosterol (cryst.)
↓
Lumisterol (cryst.)
↓
Tachysterol (cryst. derivative)
↓
Calciferol (cryst.) (D_2; Drisdol)
↓
Toxisterol (Substance 248) (has not been obtained pure)

Suprasterol I (cryst.)
Suprasterol II (cryst.)

Calciferol, the crystalline antirachitic fraction, was isolated by Angus *et al.*, 1931, and Windaus, 1931 (Askew *et al.*, 1932), and has been made the international and U.S.P. standard of comparison for viosterol, 1 mg. corresponding to 40,000 units. It is marketed as *Drisdol.* (The substance first named Calciferol, (D_1) Angus *et al.* proved to be a mixture.)

"*Toxisterol,*" called "substance 248" from its single intense absorption band at wave length 248, has toxic and calcifying properties greatly disproportionate to the antirachitic action. It is formed most freely when an alcoholic solution is irradiated, and may be absent if ethereal solution is used. It has not been isolated (Bills, 1938).

Activated 7-dehydrocholesterol.—Cholesterol cannot easily be activated directly, but must first be converted into 7-dehydrocholesterol (J. Waddell, 1934). This is found along with cholesterol in nature and has been synthesized, and highly active antirachitic properties have been obtained by the irradiation of this (D_3), as well as the natural product (F. Schenck, 1937). The activated preparation appears to be similar to the vitamin D of fish oil. A water-soluble antirachitic derivative of this has also been announced.

E. M. Koch and Koch, 1935, 1936, obtained antirachitic preparations by the radiation of certain natural cholesterols, *f. i.*, of the spinal cord, which they attributed to derivatives other than 7-dehydrocholsterol; 22-dehydrocholesterol has also been activated and termed D_4.

The *relative antirachitic activity of vitamin D for different animals* shows marked differences between activated-ergosterol and activated 7-dehydrocholesterol, the rat unit of the cholesterol-derived vitamin (including that of fish oil) being fifteen to twenty times more potent on chicks than the rat unit of activated ergosterol (A. F. Hess, Weinstock and Rivkin, 1929; J. Waddell, 1934). For human rickets, N. Morris and Stevenson, 1939, found no significant difference in the clinical potency of D_2 and D_3. Gerstenberger *et al.*, 1940, reports D_3 more potent than D_2 in treating rachitic monkeys.

The **absorption of viosterol** apparently requires the presence of *bile* in the intestines. Exclusion of the bile from the intestinal tract of dogs results in osteoporosis (Hawkins *et al.*, 1938); and none of the effects, toxic or therapeutic, of viosterol or vitamin D occur in dogs with biliary fistula until bile is fed (or desoxycholic acid, with rats; J. D. Graves and Schmidt, 1933) or until viosterol is injected intravenously (N. B. Taylor and Weld, 1932). The bile of normal animals is itself antirachitic, indicating that vitamin D is also *excreted in the bile.* The reabsorption of this probably explains why hypercalcemia may outlast the administration, often after a single dose. The *excretion by the milk* is attested by the anitrachitic activity of butter, which is increased by feeding cows irradiated yeast. The diet of the mother during pregnancy and breast feeding therefore influences the susceptibility of the infant to rickets (Hess, 1923). *Storage* of viosterol has been demonstrated (for dogs) in the liver, adrenals, lungs, spleen and kidneys; none in the heart, brain, skin and pancreas (Coppens and Metz, 1933). Mammalian lung, however, and presumably other tissues contain enzymes that destroy the vitamin, so that it does not accumulate as in fish liver (C. D. Snyder, 1922).

Calcium-Phosphate Balance; Effects in Rickets.—Vitamin D appears necessary to maintain a normal balance between the calcium and phosphate of the plasma, and to the proper fixation of these for bone formation. It prevents and cures the defective bone development and all the other manifestations of human rickets and that produced in animals by diets deficient in viosterol. The improvement starts with progressive calcification at the epiphyses, and is evidently connected with the proper relation of calcium and phosphate in the blood. Vitamin D promotes economical utilization of calcium and phosphate and largely overcomes the disturbances of improper ratios of these elements in the diet. The significant feature of clinical rickets is a decrease of the inorganic phosphate of the blood plasma, often to half the normal level; the total calcium level is generally not diminished. The administration of viosterol appears to increase the proportion of inorganic phosphate of the plasma, gradually restoring it to normal in rickets, and to high values with excessive dosage. The phosphate excretion may be increased at the same time (Warkany, 1930). *The mechanism of the regulation* is obscure, but it is believed that the essential cause of rickets and of osteomalacia is inability to absorb sufficient calcium from the intestines (R. R. Hannon *et al.*, 1934). Tracer experiments with radioactive calcium in rats show that vitamin D increases the absorption of calcium, and secondarily of phosphate; and that it also acts directly on the mineralization of bone (D. M. Greenberg, 1945).

If the calcium and phosphate of the diet are abundant, the viosterol increase of inorganic phosphate in the plasma entails:

(1) A positive calcium balance; by a smaller excretion of calcium by the urine and feces, and a better absorption of calcium and of phosphate from the intestines. (2) Restoration of the calcium level of the blood if this has been deficient; and with overdosage, great increase of plasma calcium, similar to that produced by parathyroid hormone. The hypercalcemia is the most significant feature of overdosage. (3) Deposition of the normal bone salts in the epiphyses, and thereby correction of the rickets. Excessive dosage leads to hypercalcification of the epiphyses, of the large blood vessels and of other organs. (4) It is also claimed that viosterol returns an alkaline acid:base balance to normal (Liegeois and Lefevre, 1929), and that it shortens the coagulation time of the blood. (5) *If the calcium and phosphate of the diet are low,* viosterol increases these elements in the plasma, at the expense of the skeleton, and large doses produce osteoporosis.

Ca and P Level of the Plasma.—With normal diet, vitamin D increases the phosphate considerably more than the calcium level (L. J. Harris and Stewart, 1929). Lowering of the inorganic P level to half of the normal, 5 or 6 mg. per 100 cc., is an early and important sign of rickets in babies. Treatment with vitamin D restores this promptly to normal. The plasma calcium is not greatly lowered in uncomplicated rickets, but is low in infantile tetany, rachitic or other. It is also promptly restored by vitamin D.

Administration of Calcium and Phosphate.—Viosterol, as also parathyroid hormone, slows the rate at which *intravenously injected calcium chloride* leaves the blood stream (S. Freeman, 1936). *Feeding calcium gluconate,* to dogs, produces little increase of the blood calcium; but marked increase if viosterol had been administered. *Feeding with dicalcic phosphate,* however, caused but little rise in either the calcium or phosphate level of viosterol-treated dogs (Jones and Rapoport). The temporary rise of phosphate level on oral administration of *disodium phosphate* to rabbits or babies is greatly increased by vitamin D (Warkany). The *calcium content of bile* from hepatic duct fistula dogs, normally about 14 mg. per 100 cc., rises on viosterol administration only if the blood calcium rises. Raising the calcium of the plasma to 20 mg. raised that of the bile to 60 mg. per 100 cc. (K. K. Jones and Laing, 1934). *Retention of Ca and P* follows vitamin D administration, on any diet, in normal and rachitic children as well as animals. In clinical rickets the balance of calcium and phosphate is subnormal, with increased excretion of phosphate and calcium in the feces, and decreased calcium output in the urine. Vitamin D administration increases the retention of both Ca and PO_4 and strikingly reduces their excretion, and increases the urinary Ca output (Shohl, review, 1935). The *fate of phosphorus under vitamin D* has been traced in rachitic rats with the aid of radioactive P_{32}. Vitamin administration increased the absorption of the phosphate, administered by stomach tube, by only 10 to 15 per cent. It increased the P_{32} in the inorganic P of the bones by 40 per cent; and also markedly in the protein and ester P of bone, more than in muscle, and almost as much as in urine. That of the lipoid fraction of bone was not increased. The influence of vitamin D on the deposition of P in bone seems not due merely to increased absorption or supersaturation of inorganic phosphate, but involves a special effect on the organic phosphorus in the bone (W. E. Cohn and Greenberg, 1939).

The *bone changes in rickets* come from quantitative changes in the serum calcium or phosphate or both, below the critical precipitation level. They are primarily endochondral, beginning with failure of the normal progressive degeneration of the diaphyseal cartilage cells which precedes the entry of capillary loops, osteoblasts and calcium deposition. This results in continued growth and therefore increased thickness of the diaphyseal cartilage and of the osteoid bone matrix, lack of vascular growth into the cartilage and resorption of bone formed before the vitamin deficiency. In *osteomalacia* there is excessive resorption of bone, presumably to supply calcium for other vital processes. When vitamin D is given, the normal degenerative progression starts within twenty-four hours, with extensive vascular penetration (review, S. B. Wolbach and Bessey, 1942). The *enamel of the teeth* also is not properly formed during rickets, disposing toward subsequent caries. The British Commission of 1936 (ref., Biol. Abstr., *11:* 1989) concluded that the use of vitamin D in early childhood decreased the incidence of caries in children from 18 to 8 per cent.

The **effects of overdosage** depend chiefly on the hypercalcemia and are exaggerations of the therapeutic actions. The plasma calcium may rise to 22 mg. per 100 cc. after a single large dose; the phosphate level is also increased, the phosphatase is decreased markedly in the blood and kidneys, not in the liver and spleen, variable in bone (P. D. Crimm and Strayer, 1936; Freeman and Farmer, 1935). The Ca and P balance becomes negative and their excretion shifts from the feces toward the urine, with large loss of these elements from the tissues and bones. The ascent is gradual, and the maximum level is not attained for four or five days. A single dose, even if large, does not produce permanent ill effects, but continued administration results in the depressive symptoms of hypercalcemia, analogous to overdosage with parathyroid hormone. These develop in ten to thirty-six days, varying with the kind of animal. The first sign is loss of appetite; then lassitude and drowsiness, pallor, emaciation, often diarrhea, bloody discharge from the nose, flabbiness of muscle, renal irritation, albuminuria and nitrogen retention. Calcification of bone is hyperactive, and metastatic calcification occurs in various situations; clinical metastases are reviewed by J. M. Bauer and Freyberg, 1946. Necroses of the liver, kidneys and heart muscle occur even in the absence of calcification. If the overdosage is pushed energetically in animals, death results in one to four weeks (Blunt and Cowan, 1930; Shohl, Goldblatt and Brown, 1930; T. D. Spies and Glover, 1930; C. I. Reed, 1934; G. W. Covey and Whitlock, 1946.)

The toxic symptoms are not necessarily parallel to the calcium level. When they have developed, discontinuance of the viosterol does not generally result in recovery (Reed and Thacker, 1931), and the hypercalcemia outlasts the administration for several weeks. The susceptibility varies in different animals and individuals, but the margin of safety is wide. With the purer products, toxic effects require 1000 to 100,000 times the therapeutic dose (*cf.* Hauch, 1934; clinically, Shelling and Jackson, 1934; Spies and Hanzal, 1934). Reed and Struck, 1937, claim that men and dogs generally survive 20,000 units per Kg. per day indefinitely, without toxic effects, but this is not generally accepted as safe. Indeed, L. J. Harris concludes that the margin between the optimal and harmful dosage is much smaller in the human than in rats. Clinical intoxications attributed to massive doses are reported by P. A. Tumulty and Howard, 1942, and by Yeager, 1946. The toxicity is due partly to other more toxic sterols ("toxisterol"; Laquer and Linsert, 1933) whose ratio to viosterol varies with different methods of irradiation (Hoyle, 1930; Holtz and Schreiber, 1930). However, large doses of pure crystallized "calciferol" also produce analogous toxic effects (Dale, 1932; A. M. Hartman, 1937).

The *pathologic changes in overdosage* consist primarily in deposition of calcium phosphate, first in the epiphyses and lumen of the long bones, at the expense of the shaft. The resulting premature calcification arrests the growth of young rats (J. A. Collazo, Robino and Varela, 1929). Calcium deposits also form in the thoracic aorta and other large blood vessels (A. Schiff, 1930) and especially in the renal tubules, also in the heart, stomach and bronchi (Shohl and Brown, 1930; Hauch, 1934). The calcium mobilization finally occurs by depletion of the skeleton, with osteoporosis; the ash of the bone may be reduced by half. Congestive changes occur in the gastro-intestinal tract, and degenerative lesions in the heart muscle (review, S. B. Wolbach and Bessey, 1942). Dogs develop persistent rise of blood pressure (H. Handovsky, 1937). Lead, radium, thorium and polonium, if they have been deposited in the skeleton, are also mobilized by viosterol, but not so actively as by parathyroid hormone. The *teeth* (of rats) grow more slowly, the dentine is at least not increased, but the cementum is thickened and fused with the alveolar bone (J. Weimann). In dogs, the calcium content of the dentine is not changed by prolonged administration of heavy doses, sufficient to cause markedly increased x-ray opacity of the bones (E. W. Fish, 1935). The effects on dental and paradental structures are reviewed by H. Becks, 1942.

A single massive dose of D_2, 314,000 to 530,000 I.U. per Kg. administered to young dogs killed nearly half of the animals within two weeks, with the symptoms of anorexia, polyuria, bloody diarrhea, excessive thirst and prostration. The other dogs survived over eight months. Their serum calcium remained high for six months, with marked Ca and P retention. Autopsy showed excessive calcification of the lungs, moderate in the heart and kidneys, and striking abnormalities of the teeth and jaws (A. F. Morgan *et al.*, 1946).

Differences of susceptibility to overdosage are wide. That of *species* generally parallels their susceptibility to parathyroid hormone (N. B. Taylor, Weld and Sykes, 1934); but chickens are much more susceptible to viosterol poisoning than to the hormone. *Individual susceptibility* is markedly increased by age (Demole, 1929); by high Ca and low PO_4 diet; and by the weakness induced by rachitic diet. It is not affected by iodide administration (Hauch, 1934). It increases with the duration of the administration, and with more moderate overdosage it may not become manifest till the third or fourth generation (review, Clouse, 1933). *Exclusion of short wave lengths* in the irradiation is reported to diminish materially the production of toxic components (H. Schneider and Sperti, 1926; Reerinck and van Wijk, 1930).

Relation of Viosterol and Parathyroid.—The similarity of action suggested that the vitamin might act on the parathyroid gland; this is not so, for its effects occur after removal of the glands (Dale, 1932).

Comparison of Vitamin D and Parathyroid Hormone.—The effects of overdosage are similar, but the mechansim appears to be different. Both raise the calcium level of plasma, viosterol slowly and parathyroid dramatically; but parathyroid does this by lowering the PO_4 level, while vitamin D tends to raise the PO_4, especially in rickets, and may thereby even lower the Ca level and produce tetany (Collip, Pugsley *et al.*, 1934). The difference in susceptibility of animal species also indicates a different mechanism: the toxicity of viosterol, expressed as units per Kg., is a third less for rats than dogs; with parathyroid hormone, it is less than an eightieth (J. H. Jones, 1936).

Therapeutic Use.—Viosterol prevents rickets and cures all its effects and symptoms, including the tetany and spasmophilia; also when these occur as calcium phosphate unbalance without other symptoms of rickets (Hess, Lewis and Rivkin, 1929). It is effective in osteomalacia and in parathyroid deficiency. Viosterol may be given to nursing mothers to prevent a negative calcium balance. It has been advised to accelerate the healing of fractures (Roi, 1929), and to prevent and arrest dental caries (P. G. Anderson *et al.*, 1934); it would presumably be useful if there is a rachitic background, but otherwise the efficiency remains to be established. It has been claimed that viosterol secures calcification of the lesions of experimental tuberculosis (Levaditi and Po, 1930; Simonnet and Tanret, 1931; de Savitsch, 1934), but the practical significance of this is not certain. Beneficial results have been reported from massive doses in chronic arthritis, allergic disorders and psoriasis, but the evidence is not convincing.

In *rickets and its related conditions*, vitamin D is practically specific, for treatment as well as for prophylaxis. It may take the place of direct sunlight or ultraviolet irradiation of the skin in this regard, although exposure to sunshine also has other effects. Even nonrachitic children show seasonal variations in the plasma phosphate level, which rises in spring and summer. The *regulation of Ca and P metabolism* is probably useful for general health, in adults as well as infants, especially if the income of these elements is faulty; but data regarding this are inadequate. *Growth* of the body is conditioned on growth of the skeleton and may therefore be limited by inadequate income of vitamin D or calcium or phosphate. *Injurious effects of faulty Ca and P metabolism on tooth formation* in infancy, and such caries as may be dependent on them, would tend to be prevented by adequate vitamin income. In *parathyroid deficiency*, vitamin D is useful to keep up the calcium level until adjustment of the level has been reestablished (Brougher, 1928, 1932). Its effects are slower than those of hormone injections, which restore the calcium in four or five hours; viosterol requires thirty to thirty-six hours. On the other hand, the restored level endures longer after viosterol (four to five days) than with the hormone injection (thirty-six hours) (Jones, Rapoport and Hodes, 1930). It is more effective if it is administered before the operation (J. C. Brougher, 1928; Hess, Weinstock and Rivkin, 1929). **Dihydrotachysterol**, one of the activation products of ergosterol introduced by Holtz, Gissel and Rossmann, 1934, has been recommended as especially effective in maintaining the plasma Ca continuously at the normal level, without undesirable effects. A liberal calcium income should be provided (MacBryde, 1938; Albright, 1939; see under Parathyroid). Dihydrotachysterol is reported highly effective against diffuse scleroderma caused by disturbed calcium metabolism consequent on parathyroid injury in subtotal thyroidectomy (E. T. Bernstein and Goldberger, 1946).

Chronic Arthritis.—Apparently beneficial effects from massive doses were reported by I. Dreyer and Reed, 1935; but they are variable, about as with other lines of treatment (Vrtiak and Lang, 1936). P. S. Hench, 1946, concludes that it does not give even symptomatic relief in rheumatoid arthritis, and does not justify the risks of large dosage. *Allergic disorders,* hay fever and asthma have also been treated with massive doses, at least 200,000 units daily, with claims of relief, not correlated with changes in the plasma Ca or K level (Hathaway, Rappaport, Reed and Struck, 1936). The results are uncertain, and the harmlessness of such doses appears doubtful. *Psoriasis* appears sometimes improved by similar doses (300,000 to 400,000 units, Ceder and Zon, 1937), but the same limitations apply. A fourth of the patients showed evidence of incipient overdosage. *Keratoconus,* which may be produced in dogs by D deficiency with low Ca income, is reported to be improved clinically by vitamin D administration (A. A. Knapp, 1938). Beneficial results from vitamin D administration have also been reported in the *bleeding tendency of obstructive jaundice* (L. B. Johnson, 1937), and against the *toxemia of pregnancy* (G. W. Theobald, 1937; references in the review of Park, 1938).

The **daily requirement of vitamin D** is greatest at birth and decreases progressively during infancy. It is not accurately known and varies with conditions, but the following units may be considered adequate (up to double these quantities would proabably be better): prematurely born infants, 600 to 800; full term infants, children and adolescents, 300 to 400; adults, 135; in lactation and pregnancy, 800 units (Jean and Stearns, 1938).

Rickets does not develop in the majority of full term *infants* fed with milk containing 135 units per quart, but 400 units is needed for certain protection. If given as cod liver oil or as viosterol in oil, it is safer and better to use 800 to 1000 units per day. A few observations indicate that 1500 units may decrease appetite and so retard growth. Care must be used that the oil does not run down the trachea and produce lipid pneumonia. Breast fed infants require less than those fed on cows' milk, but it is better to give the same dosage. With *children* after the second year, the needs decrease with each year, but it is advisable to continue the administration throughout the period of growth, as 750 cc. of milk with 300 or 400 additional units. *Adults* appear more efficient in absorbing calcium than the average child, and do not need to add vitamin D to the ordinary diet—a total of 135 units is certainly adequate—except for those who are quite deprived of exposure to the sun, such as invalids and nightworkers. In *pregnancy,* however, normal calcification of the fetus is influenced by the vitamin intake of the mother and it is advisable to take at least 800, better up to 1000 units, as viosterol and 1.5 Gm. of calcium as $CaHPO_4$. During *lactation,* the drain on the mother is more severe than during pregnancy, and it seems necessary to take at least 1½ quarts of milk (equal to 1.8 Gm. of calcium) and 800 units or more of viosterol.

In *active rickets,* the prophylactic dosage causes marked improvement, but because the speed of the cure increases with the dosage (Bills), 1200 units should be administered daily; in refractory cases this may be increased to 20,000 units daily for infants, 50,000 for children (Parks, 1938). *Toxic effects from overdosage* need not be apprehended unless the daily dosage exceeds 20,000 units, and not then so long as the Ca and PO_4 level of the plasma remains normal. Plasma calcium above 12 mg. per 100 cc. indicates danger; also calcium casts in the urine. The symptoms are rather indefinite. Nausea is invariably present, sometimes nocturia (Park, 1938). Large doses should not be administered in renal insufficiency, nor to old people.

A single massive oral dose of 600,000 units is reported to prevent the development of rickets during fall and winter, as also monthly doses of 100,000 units from October to April. No untoward effects were noted (A. C. Rambar *et al.,* 1943).

Vitamin D milk has the advantage that it furnishes calcium and phosphate with the vitamin. Three forms are available: (1) "*Irradiated Milk,*" activated by direct exposure to ultraviolet light, contains the vitamin, probably activated 7-dehydrocholesterol. It is generally made to contain 135 units per quart, and cannot be increased much beyond this without acquiring a disagreeable taste. (2) "*Fortified Vitamin D Milk,*" adjusted to 400 units per quart by the addition of cod liver oil concentrate or viosterol. (3) "*Metabolized Vitamin D Milk*" or "*Yeast Milk,*" the milk of cows fed with irradiated yeast, and adjusted to contain not less than 400 units per quart, as viosterol. For equal unit dosage all three are equally effective in protecting infants against rickets, as judged by the roentgen picture and the serum Ca and PO_4 (Gerstenberger, Horesh *et al.,* 1935).

Parenteral administration of viosterol, by intravenous or peritoneal injection, is more effective in dogs than comparable doses by mouth (Reed and Thacker, 1931). This would be particularly desirable during acute infections, especially of the gastro-intestinal tract, when vitamin D may be poorly absorbed; but it has not been well worked out clinically. *Application of vitamin D to the skin* gives sufficient absorption to cure clinical and experimental rickets; fatal hypervitaminosis has been produced in animals by this route (review, J. J. Eller and Woelff, 1930).

PREPARATIONS.—See Index for Cod Liver Oil.

*Synthetic Oleovitamin D, U.S.P., a solution of activated ergosterol (Viosterol in Oil, N.N.R.; Liquor Ergosterolis Irradiati, B.P.) or of activated 7-dehydrocholesterol (D_3) in vegetable oil. The label must specify the sterol. Each Gm. contains not less than 10,000 U.S.P. units of vitamin D. The activity of vitamin D preparations is determined by comparing their antirachitic activity with that of the official Standard Preparation of antirachitic vitamin by curative and prophylactic tests on young rats on rachitogenic diets. (The unit corresponds to 0.025γ of crystallized calciferol.) It is a clear, light yellowish, oily liquid; odorless; bland taste; slightly sol. in alc.; miscible with ether and chloroform. Dose, 1000 units; 0.1 cc., 5 drops (prophylactic daily dose for an infant); 3000 to 4000 units, 0.3 to 0.4 cc., 15 to 20 drops (curative daily dose for an infant); larger doses may be given in severe cases.

Calciferol (Crystalline vitamin D_2; 9||10 ergostatetraene, *Drisdol*), prepared by activation of ergosterol by ultraviolet light or electronic bombardmnte. A microgram of the crystals corresponds to 40 U.S.P. units. It is marketed as *Drisdol in Propylene Glycol*, N.N.R., 1 cc. containing 0.25 mg., equivalent to 10,000 units, with a dropper adjusted to deliver 250 units per drop to correspond in potency with Synthetic Oleovitamin D. The propylene glycol renders it miscible with water. It is administered in milk, water or orange juice, *not* undiluted. The prophylactic and curative dose is stated as 2 drops in milk, 8 to 20 drops in watery liquid.

◆

STRONTIUM

This cathion resembles calcium, and may take its place in some of its characteristic pharmacologic relations; but it is much weaker and also less toxic; however, acute and chronic toxic effects have been described (M. Comel, 1930). Strontium has no therapeutic indication. The isotope is being tried to convey radioactivity to bone and marrow.

Like Ca, strontium hastens the coagulation of blood, although it is much weaker (Howell, 1914). This action is not shared by Ba or Mg. In dilute solutions only small amounts are absorbed from the stomach; none from the intestine, since it is converted into phosphates. It leaves the blood rapidly, so that no trace may be detectable there twenty-four hours after its administration. When about 250 mg. of Sr were injected by vein into normal persons for five days, 85 to 135 mg. were excreted for seven days; 93 per cent of the excretion was by the urine (McCance and Widdowson, 1939). The level of plasma calcium may be lowered or remain unchanged. The strontium is deposited in the bones, like calcium. This is mobilized if the parathyroid glands are excised (Andersch and Fay, 1939). Strontium salts, when administered orally to dogs, are excreted largely by the feces; when injected intravenously, by the urine (M. Fay *et al.*, 1942). It increases the elimination of uric acid. Cows excrete 8 to 11 per cent of intravenously injected strontium in the *milk* of 102 hours. Its administration to young animals or in intra-uterine life disturbs the bone formation. The osteogenetic tissue is stimulated, but the bones are imperfectly calcified, since the Ca is deficient and the Sr is deposited imperfectly (Lehnerdt, 1909, 1913; Kinney and McCollum, 1923).

Effects of Strontium.—Injection of small doses of $SrCl_2$ raises the blood pressure chiefly by stimulation of the cardiac muscle. The respiration is also stimulated. Large doses produce apnea, inhibit the heart and cause death by cardiac arrest with cats; by respiratory failure with rats. The intravenous toxicity for rats is slightly higher than that of calcium; for mice it is considerably less (V. V. Cole *et al.*, 1941). Isolated vessels are constricted (Boriani, 1939). The effects of strontium on the *autonomic system* differ from those of calcium. However, strontium chloride can take the place of calcium chloride in Ringer's solution for excised frog heart and rabbit intestine, but fatigue sets in more quickly (Ono, 1927). The bronchioles are constricted, as with barium (Boriani, 1939).

Anion of Strontium Salts.—Strontium salts have been used, in same dosage as the sodium salts, mainly on the supposition that the anions would be more slowly absorbed, and would therefore have a more gradual and milder action. This theory is without foundation. Iodide, for instance, is absorbed with the same rapidity as from the potassium salt (Krahulik and Pilcher, 1918); and the "toxic" effects of strontium salicylate are just as pronounced as with the sodium salt (Blankenhorn, 1916).

◆

OXALIC ACID AND OXALATES

Oxalic acid and the oxalates exert a strong acid action, resulting in local irritation and corrosion. In addition, they produce violent stimulation, and later paralysis. These actions are completely antagonized by the addition of Ca. The oxalates have some toxicologic importance, but no therapeutic interest. The small quantities which occur in many vegetables (rhubarb, and so forth) are ineffective if these are consumed in the ordinary amount (review, H. Jeghers and Murphy, 1945).

Oxalate Poisoning.—When taken by mouth, the oxalates are *readily absorbed*, and poisoning is not infrequent from confusion with other salts. The *symptoms* are, at first, those of a local caustic, especially when the acid was used; then those of rapid collapse, possibly preceded by convulsions. The pulse is small and weak. *Death* by oxalic acid and oxalates usually occurs much more quickly than by other caustic substances. This is of diagnostic importance. (In one case death took place in ten minutes.) Sometimes fatal collapse may occur after hours of relatively slight symptoms (O. H. Brown and Scott, 1912; review, J. Pohl, Heffter's Handb, *1*:860).

A study of seventeen human cases of oxalic acid poisoning is reported by Wichern, 1912. The *fatal dose* varies with the concentration. The smallest recorded amount is 5 Gm. *Metabolism* is markedly depressed in oxalate poisoning, especially the production of carbonic acid. The respiratory quotient falls (Corley, 1902). The urines in Wichern's cases were scanty, with traces of albumin, and rarely calcium oxalate crystals. Polyuria developed later. Hemorrhagic nephritis was not observed. The kidneys of a fatal clinical case showed marked *renal injury*, cloudy swelling, hyaline degeneration and sclerosis of the tubules (Többen, 1938). The *toxic phenomena of oral poisoning of dogs* were studied by E. Rost. *Cumulative action* is observed after continued feeding of rabbits with oxalates or citrates (Salant and Swanson, 1918). Többen, 1938, found renal injury similar to the clinical poisoning.

Rhubarb Leaf Poisoning.—Serious and even fatal poisoning has been attributed to the eating of boiled rhubarb leaf "greens." The leaves contain about 10 grains of oxalate per pound, and this has been held responsible for the poisoning (J.A.M.A., 1917, *68:* 1928; 1919, *73:* 926). The connection appears rather doubtful. Data on the *oxalate content of vegetables* are given by Arbenz, 1917, and by E. H. Kohman, 1934. Traces of oxalate occur in practically all vegetables and fruits. Spinach and similar greens contain 0.3 to 0.7 per cent of oxalate, equivalent to about 10 per cent of the dried weight. Calcium oxalate is not absorbable, and the oxalate in vegetables interferes with the utilization of their calcium (S. K. Talapatra *et al.*, 1942). Addition of 8 per cent of spinach to the diet of rats may result in serious calcium deficiency (Kohman, 1939).

Treatment of Oxalate Poisoning.—The chemic *antidote* is calcium in any form, calcium chloride and lactate, chalk, lime water, and the like (Husemann). Liberal quantities of water should be given to prevent the deposition of crystals in the kidneys. Calcium lactate should be administered by vein; magnesium sulfate should be given as cathartic.

Fatal sodium oxalate poisoning in mice may be completely antagonized by *parathyroid hormone* (Kochmann, 1938). Experimentally, magnesium injection has proved of some value by quieting the stimulation (Gates and Meltzer, 1917; Gates, 1918).

Fate.—Oxalates are resistant to oxidation in the animal body, but it seems certain that a limited amount is oxidized. The *excretion* (92 to 95 per cent after hypodermic injections) occurs almost completely by the kidneys. In *rabbits* with a uniform diet, the urinary excretion is fairly constant, the fecal excretion varies widely. With intravenous injection it is excreted rapidly by the urine, but not quantitatively. The oxidation is reported to be increased by insulin (Lucia, 1929). Its absorption from the intestines depends on the Ca content of the food and the pH of the intestines (Oikawa, 1938). With oral administration to *dogs*, 72 per cent was recovered unchanged in nine days, 63 per cent in the urine. The remainder was probably destroyed by the intestinal bacteria. On a normal diet, dogs excreted 213 to 330 mg. per day, of which 94 per cent was in the urine and 6 per cent in the feces (Orzechowski *et al.*, 1935). The fresh urine contains mainly oxaluric acid, but on standing this decomposes into urea and oxalic acid, which forms calcium oxalate. This is almost insoluble and occurs as envelope-shaped crystals, which are diagnostic of oxalate poisoning. The crystals may be excreted in such amounts as to block the urinary tubules, and may thereby possibly lead to *nephritis*, or retention of urine and uremia. Calcium oxalate, in rod-shaped crystals, may be found in all the organs, but it may be absent from these in acute poisoning (Mürset, 1885). In administering sodium oxalate to dogs orally and parenterally, acutely and slowly, the highest content was found in the kidneys, and lasted long after the administration. There may be severe tubular necrosis and intraepithelial crystal deposits (Heubner and Hückel, 1935).

The blood normally contains traces of oxalate, not more than 0.48 mg. per 100 cc. Older figures of 2 to 4 mg. were based on faulty method (J. F. B. Barrett, 1943). Oxalic acid is formed, in dogs and rabbits, by the oxidation of glyoxal and glycolic acid (Herkel and Koch), of ethylene glycol and its monoacetate, but not by a variety of other ethylene derivatives (F. H. Wiley *et al.*, 1937).

The *calcium balance* is rendered negative by soluble oxalates, through the precipitation of calcium in the digestive tract (Kohman and Sanborn, 1935).

Tooth enamel solubility is decreased *in vitro* by sodium oxalate, as with fluoride, and is more effective than the latter to counteract erosion by dilute acid in living rats. Spinach does not have this effect, as its oxalate is not sufficiently soluble (Gortner, Restarski *et al.*, 1946; Gortner, McCay *et al.*, 1946).

Blood coagulation is prevented *in vitro* by the addition of 0.1 per cent of ammonium, potassium or sodium oxalate. This is due to calcium precipitation, and addition of calcium chloride restores the coagulability (Arthus and Pagès). However, intravenous injection of 20 mg. of oxalic acid is reported as *hemostatic*, shortening the coagulation time (without appreciable effect on prothrombin time), and producing immediate decrease or cessation of bleeding from major operative procedures or carcinoma, without bad effects (A. W. Blain and Campbell, 1942).

Intravenous Injections in Mammals.—The oxalates first affect the *central nervous system* in its whole extent, from mental functions to reflexes, producing stimulation with convulsions, and then *paralysis*, the latter being more conspicuous with large doses. The medullary centers are especially involved. The *asphyxia* causes glycosuria, and possibly indicanuria. The temperature rises. *Death* occurs from respiratory paralysis, except when the poison is injected directly into the circulation, in which event it may paralyze the cardiac muscle (slowed heart and fall of blood pressure, v. Vietinghoff-Scheel, 1901; Starkenstein, 1914). *Repeated injections* of sodium oxalate into rabbits result in *hypertension*, lasting about twelve days, with gradual return to the normal level, but with marked instability. It is probably caused by the nephritic injury (Arnott and Kellar, 1935). Oxalates, injected with Mg, increase the anesthetic effect, presumably by inactivating the antagonistic Ca (Gates and Meltzer, 1914),

Calcium and Phosphate Balance.—Intravenous injection of sodium oxalate or citrate into dogs immediately lowers the plasma Ca, more so with oxalate than with citrate. Recovery of the Ca level occurs rapidly, and is completed in a few hours. The phosphate level is slightly depressed during the Ca fall, rises markedly with the Ca recovery, and may continue elevated for twenty-four hours. The recovery is attributed chiefly to mobilization of calcium phosphate from the bones through intermediation of the parathyroid (Tsai and Hsu, 1930).

Actions on Peripheral Autonomic Nervous System.—The oxalates act like deprivation of Ca; *i. e.*, they increase the sensitiveness to epinephrine and pilocarpine; but they diminish the excitability to electric vagus stimulation (Chiari and Froelich, 1911). In *excised intestines*, the calcium precipitants increase the tone and the pendulum movements (Starkenstein). The *response of the heart to vagus stimulation* is abolished by intravenous injection of sodium oxalate (or citrate) in turtles (G. D. Shafer). Injections of oxalates produce slowing and weakening of the *frog heart;* with stronger concentrations prompt diastolic arrest, first of the ventricle, then of the auricles. This can be removed completely by rinsing with Ca solution (Januschke, 1909). Washing with NaCl alone gives much poorer recovery (Gros, 1913). Similar effects are seen with perfused mammalian hearts (Salant and Hecht, 1915).

Skeletal Muscle.—Dilute solutions of oxalates (or other precipitants or inactivators of calcium) applied directly to skeletal muscle cause fibrillation, tetanus and contracture. Diminution of the proportion of Ca by any other means has the same effect. Larger doses of oxalates depress the excitability and force of the skeletal and cardiac muscles.

Glycogenolysis of slices of rat liver is damaged by oxalates, and is arrested by quantities which would bind only a tenth of the calcium. Decrease of calcium by 30 per cent does not check the glycogenolysis in the absence of oxalate. This oxalate action is therefore not explainable by calcium precipitation, but must be more direct. However, addition of calcium antagonizes oxalate by precipitation (Brock *et al.*, 1940).

Intact frogs show progressive and descending loss of reflexes, fibrillary twitchings, central paralysis, finally cardiac arrest. This is also promptly removed by Ca and Sr.

Lower Organisms.—Oxalates are toxic to all life except to a few lower fungi which do not contain calcium. They are toxic to most plants, but certain species contain soluble oxalates. In algae the main histologic changes are seen in the portions richest in calcium—nucleus and chlorophyl (O. Loew, 1912). Oxalic acid is probably a constant product of metabolism, and one of the functions of calcium is to render it harmless.

FLUORIDES

Sodium fluoride, NaF, is a general protoplasmic poison, of some toxicologic importance and considerable scientific interest. Its use to poison cockroaches and rats, as also that of sodium fluosilicate, has led to human fatalities. It produces local necrosis of mucous membranes. After absorption it causes acute and chronic poisoning, especially gastroenteritis, even with parenteral administration, collapse, and hepatic and other visceral degeneration, with nutritional disturbances. The long-continued ingestion of small quantities, such as occur in the water supply of some districts, injures enamel formation, causing "mottled enamel" and other abnormal bone formation. It also has a protective action against dental caries. The acute effects may be due partly to disionization of calcium, similar to oxalates; but other factors are more important, especially the destruction of various enzymes. Sodium fluoride is readily soluble in water (1:25); but the sparingly soluble calcium salt is almost equally liable to produce chronic poisoning. Inorganic fluorine compounds, such as the fluosilicates, are generally toxic by liberating fluoride ions. The gaseous aliphatic fluorine compounds have a low toxicity and are discussed with the aliphatic narcotics. (Reviews, De Eds; McClure; Roholm, 1937, 1938; D. A. Greenwood, 1940.)

Occurrence in Nature.—Fluorine is one of the most widely distributed elements, ranking about twentieth in the first mile of the earth's crust. It is found chiefly as *fluorspar*, CaF_2; aluminum fluosilicate; *cryolite*, a double fluoride of aluminum and sodium, which is used extensively as a source of aluminum; *apatite*, a native calcium fluophosphate, $Ca_5(Cl,F,OH)(PO_4)_3$; and other minerals. The fluoride content of soils has been reported up to 0.15 per cent, averaging about 0.03 per cent. It has been demonstrated in the municipal water supplies of all large American cities (Churchill), often in quantities sufficient to produce mottled enamel.

Occurrence in the Body.—The wide distribution of fluorine compounds accounts for its normal presence in plants and animal tissues, generally as the sparingly soluble CaF_2. It probably does not serve a useful function (Jodlbauer, 1901). It was discovered in normal tooth enamel by Gay-Lussac and Berthollet in 1805. Gabriel, 1893, confirmed its normal presence in bones and teeth. Smaller quantities are found in the epidermis, hair, thymus, testes, blood, milk, and so forth (Gautier and Clausmann, 1913, 1916). Zdarek, 1910, found it present in the entire human body, but relatively richest in the liver, kidneys and bones. The *fluoride content of soft tissues* is as follows, mg. per 100 Gm. of dried tissue: epidermis and hair, 6 to 17; glands and blood, 1 to 4; cartilage and muscle, 0.04 to 0.5. W. C. Dreesen and Sievers, 1946, state the mean content of the blood in normal men as 0.01 mg. per 100 cc.; of urine as 0.2 to 0.4 mg. per liter; the upper safe limit of urinary excretion as 4 to 5 mg. per day.

The quantitative methods are not entirely satisfactory; but Gautier and Clausmann, 1916, made extensive studies on the occurrence of F in *foods*, and found the average 0.6 mg. per 100 Gm. of fresh material. The modern data, reviewed by Roholm, show wide variations. Sea food is relatively rich; but the largest amount, aside from vegetables sprayed with fluoride, is found in bone and teeth. *Bone ash* contains normally from 17.5 to 123 mg. per 100 Gm. (Gautier and Clausmann). Other data run from 10 to 30 mg. per 100 Gm. of fresh bone. It is probably present as an apatite, $3[Ca_3(PO_4)_2]CaF_2$. Teeth and enamel contain about the same amount. The content rises with the age of the individual. Fossil bones contain more than recent bones, presumably because their calcium precipitates the fluoride of the ground water. Addition of sodium fluoride to the food and drink of adult dogs for over two to eighteen months raised the fluoride content of the *dentine* progressively from 18 to 72 mg. per 100 Gm.; that of the *enamel* showed little if any increase (E. W. Bodine, 1942).

Use as Insecticide.—Fluoride appears to be more toxic to insects than to higher animals, perhaps because their Ca and P content is lower (Marcovitch). However, the action is not understood. *Spraying* of vegetables and fruits with cryolite is effective, but the U.S. Government regulations (1938) provide that the food as marketed must not contain more than 0.02 grains of fluoride per pound (2.8 parts per million). If *cryolite* is added to the food, its slow solubility makes it about half as toxic, and gives about half the retention, as the same amount of F in the form of NaF. When dissolved in drinking water, however, the effects are identical (Marcovitch and Stanley, 1938; R. J. Evans and Phillips, 1939; M. Lawrenz *et al.*, 1939). The retention in bones of growing rats is somewhat less if cryolite is fed intermittently than if the same total is taken continuously (Lawrenz, Mitchell and Ruth, 1940). Sodium fluoride is used extensively against *roaches.* It may be mixed with an equal quantity of flour and wrapped loosely in paper, so that it can be reached and eaten by the insects. The success with this method is limited, but it is practically devoid of danger, unless the powder itself is eaten; it should be kept out of the reach of children, and adults should be cautioned against it. Promiscuous dusting with the powder is more effective and also more dangerous.

Antiseptic Action.—Sodium fluoride is antiseptic in concentrations of about 0.25 per 10,000, and germicidal in 1:200. Before its toxicity was generally recognized, it was used for irrigations and moist dressings (0.25 to 10:10,000), and even for the preservation of food (10 to 15 mg. per liter). These uses are too dangerous. J. Head, 1913, employed "*ammonium bifluoride*" in the treatment of pyorrhea (injection of 23 per cent solution around the loose teeth twice a week).

Local Action.—A 2 per cent solution of *sodium fluoride* kills the cells of mucous membranes, and produces corrosion. Oral administration of soluble fluorides and silicofluorides causes hemorrhagic gastro-enteritis.

Hydrofluoric acid produces vesication and deep and progressive destruction of tissue, suppuration, and painful slowly healing ulcers (Gay-Lussac and Thénard, 1809). This is not due merely to the acidity, for undissociated HF appears to penetrate through intact epidermis (Görlitzer, 1932). Slight exposure causes rubefaction and a burning sensation; 2 to 5 per cent solutions have little or no effect on human skin; stronger solutions produce a yellow, leathery change of the epidermis, and the corrosive effects as described. Local injection of calcium gluconate appears to arrest the process and to secure prompt healing (Paley and Seifter, 1940).

Acute Fluoride Poisoning.—Fatal acute and chronic poisoning in man has resulted from careless use of fluorides as vermin poisons, especially where it may be mistaken for baking soda or baking powder. The *phenomena of sublethal acute poisoning* are chiefly gastro-enteritis and collapse, and may run a rapid course, with sudden nausea and vomiting, abdominal burning and cramps, diarrhea, for three to six hours; stupor and weakness for thirty-six hours (Vallee, 1920, 0.23 to 0.45 Gm.; Sharkey and Simpson, 1933, literat.). *Fatal cases* develop muscular weakness and tremors progressing to clonic convulsions originating in the cord and higher centers (decalcification?), fall of blood pressure, general collapse, sometimes with grayish-blue cyanosis, dyspnea, arrest of the respiration and of the heart. Death occurs in a few minutes to ten hours or longer. Rigor sets in promptly. *Frogs* also show fibrillary contractions of the skeletal muscles which are arrested by section of the nerve (Tappeiner, 1889; human cases, Raestrup, 1925; Pietrusky, 1930; Zeyneck and Stary, 1931). The *gastro-enteritis* is not merely local, but occurs also if the drug is introduced by other channels, the intestinal epithelium being destroyed, while the cilia of the respiratory epithelium may still be moving (Siegfried, 1901). The primary injury is probably to the capillaries, the permeability of which is increased even by small doses (Asher, 1910). *Necropsies* show inflammation of the mucosae of the esophagus, stomach and small intestines, with petechiae, but without corrosions. It may be due to injury to the capillaries. The stomach generally contains 70 to 200 cc. of bloody fluid (Raestrup). Frequently there is also marked cerebral hyperemia and edema, and edema of the lungs with petechiae of the pleura and pericardium. Muehlberger, 1930, considered that the chief changes consist in congestion and hydropic degeneration of the liver and kidneys. Albuminuria is generally present. The *parathyroid glands* are reported to show marked degenerative changes in rabbits killed acutely by fluoride; and less severe effects in chronic poisoning (Pavlovic and Tihomirov, 1932).

Toxic Dosage.—Dangerous symptoms have been reported in man from 0.25 Gm. of sodium fluoride. Recovery has followed 0.5 Gm., and death has been caused by 4 Gm. The acutely fatal dose for mammals averages about 0.5 Gm. per Kg., by mouth; about 0.15 Gm. per Kg., hypodermically or by vein (Tappeiner, 1889).

Treatment.—Gastric lavage with calcium chloride followed by adsorbents (charcoal) should be tried; intravenous injection of calcium chloride might be useful. Fatal fluoride poisoning in mice can be successfully *antagonized* by parathyroid hormone, so that this may be used for the bio-assay of the hormone (Kochmann, 1938).

Fluoride on Calcium Metabolism.—Fluoride poisoning tends to lower the calcium level of the plasma. In rabbits on calcium deficient diet this may amount to 50 per cent in acute poisoning, 13 per cent in chronic poisoning (Jodlbauer, 1932). The plasma phosphate is also lowered in acute, but not in chronic, poisoning (Pavlovic and Bogdanovic, 1932). The calcium level may be but little lowered even in acute poisoning, and may be normal in chronic poisoning (J. A. Schulz, 1931; Greenwood, Hewitt and Nelson, 1935). The changes in the blood calcium level are not sufficient to explain the fluoride toxicity, even in acute poisoning. The antagonistic effects of calcium injection (Schlick, 1895) are due to defluorization, rather than to correction of a calcium deficiency.

Enzyme Processes.—Fluorides are strongly inhibitory to some enzymes, while others are little affected. Anaerobic *glycolysis* in yeast, muscles and other tissues is especially susceptible, the action resembling that from monoiodoacetic acid (F. Lipmann, 1930). Injection of sodium fluoride into the carotid artery depresses the *electric activity of the cerebral cortex* by momentary inhibition of cortical glycolysis (Moruzzi, 1938). *Other enzymes* that are strongly restrained include lipase, esterases and urease. Proteolytic and diastatic enzymes are not very susceptible. Salivary amylase is not affected even by fairly high concentrations (F. J. McClure, 1939). Alcoholic fermentation is inhibited, as is also the coagulation of blood or of milk.

Blood Coagulation.—The addition of 0.4 per cent of sodium fluoride renders shed blood noncoagulable. This is due chiefly to inhibition of the formation of fibrin ferment (Calugareatu), and not to precipitation of calcium, for the coagulability is not restored if the calcium is restored, but only if thrombin is also added. It has been suggested that the fluoride prevents the breaking up of the platelets and leukocytes, but this requires confirmation. The action may be due to the liver injury. Feeding sodium fluoride does not diminish the coagulability of the blood (Greenwood *et al.*, 1935). The *clotting of milk* by pepsin or rennin is inhibited by fluoride (Clifford), but occurs if calcium is added, so that the interference in this case is not with the enzyme action. *Lipase* is inhibited by NaF, 1:5000, and checked by 1:15,000,000 (Kastle and Loevenhart, 1900). Esterases which are inhibited include *phosphatase* (Lipmann, 1928; Kay, 1928); and *cholinesterase* (1:15,000), thereby increasing susceptibility to acetylcholine (Matthes, 1930; Kahlson and Uvnas, 1935). Fluoride interferes with the catalase and oxidase of *insect tissue extracts*, but not with the reductase (G. D. Shafer, 1915)

Glycolysis and Muscle Enzymes.—Sodium fluoride depresses the respiration of finely divided muscle, and still more the formation of lactic acid and the hydrolysis of glycerophosphoric and hexose-phosphoric acids. It acts differently from cyanide in this respect (F. Lipmann, 1928). The effect is due to inhibition of the magnesium enolase that converts 2-phosphoglyceric acid into 2-phosphopyruvic acid. (This conversion is also effected by zinc and manganese enolase, which are inhibited by cyanide; O. Warburg and Christian, 1941.) This inhibits the formation of lactic acid (Meyerhof, 1935). The muscle can perform work without raising its lactic acid content, by the more rapid decomposition of phosphagen, esterification of hexose with phosphoric acid, and splitting of adenyl pyrophosphate (Lipmann, 1930). It does not prevent the decrease of glycogen in muscle pulp, but inhibits and may reverse the glycogen breakdown in intact muscle (Embden). Muscle immersed in fluoride shows spontaneous fibrillary contractions, tetanus and rigid *contracture.* It is toxic to *nerve.*

Heart.—The SA and AV conduction is changed in the excised *frog heart* by 10 to 20 of NaF or 10 of CaF_2. The latter shows that the effect is not due to decalcification. The effects resemble those of monoiodoacetic acid, and may be ascribed to the changes in the intermediate carbohydrate metabolism of the cardiac muscle (Chang, 1938). With *dogs,* 20 to 70 mg. of NaF per Kg. lowers the blood pressure. The heart dilates temporarily, often with auricular flutter; then returns to normal; and finally dilates again, with sinus block, extrasystoles and ventricular flutter (Gottdenker and Rothberger, 1935).

The **excretion** of fluoride occurs chiefly by the urine (O. Schultz, 1889), considerably by the sweat (F. J. McClure, Mitchell *et al.*, 1945), and some by the feces. Some is also secreted into the milk, enough to cause the death of nursling rats (Goldenberg, 1928). It passes freely across the placenta to the fetus (M. M. Murray, 1936). Considerable may be *retained,* increasing the F content of the tissues (Tappeiner). Retention occurs in man with daily ingestion of 5 mg. (F. J. McClure *et al.*, 1945). In five instances of fatal clinical poisoning, the F content of internal organs ranged between 0.14 to 1.6 mg. per 100 Gm. (Gettler and Ellerbrook, 1939; improved test). The *normal daily exchange* for man was estimated by Gautier and Clausmann as: income, somewhat about 1 mg.; excretion by urine, 0.23 mg.; by feces, 0.80 mg. The food, exclusive of drinking water, averages 0.92 mg. per Kg. Variations of income and excretion are chiefly due to the domestic water supply. When this is practically fluoride free, the urine contains 0.3 to 0.5 mg. of F per liter. When the water contains 0.5 to 5 mg. per liter, the urinary concentration rises proportionately (F. J. McClure and Kinser, 1944).

Chronic Fluoride Poisoning.—Small quantities of fluride that produce no apparent effects when administered singly, lead to marked changes when their administration is continued. The smallest effective quantities, as drinking water or food, show only faulty tooth formation in children, "mottled enamel." *Mottled nails* are also an early sign of chronic fluorosis (L. Spira, 1943). Somewhat larger amounts, experimentally or in industrial exposure, may cause bone changes in adults, osteosclerosis in man, osteoporosis and osteomalacia in animals. Still larger amounts produce anorexia, anemia (probably by interference of the bone changes with the marrow) and cachexia, loss of weight and impairment of growth and impaired reproduction. The toxic effects are inverse to the *intake of calcium* (S. Ranganathan, 1941). They appear to be aggravated by dietary deficiency of ascorbic acid (J. F. Linsman and McMurray, 1943); this is practically important in India (C. G. Pandit *et al.*, 1940).

Endemic fluorosis, characterized by "*mottled enamel,*" exists in various areas of the world; in the United States especially in regions of the Rocky Mountains and Mississippi Valley, but to some degree in practically every state. It is a serious problem in Argentina. It was first described in 1916 by Black and McKay. Subsequent studies by McKay, 1926 and 1930, indicated its relation to the domestic water supply, and Churchill, 1931, showed spectroscopically that these waters contain fluorine. M. C. Smith, Lantz and Smith, 1931, found mottling in practically every person who had lived in one of these foci (St. David, Arizona) before permanent teeth erupted; and none in those who came there after this time. *Water supplies responsible for mottling* contain 2 to 7.2 mg. of fluorine per liter; none is reported with less than 0.3 mg. per liter, and practically none with 0.6 mg. per liter; slight with 1.7 mg. (H. T. Dean and Elvove. 1935). Not all the children are affected, the incidence increasing with the fluoride concentration. Change to water supply of lower content prevents further cases (Dean, McKay and Elvove, 1938). Significant delay of tooth eruption occurs with 2.6 mg. per liter, but not below (E. M. Short, 1944). *The fluoride may be removed from the water* by treatment with tricalcium phosphate, or magnesium oxide or hydroxide. Commercial calcined magnesite (MgO) is effective and cheap (Elvove, 1937). Ingestion of aluminum sulfate was also reported to decrease the dental injury (C. A. Kempf *et al.*, 1937); but R. J. Evans and Phillips, 1939, failed to obtain any protection by adding this to the fluorided food of rats; nor by administering vitamin A.

On the other hand, it has been demonstrated that children living continuously for the first twelve years of life in fluoride areas have a lower attack rate of *dental caries* than those in nonfluoride areas. It has not yet been demonstrated that the addition of fluoride to the water supply has this effect. The mechanism is not known. It has been suggested that it modifies tooth structure so as to decrease the solubility of the enamel in acid. Others believe that it checks the growth of

Lactobacilli; but there is no evidence that it is effective after the teeth are fully formed (report, J. Am. Dent. Assoc., *34*:345, 1947).

H. T. Dean *et al.*, 1941, observed that the prevalence of tooth decay tends to be inverse to the fluoride content of the water supply of the locality. This has been abundantly confirmed (F. S. McKay, 1945; Klein, 1945). A concentration of 1 ppm during the first eight years of life suffices, with little or no mottling. F. J. McClure, 1943, recommends that fluoride should be added to the water supply to bring it to this level. However, if caries does start in mottled teeth, it spreads rapidly (M. C. Smith and Smith, 1940). J. D. Boyd and Cheyne, 1946, point out that some tooth decay is almost universal, even in areas of endemic fluorosis, and it is often high in mottled teeth. After the teeth are calcified, topical application is probably more effective. J. W. Knutson and Armstrong, 1945, applied a 2 per cent solution of sodium fluoride twice weekly for eight to fifteen treatments. They report the caries incidence reduced by over half, both in the first and in the second year after treatment. However, the incidence of caries is not reduced in two years, as compared with a control group, by dentifrices containing 0.01 and 0.1 per cent of NaF (B. G. Biddy, 1945). Prophylactic cleansing with pumice powder containing 1 per cent of fluoride is reported to decrease the incidence of new caries by 25 to 43 per cent. A mouthwash containing 0.1 per cent, used three times weekly for a year, did not decrease the incidence (B. G. Biddy *et al.*, 1946). Other enzyme inhibitors, monoiodoacetate and menadione, also tend to reduce caries (M. Massler, 1944). Experiments on rats show that the fluoride is absorbed into the enamel (M. W. Perry and Armstrong, 1941). It should not be applied to cavities, for this leads to inflammation, abscess and necrosis of the tooth pulp (W. Lefkowitz and Bodecker). Topical application of fluoride also reduces the caries incidence in *rats* on caries-producing diet (Sognnaes, 1941). Oral administration restricts caries according to most observers (F. V. McClendon and Foster, 1941), and decreases the enamel destruction when an acid phosphate sucrose solution is ingested (C. M. McCay *et al.*, 1945, 1946).

Fluorine in food is at present of minor importance, unless the water content is also fairly high. However, the residue of fluoride spraying should be controlled by washing or peeling. It is also conceivable that extensive use of such insecticides may eventually enrich the fluoride content of the soil so as to raise the fluoride content of the crops In the meantime, however, insecticides of some sort are practically indispensable to the economical supply of vegetable food. *Bone ash* contains about 0.1 per cent of F, sufficient to produce tooth degeneration when fed to rats. Roholm, 1939, therefore advises against the use of bone ash as a mineral diet supplement for children or pregnant or lactating women.

The *changes in human teeth* consist of chalky white patches, often pitted and eroded. The mottling involves generally less than a third of the thickness of the enamel; if it disfigures seriously it can be removed by grinding or by 18 per cent hydrochloric acid (C. A. McMurray, 1941). Identical changes had been observed by McCollum and associates, 1925, in the *teeth of young rats* receiving small quantities of fluoride. The lower incisors are shortened by spontaneous fractures, leading to nonocclusion, and the upper incisors therefore continue to grow and curl backward. Chaneles, 1929, noted the dull, chalky color and roughening, and studied the histological changes. These were investigated in the teeth and jawbones by Pachaly, 1932, and W. Dittrick, 1932. They consist in deposition of hypoblastic, faultily calcified enamel and bone tissue. The enamel-forming cells are selectively vulnerable to fluoride, being injured by doses for which no other deleterious action has been demonstrated. Morphologic changes in the ameloblasts and their calcium globules may be seen an hour after injection of sodium fluoride (Schour and Smith, 1935). Dean, Sebrell and Breaux, 1934, describe the progression of the changes with increasing concentrations of NaF in the drinking water, from minute transverse brown striations with 25 parts per million; passing to irregular brown patches with 150 ppm; and becoming chalky and brittle at 300 ppm. These effects are not prevented by the administration of calcium, phosphorus, Na_2HPO_4 or parathyroid hormone (Sutro, 1935). *Dogs* develop mottled enamel, as in the human (Greenwood, Hewitt and Nelson, 1935); *cattle* and *pigs* show marked changes in the *mandibles*, with increase of thickness, roughing of the surface and enlargement of the medullary spaces (G. E. T. Taylor, 1929; Bethke *et al.*, 1933).

The *fluoride content of human teeth* is normally about 0.02 per cent of the ash; in rats on ordinary diet it is generally between 0.02 and 0.03 per cent (Bowes and Murray, 1935). Data for many other animals are reported by Klement, 1935. In industrial exposure of men to fluoride dust, with a probable daily income of 15 to 25 mg. of F for years, the tooth ash contained 0.25 per cent, about ten times the normal quantity (Roholm, 1938). On feeding small quantities of fluoride (8 to 14 parts per million of food) to rats, the F content of the dry bones increases to 0.02 to 0.065 mg. per 100 Gm., roughly proportional to the amount fed (G. Ellis and Maynard, 1936).

Bone changes are seen especially with industrial exposure to the dust of cryolite or phosphate rock, with larger fluoride income than would occur from water. With probable income of 15 to 25 mg. per day, the earliest roentgen changes are seen in about two and one-half years and become severe in about eleven years (Roholm, 1938). P. F. Moeller and Gudjonsson, 1932, found half of the workers exposed to cryolite dust affected. The changes consist in generalized osteosclerosis, involving all the bones, but especially spongy bone, including the spinal column. The density of the bone is increased, with preservation of the normal bone architecture, but change of the normal structure. The organic matrix is irregular, the calcium deposition is increased but irregular, calcareous deposits extend to the ligaments and muscles, and osteophytes form between the vertebral bodies (P. A. Bishop, 1936). Water supplies relatively rich in fluoride do not result in demonstrable skeletal sclerosis (P. C. Hodges *et al.*, 1941), nor do they influence the average height and weight, nor is the frequency of bone fractures increased (F. J. McClure, 1944).

Exposure to cryolite dust also develops other symptoms. Anorexia, nausea and vomiting appear early, but tolerance to these is soon established. Continued exposure leads to functional dyspepsia, rheumatic pain, obstipation and the osteosclerosis, demonstrable by roentgen examination. Postmortem examination of two workers exposed for many years revealed no visceral changes definitely attributable to the intoxication (Roholm, 1938).

In *young rats*, fluorosis leads to generalized osteoporosis or osteomalacia, resembling rickets. The organic matrix and the calcium deposition are irregular. The ossification of the cartilages is retarded; the roentgen transparency of the bones is increased (Bergera, 1927). The bones become much more brittle (Cristiani, 1929; Sutro, 1935). Many guinea pigs with chronic fluoride poisoning show bony hypertrophic deformations of the tibia (Cristiani, 1932). White mice have delayed ossification of the internal ear (A. Lewy, 1928). Fluoride administration to young dogs altered the calcium deposition as in rickets. Long-continued administration led to sclerotic processes with abundant deposition of calcium in "calcium grains" (H. Kellner, 1939). Addition of fluoride to the diet of rachitic *rats* interferes with healing by vitamin D, the new bone being being atypical (Morgareidge and Finn, 1940).

Bones store fluoride, so that *ordinary bone meal* contains 0.04 to 0.05 per cent of F. In industrial chronic fluorosis this rose to 1.3 per cent of the bone ash, 60 times the normal (Roholm), presumably by the replacement of hydroxylapatite by fluorapatite (Huggins, 1937). McClure and Mitchell found abnormal deposition of mineral constituents other than calcium; the total ash is greater than normal and the calcium less than normal.

The *cause of the bone changes* is presumably through interference with the enzyme processes of ossification. Very dilute solutions of fluoride affect the deposition of calcium salts in the matrix profoundly *in vitro*. Monoiodoacetate has similar effects. Phosphatase does not seem to be materially concerned in fluorisis, but De Eds, 1936, reports decreased activity of the bone phosphatase in chronic fluoride poisoning of rats. P. H. Phillips, 1932, reported rise of the plasma phosphatase.

Fluorosis and Scurvy.—P. H. Phillips, 1933, found that guinea pigs receiving fluoride develop a scurvy-like condition on diets containing several times the amount of ascorbic acid which protects normal animals, and the adrenal glands hypertrophy (Phillips and Chang, 1934). Fluoride probably inactivates the enzyme reaction that involves ascorbic acid (Phillips, Stare and Elvehjem, 1934). *Bone marrow* hyperplasia and atrophy and severe *hypochromic anemia* have been reported for long-continued administration to dogs (Roholm, 1937).

Thyroid Relation.—Goldemberg, 1921, reported that rats which received small doses of sodium fluoride (2 or 3 mg. per day for six to eight months) developed marked thyroid hyperplasia, and young rats showed the phenomena of cretinism. Similar effects were observed on rabbits. On this basis he suggested fluorosis as the cause of endemic goiter and cretinism. He also reported, 1930, that fluoride administration decreases the basal metabolic rate of rats and guinea pigs. He concluded that it inactivates thyroxin and used it to treat the thyrotoxicosis of Basedow's disease (1932). Others have failed to confirm these observations: Chaneles, 1929, and Cristiani, 1930 and 1931, obtained little effect on the thyroid structure. Seevers and Braun, 1935, found that fluoride did not prevent the toxic effects of thyroid administration in rabbits, and the histologic picture was the same with or without fluoride treatment. P. H. Phillips, 1926, found that fluoride increased basal metabolism and toxicity of thyroid administration in rats. Schteingart and Sammaptino, 1932, did not observe improvement in Graves' disease. W. May, 1937, however, claims good clinical results, and Kraft and May report that the fluoride level of the plasma in thyrotoxicosis is only half the normal, 0.1 to 0.12 mg. per cent. Rats on subeffective fluoride diet develop fluoride teeth if thyroid is administered. This is not due to increased food consumption, for increase of appetite by insulin does not provoke the tooth changes (R. H. Wilson and De Eds, 1940).

The *thyroid glands store fluorine* much more actively than other organs (Chang, Phillips *et al.*, 1934). R. J. Evans and Phillips, 1938, found the content in hyperthyroidism variable and without relation to the basal metabolic rate, or to the iodine content of the gland. They consider that there is no evidence for any role of fluorine in human thyroid disease.

3-Fluoro-tyrosine is reported to act antagonistically to thyroxin (Litzka, 1936, and Kraft, 1936).

Hyperglycemia is reported to result from intravenous injection of sodium fluoride, 0.5 to 10 mg. per Kg. (Goldemberg, 1928).

Parathyroid Function.—Hauck, Steenbock and Parrons, 1933, found no effects.

Kidneys.—S. Marconi, 1939, reported severe acute parenchymatous nephritis on chronic poisoning of guinea pigs with fairly large doses of fluoride. Others have found chiefly interstitial nephritis, but with degeneration of the tubular epithelium in the severer grades. The histologic changes in the kidneys and thyroids are described by Phillips and Lamb, 1934.

Growth and Nutrition.—Sodium fluoride administered to rats over prolonged periods (Goldemberg, 1917, 1919; Sollmann, 1921; A. R. Lamb, Phillips *et al.*, 1933), in daily doses of 15 to 150 mg. per Kg. of body weight, produces cachexia with progressive impairment of growth and food consumption, but with little mortality, and without histologic lesions. There is also marked interference with estrus and reproduction, but this is secondary to the malnutrition (Lamb *et al.*, 1933). The damage is proportional to the dose, and tends to outlast the administration of the drug; so that the growth of animals poisoned with fluoride remains permanently below that of unpoisoned animals. The diminished food consumption is not due to distaste of fluoride food, for the animals do not prefer unpoisoned food (except with the highest concentrations). The effects are not due to "general salt action," for corresponding doses of NaCl are not harmful. No deleterious effects on growth or food consumption occurred in nine weeks with daily doses, 8 mg. of NaF per Kg. of body weight, or with smaller doses. In rats the malnutrition may be due largely to the deformation of the teeth, which prevents occlusion. However, similar effects from analogous doses have been observed on other animals in which the teeth are not deformed. Cows appear to be more susceptible to the malnutrition than rats, especially during lactation (Phillips, Hart and Bohstedt, 1934). Pigs are less susceptible. Calcium fluoride in the form of "*phosphate rock*" produces the same effects as NaF and in nearly corresponding doses; the chronic fluoride intoxication is, therefore, not due to disturbed calcium balance. The deleterious effect of phosphate rock is not shared by other insoluble Ca salts (phosphate and carbonate) in equal concentration.

Hair growth in rats is retarded by feeding or intraperitoneal injection of fluoride (E. O. Butcher, 1946). S. Spira, 1946, considers the alopecia comparable to thallium poisoning.

Diets low in fluoride (0.05 mg. per Kg. of body weight, daily) do not impair growth. Incisor bleaching begins with 2.5 to 3 mg. (R. J. Evans and Phillips, 1939).

Fluosilicate.—These are generally more soluble than fluorides, except sodium fluoride. Sodium fluosilicate, Na_2SiF_6, is used as a rat poison and has produced fatalities in man. Water converts it partly into NaF and SiF_4, the reaction being favored by alkalinity. Its effects are identical with those of fluoride; indeed quantitatively so, when the dosage is adjusted to the fluorine content. This holds for oral as well as for hypodermic administration (C. W. Muehlberger, 1930). In chronic intoxication by minimal doses, the fluosilicate is the more toxic (Cristiani and Chausse, 1927).

Fluoroacetate of sodium ("Compound 1080") is a highly effective poison for rodents (E. R. Kalmbach, 1945). It occurs in certain poisonous plants of South Africa (C. W. Klingensmith, 1945; see Index).

Gaseous silicon tetrafluoride, SiF_4, is decomposed by the moisture of the air passages into HF and H_2SiF_6, and the latter again into silicic acid, which is precipitated in the air passages (Cameron, 1887).

Organic Fluorides (see Index) are generally less toxic than other halogenated hydrocarbons (Kant, 1933). *Alpha fluoronaphthalene* produces mottled teeth in dogs; fluorobenzene does not (Kempf *et al.*, 1937).

◆

BROMIDES

Fairly large doses of bromides depress the psychic functions and the reflexes, leading to a condition of mental apathy, which conduces to sleep, particularly in nervous insomnia. The bromides are employed to secure sleep, and for sedation in nervous hyperexcitabilities, Graves' disease, hysteria, hyperemesis, cinchonism, and so forth, but their continued use is likely to result in toxic effects, and barbiturates are generally preferred. Their anticonvulsant action is utilized against epilepsy, but they have been largely displaced by phenobarbital and diphenylhydantoin. They generally suppress or mitigate the convulsions, at least in the idiopathic form; but they do not effect a cure. The effects occur slowly and are correspondingly lasting. The administration must be fairly continuous. The action seems to be due to the Br ion as such. It is produced by all the bromides, and to a less degree by the organic bromine compounds. NaBr is generally preferred. The mechanism is not explained. The excretion of Br is analogous to that of Cl. A part is retained persistently. The elimination is hastened by Cl administration; conversely, the Br retention effects are increased by Cl-poor diet. Continued administration of large doses often results in bromide acne, and other symptoms analogous to those of iodism. There may also be considerable psychic depression, malnutrition and lowered resistance. These may contraindicate the use in neurasthenic patients, and the like. Acute bromide poisoning is rare, occurring only after enormous doses. Ordinary doses have no effect on the circulation.

Historical.—Bromine was discovered by Balard, 1826, in sea-water. Its chemical similarity to iodine prompted its trial against glandular swellings, syphilis and thyroid disorders. This was unsuccessful, but led to the observation of its sedative action. Its use in epilepsy is said to date from Laycock, 1853; as hypnotic, from Behrend, 1864. The older literature is reviewed by Krosz, 1876.

Fate.—The organism does not distinguish sharply between the halide and related anions (E. Frey, 1910), which are to a large extent interchangeable; so that the absorption, distribution and excretion of bromide are essentially like those of chloride, iodide, thiocyanate or nitrate. Bromide does not readily penetrate cells, and therefore remains almost exclusively in the extracellular fluids of the body. The renal permeability is somewhat less for bromide than for chloride, and this is less than for iodide.

Absorption.—The bromides are rapidly absorbed from mucous membranes. It was believed that calcium bromide is absorbed more slowly, but Hales and Fishman, 1908, found it excreted at about the same rate as NaBr. In ligated *intestinal segments*, the absorption of bromides is not delayed by the presence of chlorides; but bromide somewhat delays chloride absorption. The lower segments of the small intestine are said to absorb bromide better than the upper (Bolgar, 1910).

Channels of Excretion.—The excretion occurs as bromide mainly by the urine, but with protracted administration, the feces may represent up to a fifth of the total excretion (O. Bodansky and Modell, 1942). Small quantities are also eliminated by the feces, sweat (Tachau, 1911) and other secretions, including the cerebrospinal fluid (Hald, 1911). The amount excreted in the *milk* of a nursing mother who is taking bromide may have a sedative effect on the nursling (Tyson *et al.*, 1938). The excretion of Br by the *sweat* is quite limited. The *epithelium of the skin* may accumulate unlimited quantities of bromide during continued administration, returning gradually to normal when the income is discontinued (Cornbleet, 1938).

The *course of urinary excretion* depends on the total halide concentration of the plasma rather than on the bromide concentration. It starts promptly, but proceeds slowly; *f. i.*, in one to one and one-half days only one-tenth may be excreted, and traces are found after twenty days. The rate is only half or less that of iodides (Herzfeld and Gormidor, 1912). The kidneys are also less permeable to bromides than to chlorides (U. J. Wile, 1923; Hastings *et al.*, 1932). The bromide excretion depends somewhat on diuresis, but only imperfectly (Hales and Fishman, 1908). Salyrgan and theophylline increase the bromide and chloride excretion considerably, sodium sulfate and water very little (O. Bodansky and Modell, 1941). The quantity excreted is proportional to that administered, but always with considerable retention. With continued use, the percentage excreted increases until it equals the ingestion, constituting equilibrium or saturation for that dose. This is reached in about sixteen days (Markwalder). The excretion thus totals one or two-thirds of the amount ingested (O. Bodansky and Modell, 1942). When the administration is stopped, the excretion diminishes, at first rapidly, then more slowly, so that traces may be present for a month or longer. The excretion follows the same course in epileptic as in normal individuals (v. Wyss, 1906).

Chloride administration hastens the elimination of both Br and I (Herzfeld and Gormidor, 1912; Wyss, 1913); Cl-poor foods slow the excretion (Sarvonat and Cremien, 1911). Conversely, the administration of bromides increases the elimination of Cl (Wyss, 1913). Iodide also displaces Br and Cl. Wagner and Bunbury, 1930, reported that the administration of large doses of sodium chloride (15 Gm. three times daily) to patients who had been under bromide treatment actually increased the bromide content of the blood, by mobilizing the tissue bromide faster than it can be excreted. Further studies are desirable.

Bromides on Diuresis.—The urine flow is increased by salt action (Wolf and Opp, 1912).

Bromides in Uranium Edema.—Uranium animals become less edemic when bromides are administered. These cause a greater diuresis; the Cl excretion is as high as normal; and the urine contains a part of the Br. The body therefore loses both water and salt (Leva, 1912).

The distribution of bromide is similar to the normal Cl, which it partly replaces in the blood, gastric juice and other extracellular fluids (Nencki and Simonowski, 1893; Ellinger and Kotake, 1911).

Partition Between Blood Corpuscles and Plasma.—After injections or *in vitro*, the bromide is confined almost exclusively to the serum. A small quantity, however, does go into the corpuscles, more readily than does Cl, so that the Br:Cl ratio is higher in the corpuscles than in the serum (Hastings *et al.*, 1931, 1932). With continued administration, the ratio gradually becomes equalized (M. F. Mason, 1936). The *cerebrospinal fluid*, which has a somewhat higher chloride concentration than the serum, contains distinctly less bromide, if this has been administered by mouth or vein, and eventually even after cisternal injection (Notkin *et al.*, 1936; Wallace and Brodie, 1939, 1940). The ratio for iodide is even lower than that of bromide. The bromide, iodide or thiocyanate content of the plasma must therefore exceed a certain threshold before they pass into the central nervous system.

The *gastric juice* after bromide administration contains a higher bromide concentration than the blood (Quastel and Yates, 1934). Its Br:Cl ratio is the same as that of the blood serum, regardless of the rate of gastric secretion, even when half of the chloride has been replaced by bromide (H. W. Davenport and Fisher, 1940).

The *urine concentration* fluctuates widely (Hastings and Van Dyke, 1931). E. Frey, 1937, claimed that the Br:Cl ratio in the urine is the same as in the serum; and P. K. Smith and Walker, 1938, that it is less than in the serum.

The organ distribution of bromide, iodide and thiocyanate shows approximately the same ratio to chloride as exists in the serum, except in the central nervous system. This appears best explained by the assumption that these ions are confined essentially to the extracellular fluid, since the chloride is almost entirely extracellular (G. B. Wallace and Brodie, 1937). Accordingly the bromide, iodide or thiocyanate content of the organs parallels their content of extracellular fluid. The low bromide:chloride ratio and similarly the low ratios of iodide and thiocyanate of the central nervous system are explained by the fact that these ratios are characteristic of cerebrospinal fluid (G. B. Wallace and Brodie, 1938, 1940; Smith and Walker, 1938). Pathological tissues, tuberculous, syphilitic, tumors, cystic and transudate fluids, all show practically the same bromide (iodide and thiocyanate):chloride ratio as the serum, so that their halides are also extracellular (Wallace and Brodie, 1937). *With long-continued administration*, some of the bromide penetrates the cells, so that its organ distribution is not strictly parallel to the chloride content; but they do tend markedly in the same direction (E. Frey, 1937).

It follows that the *bromide content and concentration of organs* depend on their normal chloride content (Ellinger and Kotake, 1911). Wyss, 1906, found the largest quantity in the blood. Even after long administration, the brain contained a relatively small proportion. The distribution after therapeutic administration is described by Carnot and Coirre, 1914. In a case of acute clinical poisoning, from 100 Gm. of NaBr, the bromide concentration was highest in the blood (E. Vilén, 1926).

The *total volume of extracellular fluid* can be estimated by determining its serum concentration after the administration of a single dose of bromide and making allowance for the excretion. Thiocyanate is also commonly used (Krogh, 1938), but bromide gives better results since its distribution is more uniform. The blood sample is taken three hours or more after the oral administration of sodium bromide, 30 to 50 mg. per Kg. of body weight, the urine being collected during the period (B. B. Brodie *et al.*, 1939). By this method the total extracellular fluid averages 9.7 liters per square meter of body surface for normal males, 9.4 for females (Brodie, Friedman and Ferraro, 1941).

The *normal presence of bromide* depends on the introduction of small quantities in water and food and on occasional medicinal use. Serbescu and Buttu, 1934, found less than 0.1 mg. per 100 cc. of blood in thirty subjects. Ucko, 1936, found between 0.15 and 0.33 mg. per cent, the concentration in the corpuscles being a third of that of the plasma. Normal fasting gastric juice contained 0.5 to 0.9 mg. per cent. The daily excretion was 1.0 to 2.5 mg. The *thyroid gland*, especially if hyperplastic, often has a relatively high bromide content. This is lowered by the administration of iodide or thyroid (E. J. Baumann, Sprinson and Marine, 1941).

Relative Retention of Organic and Inorganic Br.—The organic Br compounds are apparently retained somewhat more efficiently than the inorganic. This has been cited as a proof of superiority; but it is doubtful whether the retained Br is the bearer of the therapeutic action (Magnus-Alsleben, 1911). *Sabromin* is retained more in the adipose tissues, but not in the brain (Ellinger). *Bromipin* is eliminated by the urine, partly in organic combination, but mainly as inorganic bromide (Bermann, 1910. He has also studied the fate of other organic Br compounds). The lipid soluble *bromural* passes at first mainly into the nervous system; but it is rapidly decomposed into a water-soluble form, presumably bromide, which then follows the course of the ordinary bromides (Takeda, 1911). *Tetrabromostearic acid,* which may be ingested by man in quantities of 100 to 150 Gm. without deleterious symptoms, is broken down, the urine containing organically bound bromine (Corley, Tripp and Newton, 1935).

Sulfobromophthalein Sodium, U.S.P., *bromosulphalein,* disodium phenoltetrabromphthaleinsulfonate, leaves the blood stream rapidly after intravenous injection. It is probably taken into the Kupffer and other reticulo-endothelial cells, from these gradually into the polygonal cells of the liver, and then excreted by the bile (A. Cantarow and Wirts, 1941). The rate of its disappearance from the blood stream after intravenous injection is used as a liver-function test (Soffer, 1935, review). Bromosulphalein retention has also been proposed as a measure of the functional activity of the *reticulo-endothelial system.* The retention is increased in dogs by the daily intravenous injection of India ink or ferric oxide (M. A. Mills and Dragstedt, 1936).

Sulfobromophthalein sodium, U.S.P., occurs as a white crystalline powder, very soluble in water. *Sulfobromophthalein Injection,* U.S.P., a watery solution, is usually available in ampuls of 150 mg. in 1 cc. *Average dose,* by vein, 2 mg. per Kg. of body weight.

Roentgenography.—Bromine compounds are nearly as opaque as iodine compounds and are less toxic, less irritant and cheaper. Sodium bromide solution is used especially in the urinary bladder and may be employed in the renal pelvis and ureters (Weld, 1918).

Sedative Action on Man.—A single dose of *1 to 2 Gm.* of sodium bromide is somewhat calming, tends to decrease worry, and inclines to sleep, which is deeper and more dreamful. Conditioned reflexes are slower but truer (Pavlov). Arithmetic performance is improved more than with caffeine, chiefly by decreasing subjective fatigue (Allers, 1929). *Above 4 Gm.,* depression and decrease of reflexes become apparent. The effects are rather different from those of the ordinary hypnotics: the bromides tend to produce a mental calm, aloofness, and imperturbability, progressing to sluggishness, lack of attention and lassitude. These all dispose toward sleep, which it is fairly easy, however, to resist. Perception, observation, and motor reactions may be normal, and the soundness of the mental processes is not impaired, if the effort is made to use them. With the smaller doses the subject awakens refreshed; but with larger doses, the psychic depression persists because of the slow excretion. Very exceptionally (more commonly with cats), bromide causes acute cyclic excitement and mania.

The effects of 5 Gm. of NaBr on the *mental functions* of normal individuals are described in detail by R. F. Stanley and Laird, 1930. The involuntary tonic contraction of skeletal muscles which continues after resistance to the effort is discontinued, is diminished by bromide, little affected by barbiturates, chloral or strychnine, and increased by caffeine (Sapirstein *et al.,* 1936). *Electroencephalograms* show damping of the alpha waves (which are increased in epileptic attacks), indicating cortical depression (H. Berger, 1934).

Still larger doses (*10 to 15 Gm.*) cause some nausea, considerable apathy and confusion of speech, but not sleep (Binz). These doses also lower the reflexes from the skin and mucous membranes, so that irritation of the fauces does not produce retching (Krosz, 1876). This was utilized, before the introduction of local anesthetics, for examinations of the throat, and so forth.

The **central actions of bromides on animals** are analogous to those on man, and can be utilized for studying the mechanism of bromide action.

Experimental neurosis in dogs, produced by confusing conditioned reflexes, is improved within ten days by relatively small doses of bromide. The differentiation of stimuli is reestablished, and the improvement continues to normal after the bromide is discontinued. Alcohol, avertin and barbiturates remove the neurotic inhibition only temporarily, without restoring the differentiation (Petrova, 1934; Dworkin *et al.,* 1936).

Narcotic Actions.—*Rabbits* show both acute and chronic effects closely resembling those observed in man. The symptoms, rapidity and dosage are nearly the same, whether the administration is by mouth, hypodermic or vein (Bernoulli, 1913). Doses of 2.3 to 3.2 Gm. per kilogram, by vein, generally produce little immediate effect After several hours to three days, the rabbit becomes apathetic and sluggish. The sensibility and reflexes are somewhat depressed and delayed. Muscular coordination is often disturbed and ataxic. Ascending muscular debility and pareses are frequent. *Chronic poisoning* also produces these pareses, but no narcosis or other cerebral depressions (Januschke, 1913). Both forms prevent camphor and picrotoxin convulsions. The rabbits often show slowly developing irritant phenomena in the skin and mucous membranes, analogous to bromism: general dermatitis, loss of hair, conjunctival congestion, coryza, and so on. If the acute nervous symptoms are fully developed, spontaneous improvement is exceptional. The rabbits die in coma after several days. *Spontaneous activity of mice* is decreased by single hypodermic doses of 0.2 to 0.6 Gm. of NaBr per Kg., about a sixth of the fatal dose, but within the toxic range. The effect is increased by dividing the dose (Perez-Cirera, 1895). With *guinea pigs,* large doses of NaBr (0.1 to 1 Gm. per pig of 200 to 250 Gm.) produce a deep sleep, lasting two or three days. This is preceded by a long latent period, even if the administration is hypodermic or by vein. The hypnotic effect is antagonized by picrotoxin or strychnine (Januschke and Inaba, 1913). *Cats* receiving 1 Gm. of NaBr per Kg. for three or four days develop cycles of narcosis alternating with excitement. The latter appears analogous to the excitement stage of aliphatic narcosis, and is accentuated by light etherization, abolished by deep ether anesthesia. It does not occur in decerebrated cats, or with rabbits, and but little with dogs (Blume, 1928).

Sedation of Experimental Convulsions.—Albertoni, 1882, found that bromides lower the excitability of the motor cortex of dogs, so that a stimulation of the motor areas which, under the conditions of the experiment, gives rise to general epileptiform convulsions, will, after the administration of a bromide, be confined to the area directly stimulated. The calming effect of bromide renders animals less subject to the "startle reflex," and therefore less liable to *strychnine convulsions;* although the increased primary reflex, for instance the patellar, persists. *Intravenous injection* of sodium bromide suppresses the epileptic convulsions of camphor and the medullary convulsions of cocaine, but not the spinal convulsions of strychnine or picrotoxin (Januschke and Inaba, 1913). The effects of bromide treatment on the response to convulsants were further studied by K. Meyer-Nobel, 1928, and by Boshes, 1934.

The ultimate mechanism of bromide narcosis appears to be a direct effect of the bromide ions, and as these do not readily penetrate into cells, it is presumably exerted on the cell surface. It is not due to deficiency of chloride nor to organic binding of bromide.

The effects are due to the bromide ion. The characteristic action is produced in animals by all bromides, but not by organic Br compounds or by bromates (Januschke, 1913). *The chloride deprivation theory,* suggested by Wyss, 1913, is disproved by the difference of symptoms; for animals remain apparently normal when more than half of their chloride store has been removed in a week, by feeding nitrate with chloride-poor food (Hiatt, 1939). In man, acute chloride deficiency produces tremors, weakness and fever, and not narcosis. Injection of chloride causes some recovery from bromide poisoning; but citrates, sulfates and nitrates have a similar, though weaker, saving action (Bernoulli, 1913). Januschke and Inaba, 1913, found that the bromide depression in animals could not be efficiently antagonized by the administration of NaCl, nor reinforced by Cl-poor food.

Clinical Use of Bromide as Somnifacient.—Bromides enable rather than enforce sleep, by calming excessive restlessness and worry and by quieting pathologic excitability. The dose should be 1 or 2 Gm., or more if necessary, one to two hours before retiring. The bromides may be usefully combined or alternated with the more powerful aliphatic hypnotics. The effect is simply additive (Klammer, 1913), or perhaps slightly potentiated (Januschke and Inaba, 1913). Bromide has little if any action on pain, except that it renders the patient less apprehensive.

Sedation of nervous hyperexcitability is utilized in hysterical conditions, Basedow's disease, acute cerebral excitement, meningitis, the nervous vomiting of seasickness and pregnancy; to prevent cinchonism; against incontinence of urine; as an aphrodisiac in sexual hyperesthesia; against delirium tremens and convulsions—epileptic, chorea and others, and as preanesthetic sedative (0.2 Gm. per Kg., intravenously, thirty-five to forty minutes before the operation; Bréchot, 1932). Barbiturates have largely supplanted all these uses, but bromide is less narcotic and may be useful at least for alternation and potentiation. The dosage for the minor nervous conditions is 0.5 to 1 Gm. two or three times daily; against cinchonism, 3 parts of bromide to 1 of quinine; against seasickness, 4 to 5 Gm. daily for several days before the voyage; in pertussis, it is said to allay the paroxysms, without shortening the course. Convulsions require at least 15 Gm.; if necessary by rectum. Large doses have been given in acute mania, but probably without much benefit.

Psychological performance of healthy human subjects kept on a fixed dosage of bromide for several weeks is not materially affected; if anything, it is improved, except that reaction time is slightly delayed (M. Moore *et al.*, 1942). Large daily doses to dogs increase the volume of *gastric juice,* the free acidity, and the total halogen (I. A. Epshtein, 1939). Bromide treatment does not alter experimental hypertension (H. Goldblatt *et al.*, 1942).

In idiopathic epilepsy bromides produce marked symptomatic improvement in 90 per cent of the patients. Large doses, near the limit of toleration, must be continued for some time. The attacks become milder and less frequent, or may be suppressed entirely; but they usually return soon after the remedy is removed. The rare cases in which the convulsions disappear permanently are presumably spontaneous recoveries. The disadvantages of bromides have led to the partial or complete substitution of phenobarbital, which is at least equally effective. They may be alternated with advantage. Diphenylhydantoin is more potent than either (see Index). The required dose must be ascertained by trial. The efficiency may be increased by Cl-poor food (Ulrich, 1912), or by the administration of calcium (Januschke, 1913). These modifications may succeed when the simple bromide treatment fails. The daily dose of bromide should be divided into three or four fractions, and freely diluted with water. Tablets are undesirable, because of the local salt irritation.

Poulsson recommended the following routine, to be modified as needed: in the first week, 3 Gm. daily; second week, 4 Gm.; increasing by 1 Gm. each week, until 10 Gm. are reached in the eighth week. If well tolerated, and if the attacks persist, the weekly increase may be continued until 15 Gm. are reached in the thirteenth week. The dosage is then reduced in the same way until the attacks recur, when the treatment is again started in the same way. A few trials ascertain the doses required to reduce the attacks to a minimum. This dosage is then continued as long as needed, and renewed at intervals even after complete disappearance of the attacks, to anticipate recurrence. Bromide acne need not interfere with the treatment; but severe depression necessitates reduction, or even discontinuation. The bromide level of the blood should be determined if large doses are used.

Choice of Preparations.—Inorganic bromides are most effective. NaBr is preferred. It is quite as sedative as equivalent doses of the K, NH_4, Ca or Mg bromides (E. Spiegel, 1939); it is less irritant and has a less disagreeable taste than KBr, or especially NH_4Br and LiBr. NH_4Br liberates bromine on exposure to air, which is a serious objection. The long-continued administration, for epilepsy, of large doses of a single bromide would be expected to disturb the cation balance of the body, and a mixture of bromides, such as the "Erlenmeyer Mixture" ($KBr:NaBr:NH_4Br::$-1:2:1) might have advantages. There are no data, however, that this particular ratio is well balanced; and the normal ratio in the body is perhaps sufficiently well maintained by adaptation of the excretion.

$CaBr_2$ adds the depressant action of Ca and is said to be more efficient; but the continued administration of the large quantities of Ca may be detrimental. The same holds probably also for strontium bromide. HBr is too irritant. *Organic Br Compounds* are said to be less likely to produce toxic Br effects; but this could be explained entirely by their low Br content. No real advantage has been established for them, and they are probably much less efficient. No effect can be expected from the bromide in salts which are used in small doses—*e. g.*, bromide of quinine, or arsenic, and so forth. In these it can be useful only by influencing the solubility of dissociability of the compound.

Because of the depressant effects, large doses of bromides should be *avoided* in mental or physical debility, old age, melancholia and neurasthenia.

Gastric Irritation.—Large doses of bromide, especially in concentrated solutions, produce nausea, vomiting and gastralgia, by local salt action.

Acute bromide poisoning is rare, but may occur from large doses, especially if the excretion is imperfect in nephritis. There are mild collapse, impaired speech, stupor and paralytic phenomena. The treatment would be by sodium chloride infusion.

Vilén reports a patient who had taken 100 Gm. of NaBr in the course of thirty-six hours, became deeply unconscious, developed bilateral pneumonia, and died in six days. Blisters formed in the skin.

Bromide rashes ("*bromoderma*") occur frequently, especially on the face, sometimes early, sometimes late, when the administration of bromide is prolonged. They resemble those of iodism. The mucous membranes may also be irritated. Similar effects occur in animals (Bernoulli, 1913). Bromide (or iodide) administration may also cause the "lighting up" of latent inflammatory processes, for instance tuberculosis (Block, 1920). Bromoderma has no direct correlation with the level of bromide in the plasma (Kimberly, 1939). Even acne is generally absent in patients with severe mental symptoms (Gundry, 1939). The rashes are best prevented or treated by cleanliness. They disappear rather slowly after discontinuation.

The *bromide rashes* resemble acne vulgaris (but without comedones). They sometimes become confluent, forming superficial carbuncles. Children are especially susceptible and may show pustules and fleshy masses, distributed symmetrically over the face, trunk and limbs, often becoming confluent and occasionally vegetating (H. MacCormac). An *older explanation* (Adamkiewicz) attributed the bromide and iodide acne to direct irritation by the liberation of free bromine or iodine by the acid secretions of the sebaceous glands, and the like. This cannot be accepted (Unna, 1912), for these elements could not exist free at the reaction of the body. Bromide administration sensitizes to the "*luetin*" *test*, although less actively than iodide (Cole and Paryzek, 1917; Kolmer, 1917).

Chronic Bromide Depression, Psychosis and Cachexia.—Long-continued use generally leads to psychic deterioration, weak memory for recent events, apathy, somnolence, unequal pupils commonly widely dilated; thick and unintelligible speech; coarse tremors of the lips and hands; ataxia, diminished deep reflexes; loss of sensitivity to touch and pain; tenderness of the calf muscles; sexual impotence; and to nutritional disturbances: anorexia, fetid breath, coated tongue; malnutrition, anemia, emaciation, diarrhea, often fever of 100° to 103° F., tachycardia of 120 to 140 and lowered resistance. The symptoms disappear fairly rapidly when the drug is stopped or the dose reduced, and especially if 6 to 8 Gm. of sodium chloride are taken daily (Schabelitz, 1916); but the resistance remains low for some time. With persistent intensive administration, *serious psychic phenomena* develop, colored by the personality of the patient (Diethelm, 1930); beginning with restlessness and disorientation, followed by paranoid trends, hallucinations, apprehensions, delirium, finally stupor and coma. Many cases are caused by failure to recognize the symptoms (W. Sensenbach, 1944). The paranoid schizophrenia usually clears fairly soon after withdrawing the bromide (M. Levin, 1946).

The *relation between bromide concentration and symptoms* is fairly close in a given patient subjected to intensive bromide treatment, but differs considerably for individuals. In general, 50 to 150 mg. of Br per 100 cc. of serum corresponds to some confusion; 150 to 250 mg. to incoordination and emotional outbursts; about 200 mg., toxic psychosis; concentrations about 300 mg. are dangerous to life. On discontinuing the administration, the blood concentration falls slowly, at the rate of about one-half per month (C. P. Wagner and Bunbury, 1930; L. P. Gundry, 1939; Sharpe, 1934). The mental symptoms often respond more slowly to withdrawal than does the blood bromide level. A clinical method for determining the bromide concentration was described by O. Wuth, 1927 (J.A.M.A., *88:* 2013). *The chloride concentration* of the plasma decreases as the bromide rises. It has generally fallen 25 to 30 per cent, when intoxication symptoms appear; more than 40 per cent of fall is generally fatal (Bernouilli, 1917).

Bromide administration to pregnant rats, throughout gestation, reduced the maze-learning ability of the offspring, although these had a normal bromide content at the time (B. K. Harned *et al.*, 1944).

Nutrition.—Bromine does not appear to be an essential element; rats on a diet as Br free as possible grew as well as those fed on ordinary food (Winunek and Smith, 1937).

Bromides on General Metabolism.—The actions are not important (Chittenden, 1884; Jappelli, 1913).

Muscle respiration and contraction are affected by sodium monobromoacetate in the same manner as by monoiodoacetate—indeed, the characteristic muscular effects were first described by J. Pohl, 1888, for the bromoacetate. He reported that small doses administered to frogs produce muscular stiffness and fibrillation, terminating in contracture, while the heart was still beating, although this was also killed eventually. He showed that the effect is not prevented by curare, but that it does not occur if the nerve is divided, unless it is stimulated. The action is therefore a modified peripheral response to fatigue. Mono- and dichloroacetate caused less of this effect; trichloroacetate, none. He also investigated a number of other substituted fatty acids, and pointed out the difficulty of correlating these actions with the chemical constitution. Sodium bromide itself tends to produce muscular contracture, iodide more so, and thiocyanate still more (Gasser, review).

Actions on Circulation.—Bromide has no effect, except slight depression with single doses above 10 Gm. Sedative doses may indirectly slow the heart and lower the blood pressure somewhat, especially in cardiac neuroses. Larger doses of KBr may show the depressant potassium action.

In the cat, the *intravenous injection* of the NaBr, 3 cc. of 1.5 per cent per kilogram, had no effect (Lehndorff, 1914). In *perfused hearts,* the substitution of bromides for chlorides in Ringer's fluid produces practically no effect in cold-blooded hearts, except a slight acceleration in starting. In warm-blooded hearts, there was a slight decrease in rate and amplitude (Greene and Kruse, 1913).

In *perfusion of isolated respiratory center,* this is stimulated with iodide, bromide and nitrate ions (Macht and Hooker, 1918). The conditions and concentrations, however, are too artificial for practical application.

Excised Uterus.—Replacement of Cl by Br or I produces a slight increase of tonus, without affecting the rhythmic contractions. Fluoride increases the tonus and rhythmic contractions, without injuring the muscle (Prochnow, 1911).

With **isolated intestine** and other smooth muscle, the replacement of the chloride of Ringer's solution by bromide increased the tone, amplitude, rate and rhythmic excitability, especially in mammals (T. K. Kruse, 1917).

Secretions.—Bromide somewhat increases the secretion of mucus by salt action. It diminishes the milk. Variable results have been reported as to menstruation.

PREPARATIONS.—***Sodium Bromide,** U.S.P.; NaBr; occurs as colorless, cubical crystals or white granular powder; odorless; saline taste. Freely sol. in water (1:1.2); sol. in alc. (1:16). All bromides are *incompatible* with strychnine. Average dose, 1 Gm., 15 grains. *Potassium Bromide,* U.S.P., freely sol. in water (1:1.5).

◆

IODINE, IODIDES AND THYROXIN

These may be discussed together, since all iodine compounds have features in common. All are convertible into thyroxin, and in this manner affect metabolism and the associated phenomena in thyroid disease. Those which can be administered in relatively large doses, and presumably give rise to iodide ions, produce iodism, and characteristic inflammatory reactions in syphilitic and other pathologic formations. The inorganic iodides exert osmotic and other indifferent "salt actions." Elementary iodine is eventually converted into iodide, but first combines locally with the proteins of the cells and is irritant and antiseptic.

Historical.—Iodine was discovered in 1811 by Courtois, was studied by Gay-Lussac, 1813, and by Humphry Davy, about the same period. Its effects were investigated by Vulpian and his pupil Magendie. The latter's "Formulaire" of 1824 contains fairly comprehensive data. It was introduced into medicine by J. J. Coindet of Geneva, in 1820, for the treatment of goiter. It aroused considerable enthusiasm, and its use was extended to other diseases. Berton, 1829, advocated the inhalation of the nascent fumes. The occurrence of mishaps brought it into disrepute, and the resulting abuse greatly embittered Coindet's life. Coindet, in 1820, proposed the use of iodide of mercury in "venereal affections complicated with scrofula," and this was employed by Biett, 1821, in the treatment of syphilides. Effective therapy of tertiary lesions with iodine was first reported by Lugol, 1831, but the credit of establishing its usefulness is generally given to William Wallace of Dublin, who published in 1836 a series of cases treated with effective doses of potassium iodide (2 Gm. three times daily). Its employment spread rapidly, especially through the authority of Ricord. The use of iodine as a surgical antiseptic appears to have originated with Boinet, 1839, who treated an inguinal abscess with injection of a diluted tincture of iodine, and then used it also against infection of the vagina and the skin; shortly after he introduced the injection of the tincture into ovarian cysts. Iodine for goiter prophylaxis was proposed by Chatin in 1850. Medicinal qualities of iodine were known long before the element was isolated. In the thirteenth century, Arnold of Villanova described the use of "*Burnt Sponge*" in "scrophula," which probably covered goiter and perhaps even syphilis. This carbonized sponge contained ½ to 3 per cent of sodium iodide and its dosage of 1 to 3 drachms therefore contained 0.06 to 0.4 Gm., 1 to 6 grains of NaI. The origin of this use is not known, but a Chinese codex of 1567 B.C. is said to advise seaplants against goiter. *Cod liver oil* also contains iodine, from 3.6 to 14.9 mg. per liter (A. D. Holmes and Remington, 1935). The usual daily dose of 10 cc. averages about 0.085 mg.

IODINE

Elementary iodine precipitates proteins, the iodine being partly adsorbed, partly loosely bound and partly converted into iodide ions. This precipitation causes persistent irritation, usually short of corrosion. Since the iodine itself is but loosely bound, it continues to penetrate, so that the action extends deeply. It may be conveniently graduated by successive applications of the alcoholic or watery solutions. The official tinctures and the "strong solution" (Lugol's solution) contain potassium iodide to make them more stable and more miscible with water. Iodine ointments give up their iodine slowly, so that their action is milder. A part of the iodine is chemically combined with the base—all, in some proprietary ointments—so that it cannot react with the proteins, and is therefore ineffective.

Local Phenomena.—Applied to the skin, iodine produces a mahogany stain, smarting, erythematous inflammation, infiltration of subcutaneous tissue, desquamation of the epidermis in large shreds; if repeated, vesication results. The effects on mucous membranes are more severe and may produce corrosion. Its action is chemical, since it precipitates proteins as easily dissociated compounds. It is absorbed somewhat from the skin and excreted mainly in the urine as iodide. Iodine is used as *counterirritant*, especially in chronic pleural effusions, chronic rheumatism, diseased joints, enlarged lymph glands, lymphangitis, and so forth. It has also been employed in erysipelas, painting the tincture from the periphery toward the center, five or six times daily (Ferrari, 1911), but Wood warns that the action must be graded very mildly, or it will produce extensive necrosis.

The "*absorptive*" *effect* of iodine was demonstrated experimentally on the fibrous nodules following intradermic injection of local anesthetics (Sollmann, 1919). Positive results were obtained only if the iodine was applied daily for eight days, and pushed to considerable irritation of the skin. Shorter continuance was ineffective, even if a larger amount of iodine was applied and the irritation was more intense. *Injections into cysts*, hydrocele, empyema, and the like, produce at first increase of the fluid, then adhesive inflammation. The injections are painful, and have often caused serious poisoning. They have been displaced by surgical procedures.

Severe injury to the female genito-urinary tract has followed intra-uterine injection of iodine solution.

In rabbits and guinea pigs, repeated injections resulted in inflammatory reactions, ranging from endometritis to cysts of the uterine horns and tubes, by occlusion of the abdominal end; and in degenerative changes of the ovaries, their degree depending on the duration of the treatment, rather than on the amount injected (Sodano, 1934).

The **antiseptic action of iodine** is used to *prepare the skin for operations* (introduced by A. Grossich, 1908, 1910). A 3 per cent alcoholic solution is painted over the dried skin of the operative field on the preceding day, and again just before operating. This is preferable to the official tinctures, since the potassium iodide of the latter delays drying and penetration. There may be rather severe irritation (Herzog, 1914). R. A. MacDonald and Peck, 1928, recommended a 1.25 per cent solution in 70 per cent isopropyl alcohol. The stain may be removed by warm concentrated solution of sodium thiosulfate (Snoy, 1911) or by ammonia. The value of iodine for *wound disinfection* is in dispute, on the basis that the tissue injury may more than offset the antiseptic action. It may be used as the official tincture, or better the official Iodine Solution.

Streptococci in *cultures* are destroyed by iodine, 1:1000, in one-fourth of a minute, even in moderately albuminous fluids (Albert and Taylor, 1918). Experimental results with *infected wounds* were also good, the iodine being effective within five hours after injection, *i.e.*, until the bacteria have spread too deeply (Brunner, 1915). On the other hand, bacterial tests from the *skin* after iodine application have given questionable results. Experiments with *tissue cultures* show that iodine is rather more toxic to bacteria than to human connective tissue cells. It tends to dissolve the fibrin of the cultures (R. A. Lambert, 1916). *Spirochete cultures* are not especially susceptible to iodine; the fatal concentration is 1:75 in KI solution (Akatsu, 1917).

Against *tinea capitis*, the Iodine Tincture, N. F. (2 per cent), may be dabbed on morning and night, or a 10 per cent ointment in adeps lanae, suspending the applications if the reaction becomes severe (Wise and Wolf, 1936).

Individual water sterilization may be effected by the "*Violle and Seigneurin mixture*," a powder added to the water in the ratio of 60 mg. of iodide, 30 mg. of iodate, 3 mg. of potassium permanganate and 60 mg. of citric acid. This secures an iodine concentration of 12 ppm, which destroys intestinal bacteria in about twenty minutes. It is more effective and more stable than Halazone, but has a slight iodine odor and color.

Tablets of *triglycine hydroperiodide* for individual water canteen purification are reported superior to the chlorine type (J.A.M.A., *132*:930, 1946).

Iodine Against Burns.—A 10 per cent tincture has been used. It causes severe pains for four or five minutes, said to be succeeded by complete relief of pain (Mercier, 1919), presumably owing to a precipitation pellicle. The advantage of iodine over other astringents is doubtful; the irritation and systemic effects may be harmful.

Pharmaceutic Preparations.—Simple alcoholic solution of iodine spreads more evenly and coagulates protein more rapidly. These are advantages in skin infections. The skin should be dry, to avoid precipitation of the iodine. The presence of KI, as in the official Tincture, and in Compound Solution, delays precipitation and favors penetration, and is therefore better for wound disinfection. It is not more irritant to the skin. The presence of an iodide is essential if the iodine is to be diluted with water. It also retards the formation of HI in the tincture. In watery solutions, a minimal iodide-iodine ratio favors adsorption and therefore gives a maximal surface activity (Karns *et al.*, 1932). Some proprietary "soluble iodines" use HI in place of KI. This has no advantage, either as to efficiency or irritation (Sollmann, 1919).

"*Starch Iodide*," the blue adsorption product of iodine and starch, combines slowly with protein and is but slightly irritant. Starch containing 1 per cent of iodine has been used as an antiseptic wound dressing (Luncere, 1917).

Toxicology.—If iodine or its solutions are swallowed, the *symptoms* develop in the order: gastric uneasiness, disagreeable metallic taste; vomiting; violent abdominal pain; severe collapse with feeble pulse; diarrheic stools, sometimes bloody. Severe cases may develop hemorrhagic nephritis. The collapse may be postponed to the second day. The vomit has the color of iodine, or is blue if starch is present. Extensive application to the skin sometimes produces nervous phenomena and fever. *The treatment of iodine poisoning* consists in evacuation; demulcents (eggs, milk, oils and cooked flour or starch, which form loose compounds with iodine); dilute alkalis ($NaHCO_3$); and 5 per cent sodium thiosulfate ("Hypo"). This binds the iodine: $2Na_2S_2O_3 + 2I = 2NaI + Na_2S_4O_6$ (Sabbatani, 1913). The further treatment is symptomatic. The *prognosis* is generally favorable; but Velpeau recorded thirty deaths, in 130 cases. Iodine tincture caused four suicidal deaths in New York City in 1937. *The fatal dose* is usually to about 2 or 3 Gm.; but recovery is said to have occurred after 10 Gm.

Toxic effects from iodine absorption from cysts consist in cyanosis, salivation, vomiting, skin eruptions, high fever and collapse. The urine is scanty and albuminous. The intoxication may persist for several days and then end with sudden death.

Toxicity of Iodine Fumes.—The inhalation of iodine vapor produces pulmonary irritation (dyspnea, and so forth). The inhalation of more than 18 mg. per Kg. is fatal. The danger is increased by the presence of respiratory disease, bronchitis, and the like. This should enjoin caution in the therapeutic use of iodine inhalations. The iodine is partly absorbed, appears promptly in the urine and produces histologic changes in the thyroid (Luckhardt *et al.*, 1920).

Intravenous Injection of Iodine.—Boehm, 1876, found that 0.04 Gm. per Kg. was fatal. Symptoms set in only after six or eight hours, with exhaustion, dyspnea and death in twelve to twenty-four hours. Necropsy showed bloody pulmonary and pleural exudate and renal congestion and hemorrhages. Salant and Livingston, 1916, reported that the intravenous injection of iodine depresses the circulation greatly in cats, not in dogs.

Local Action of Iodine on the Heart.—Perfusion of excised frog hearts with dilute iodine solutions produces irregularities, followed by depression. Stronger solutions result in diastolic arrest.

PREPARATIONS.—*Iodine*, U.S.P. (Iodum); occurs as bluish-black, friable scales, of distinctive odor and acrid taste. Slightly sol. in water (1:3000); sol. in alc. (1:13) or glyc. (1:80); freely sol. in fat solvents or aqueous solutions of iodides. Its solutions are *incompatible* with alkaloids, alkalis, carbonates, tannic acid, turpentine and volatile oils. *Strong Solution of Iodine*, U.S.P. (*Lugol Solution; Compound Solution Iodine*), contains 5 per cent iodine, 10 per cent KI, in water. Average dose, 0.3 cc., 5 minims. ***Tincture of Iodine, U.S.P. XIII, is a solution of 2 per cent of iodine and 2.4 per cent of NaI, in** diluted alcohol. The "Tincture of Iodine" of the U.S.P. XII was a stronger preparation, containing 7 per cent iodine and 5 per cent KI in diluted alcohol. This is now official as *Strong Iodine Tincture*, N.F. VIII. The iodide in the tincture makes it miscible with water and insures against loss of strength on keeping (Wetterstroen, 1908). When iodine is administered in milk, it is largely converted into iodide and albuminates. *Iodine Ointment*, N.F., has 4 per cent each of iodine and KI, in glycerin and yellow ointment. When free iodine is rubbed with fat, it combines almost immediately and completely; but when KI and glycerin are added, as in the official ointment, this combination is restricted; these ointments contain permanently about 3 per cent of free iodine (Warren, 1917). The most stable ointment is made with yellow petrolatum (Ewe, 1920). Iodine is soluble in *liquid petrolatum* to 1.4 per cent, practically without combination (A. M. Clark, 1919).

IODOFORM

This is obtained by the action of iodine on alcohol or acetone, in the presence of alkalis. It has been known since 1832 and was introduced as antiseptic about 1879. It came into extensive use as a dusting powder, especially to promote granulation and to diminish infection of open wounds. It was also injected into tuberculous joints, usually as an emulsion with glycerin (iodoform 10, alcohol and glycerin each 45). It has been practically abandoned because of its *disadvantages*, especially the persistent odor, which cannot be disguised by any perfume. Iodoform is also liable to develop iodism and irritant phenomena in susceptible individuals, producing particularly *eczemas*, even in minute amounts. It may cause severe poisoning with narcotic symptoms, different from those of other iodides.

Iodoform itself is practically insoluble and probably inactive. It is also quite stable outside of the body; but in contact with tissues or their extracts, and particularly with diseased tissues and with bacteria, it slowly *evolves iodine* (Altenburg, Schmidt, 1901). This occurs so slowly that the effects are mild, but somewhat antiseptic to bacteria and stimulant to the cells. It dries the wound secretions and is mildly hemostatic and analgesic. Hamburger found that it stimulated phagocytosis. Its injection into dogs leads to persistent leukocytosis (W. Weil, 1913).

General intoxication may occur when iodoform is applied over a large area, or when it is injected. The symptoms are diuresis, nausea and anorexia, lassitude and somnolence, headache, confusion, apathy or marked irritability, striking pallor, hallucinations, diminished reflexes, light convulsions and paralyses. The temperature rises, then falls. Death occurs through general paralysis of the central nervous system (M. Grossman, 1920). Sodium bicarbonate is said to be antidotal. *Chronic poisoning* is also characterized by paralytic phenomena. The heart, liver and kidneys exhibit fatty changes. Iodoform dermatitis is sometimes seen. It resembles ivy poisoning (Bryan, 1903). The idiosyncrasies cannot be transferred passively (Stropeni, 1912). Fatal poisoning from intrapleural injection is reported by v. Bonsdorff, 1916.

Excretion.—Iodoform is not excreted as such. It appears in the urine as iodide and iodate, and as unknown organic compounds (Angliolani, 1903).

Iodoform (Triiodomethane), CHI_3, contains 97 per cent of iodine. Usually obtained by the action of iodine upon alcohol or acetone, in the presence of an alkali. Fine, lemon-yellow powder or crystals; peculiar, very penetrating and persistent odor; unpleasant, slightly sweetish taste suggestive of iodine. Nearly insol. in water; sol. in alc. (1:60), in glyc. (1:80) or olive oil (1:34); freely sol. in eth. (1:7.5). Dose, 0.03 to 0.2 Gm., ½ to 3 grains, in pills or capsules. Iodoform (and other loose iodine derivatives) are *incompatible with starch.* They are generally *decomposed by heat*, and can therefore not be sterilized in this manner. Since they become antiseptic when applied to wounds, sterilization is usually superfluous. "*B.I.P.P.*" (Bismuth-iodoform-petrolatum paste), an ointment used as a dressing for infected wounds, is a mixture of one part of bismuth subnitrate and two parts of iodoform, with sufficient liquid petrolatum to make a paste (Morison, 1916). A similar mixture was used by Calandra, in 1908.

Iodoform Substitutes.—A number of odorless iodine derivatives were tried, especially *thymol iodide* (*aristol*), but they do not seem to have the peculiar activity of iodoform. They are all insol. in water, and, like iodoform, injured by light and heat.

Thymol Iodide, U.S.P. (Dithymol-diiodide; Aristol); a mixture of iodine derivatives of thymol. Insoluble in water, readily soluble in fat solvents. Chocolate-colored powder with slight aromatic odor

Iodochloroxyquinoline (Vioform) is now used chiefly as amebicide (see Index). It is administered in capsules, 0.25 Gm. three times daily for ten days; the course may be repeated after ten days of intermission. This dosage does not produce irritation or other untoward symptoms. The lethal dose for rabbits, 0.25 Gm. per Kg., injures the liver. In man, it is rapidly excreted by the urine (C. D. Leake, 1931).

IODIDES

The behavior of the iodides in the body is similar to that of the corresponding chlorides and bromides. The immediate toxicity is low, even with intravenous injections, although these disturb the colloidal equilibrium more profoundly than sodium chloride solution. The acute reactions that occur during or shortly after such injections are salt-colloidal. The special iodide reactions which are more toxic occur later and will be described under iodism. The distribution and excretion of the iodides is similar to that of the chlorides and bromides, except for the affinity for the thyroid gland. Like other neutral salts, the iodides are diuretic and expectorant. Salt action plays a part in these effects; but other factors cooperate at least in the expectorant action. *In vitro*, iodides tend to render colloids more soluble and less viscid. It is doubtful whether this occurs with the concentrations reached therapeutically. The effect on the thyroid gland is considered under that heading.

Expectorant Action.—Iodides increase the secretion of bronchial mucus and render it less viscid; they are therefore used in cough and especially in chronic asthma (H. M. Carryer *et al.*, 1946). The secretion may be partly a reflex from the peculiar saline taste that is excited by the secretion of the iodides in the saliva and mucus.

The amount of fluid collectable from the respiratory tract of cats and rabbits is increased by potassium iodide, not by iodized fats or proteins. The increase is a gastric reflex; there is no evidence of any direct effect on the bronchial glands (E. M. Boyd *et al.*, 1945).

However, there may be a more direct effect, for E. J. Stieglitz, 1923, found by histochemical methods that the free borders of the bronchial and tracheal epithelium become especially rich in iodides. Gordonoff and Lehmann, 1936, report that intravenous injection of potassium iodide secures a higher and more prolonged blood sugar rise when isotonic dextrose solution has been injected into the bronchial tree.

The *secretion of saliva* is not normally affected by iodide administration (V. E. Henderson, 1910); but inflammation of the parotid gland is one of the phenomena of iodism.

Urine Flow.—Iodides have a saline diuretic action somewhat greater than that of chlorides, because they are not reabsorbed so well from the urinary tubules.

Lactation is increased by small doses of iodide, as to volume and the percentage as well the total fat. Larger doses, pushed to cachexia, arrest lactation in women and in animals (bibliography, Scharrer).

The *acute effects of intravenous injections of sodium iodide* are practically important because it has been proposed to administer the drug clinically in this manner. The immediate toxicity is not very high. Weld, 1918, for instance, observed no acute toxic effects in dogs with 8 cc. of 25 per cent per Kg., *i. e.*, 2 Gm. of NaI per Kg.; but 0.8 Gm. per Kg. is followed in one-half to one and one-half days by edemas and nervous phenomena, often fatal (see below). Clinically, 5 to 20 Gm. of NaI as 20 per cent solution are injected slowly; symptoms arise when 10 Gm. (about 0.15 Gm. per Kg.) are exceeded. Up to this dosage it is said to be generally safe (E. D. Osborne, 1922). However, the possibility of undesirable changes in blood colloids (increased sedimentation rate; Hanzlik *et al.*, 1925) should be borne in mind. As the iodides are absorbed rapidly and completely there seems no reasonable justification for intravenous administrations, unless, indeed, the colloidal "reactions" are desired, and not the iodide effects. This is probably the mechanism of the rapid relief of herpes zoster, reported to occur after four intravenous injections of 20 cc. of 10 per cent sodium iodide (Reynolds). Before injecting iodide intravenously, the patient should be tested for the absence of exaggerated susceptibility, by administering by mouth, 1 Gm. three times a day, for two days (Osborne).

Delayed Toxicity of Intravenous Injections; Iodide Edema.—Large doses (0.8 Gm. of NaI per kilogram) produced death in twelve to thirty-six hours, with symptoms of central paralysis. Autopsy shows pleural exudation, often with pulmonary edema and pericardial effusion (Boehm, 1876; Chiari and Januschke, 1910). Serous effusions develop in about 30 per cent of dogs with 0.5 Gm. of NaI per Kg.; with 0.8 Gm., 75 per cent develop the effusion (Chu and How, 1931). Similar effects are produced with hypodermic, but not with oral administration (Sgalitzer, 1908). The symptoms are complex, and the statements regarding central actions are contradictory and probably untrustworthy (Jodlbauer, 1902). Intravenous injection is said to paralyze the *vagus endings* and to lower the excitability of the *depressor*. The *perfused respiratory center* is stimulated by iodide, bromide and nitrate ions (Macht and Hooker, 1918).

Use in Circulatory Diseases.—Iodides are employed in arteriosclerosis, coronary sclerosis, angina pectoris, aortic aneurysm (Bouillaud, 1858), and the like. In the lighter grades of these conditions their continued administration seems to give gradual relief to the functional phenomena, especially the pain. The effects are not due to any change in the blood pressure, but probably to structural alterations in the vessel walls, perhaps absorption of cellular exudates; analogous to the effect on syphilis. In many cases a syphilitic factor is directly concerned. In some cases they may be effective by correcting the circulatory erethismus of hyperthyroidism (McEachern and Baker, 1930). They may also cause general lassitude as do thiocyanates.

Direct Action on Circulation.—Potain and others supposed that the iodides lower blood pressure by depressing the heart or blood vessels. This applies to fatal doses of

KI, but is then a potassium effect. Ordinary doses have no effect on the blood pressure in normal men or animals (Stockman and Charteris, 1901). Salant and Livingston, 1916, observed no effects on the circulation of frogs or mammals, even with fairly high concentrations of NaI. The blood pressure *in arterial hypertonus* is also unaffected acutely, and probably even with continued administration (Hewlett, 1912). On the other hand, some clinicians claim a definite fall (*f. i.*, Rutkewitch, 2 Gm. daily). There is also a fall in lead poisoning, probably indirect (Capps, 1912). Guerwitsch, 1907, frequently observed increase of pulse rate with iodide administration. This may have been a thyroid effect.

Isolated Heart and Arteries.—Macht, 1914, investigated the effects of replacing part of the NaCl of Locke's solution by NaI or KCl. The results cannot be transferred to intact animals or man, since they involve different concentrations. Guggenheimer and Fisher, 1927, reported that 0.00002 per cent of iodide in the perfusion fluid dilates the vessels. Mancke, 1930, failed to confirm the claim of coronary vasodilatation of the perfused heart.

Decreased Viscosity.—Iodides and thiocyanates decrease the viscosity of colloids (Pauli, 1903; the other haloid ions have a similar but weaker effect; Gazzeti, 1913). O. Mueller and Inada, 1904, claimed diminished viscosity of the blood from therapeutic doses and advanced this as an explanation of the circulatory effect, but it was not confirmed by subsequent workers (Partunier, 1917, and others).

Epinephrine Atheroma.—Koranyi, 1906, claimed that this could be prevented by iodides, but this has been disproved (Hedinger and Loeb, 1907). *Cholesterol aortic sclerosis* of rabbits is probably promoted by potassium iodide or organic iodine compounds, for they cause a marked increase by the cholesterol level of the liver and blood over that produced by cholesterol feeding alone; decreased cholesterol in the bile; and more marked lipid deposits in the aorta (S. R. Rosenthal, 1934).

Skeletal muscle develops contracture, rigor and acidity on immersion in isotonic iodide solution, or by injecting it into frogs (Stockman and Charteris, 1901; review, Gasser).

Metabolism of Normal Individuals.—In the absence of thyroid disease, administration of clinical doses of iodide does not alter the basal metabolism. The urinary nitrogen may be increased, and with KI (1 Gm. per day) the nonprotein nitrogen of the blood may rise 30 per cent, although the phthalein excretion remains normal (Grabfield *et al.*, 1923). Some increase of urea, total nitrogen, uric acid, purine bases and chloride excretion was reported by Chistoni, 1911. In rats, administration of more than 0.5 mg. of KI lowers the metabolic rate (Hildebrand, 1933). Hypodermic injection of large doses may produce no effect or considerable increase or decrease of metabolism (Sgalitzer, 1908).

Nutrition and Growth.—Long-continued use of large doses of iodides leads to the malnutrition described under iodism. Small amounts of iodide slightly increase the body weight of *rats* (Hanzlik, Talbot and Gibson, 1923; review of iodide on nutrition, Orr and Lutch, 1929). Oral administration of 0.1 Gm. of KI per day to *adult rabbits* causes marked loss of weight, with terminal cachexia, diarrhea and rise of temperature, similar to the effects of bromide cachexia in man. Postmortem examination shows enlarged adrenals; and pulmonary hyperemia and pleural effusion in many of the animals. *Growing rabbits* appear to be more tolerant: 0.5 Gm. per Kg. orally does not appreciably alter the rate of growth, but produces marked tolerance, so that no effects follow doses that would be fatal to the nonhabituated. Excessive doses cause flaccidity and paralysis of the skeletal muscles, especially in the hind legs (Westra, 1934).

Sexual Functions.—Iodides are said to increase menstruation, to decrease the secretion of milk, and to cause atrophy of the mammary gland. Free iodine or loose iodine compounds (not KI) produce sterility in both sexes in rabbits. The spermatoblasts show histologic changes, and the formed spermatozoa are also affected (L. Adler, 1914). It has not been demonstrated that this occurs in the therapeutic use.

Absorbent and Alterative Effects.—Iodides are administered in a variety of obscure conditions to mobilize fibrous tissue, or to alter the general disposition in the direction of health. The vagueness of these conceptions express the vagueness of the expected effects. So far as they exist, they may be analogous to iodism; not infrequently they include a syphilitic factor. These uses comprise: the absorption of nonluetic hyperplastic tissue; of fibroses and other chronic inflammatory lymphatic swellings; gout and chronic rheumatism; neuralgias; asthma, and so forth. The action on bronchial muscle is doubtful (Titone, 1913).

Chronic poisoning by lead, mercury and other metals is treated with potassium or sodium iodide, with the hope of promoting the excretion of the stored metal by converting it into more soluble compounds. There is little direct evidence for this, although there are some chemical data for lead which point in this direction. The appearance of stippled cells after iodide treatment is not distinctive (J. Bohm and Fellinger, 1936).

Iodism.—If the administration of iodine compounds is continued beyond a certain amount, which varies for different individuals, irritative phenomena tend to develop in the skin and in mucous membranes. These are quite distinct from the local action of iodine, or the ordinary salt action of iodides, or from thyroxin actions. Iodism tends to light up certain sluggish inflammatory processes, such as tuberculous and gummatous lesions, and to sensitize the skin to the injection of agar solutions. It appears quite probable that iodism consists in the unmasking of latent inflammations or subthreshold irritations. However, this intensifying effect has been demonstrated only for a few types of irritation. The provocation of this acute inflammatory reaction is also the most plausible explanation of the therapeutic effect of iodides in syphilis and other interstitial inflammations. Phenomena analogous to those of iodism are produced by bromides, nitrates and thiocyanates. Thiocyanates produce similar therapeutic effects; bromides and nitrates have not been used successfully for these actions, but the difference may be merely quantitative.

Phenomena of Iodism.—The irritations take the form of various rashes, and of coryza, headache, conjunctivitis, laryngitis, bronchitis, the various manifestations of a "cold." Less common are stomatitis, parotitis, anorexia. The skin affections generally occur somewhat later. They may consist in acne, furuncles, erythema, purpura, urticaria or vesication, and may be accompanied by fever. The lesions sometimes resemble gummas. The *susceptibility* to these irritations varies greatly. They may set in a few hours after a relatively small dose or only after the long-continued use of large doses; or the symptoms produced by small doses may disappear when the dosage is increased. They disappear in a few days when the drug is discontinued. They may be produced by any iodine compound, but probably only after the dissociation of the iodide ion. Continued administration of iodide may also lead to *iodide cachexia*, anemia, emaciation, lowered tone, mental depression, nervousness, insomnia, nervous tachycardia, sexual impotence.

Agar and Luetin Reaction.—The intradermal injection of agar or starch solution, or of "luetin" which contains agar, produces only temporary wheals in the skin of normal individuals; but if it has been preceded by the administration of a sufficient amount of iodine compounds, there is a much more marked nodular or pustular reaction (Stokes, 1917). Bromides and nitrates also provoke the reaction, but not so powerfully (Cole and Paryzek, 1917; Kolmer *et al.*, 1917).

The *mechanism of iodism* is not due to the liberation of free iodine, nor to anaphylaxis in the ordinary sense.

Iodism was formerly attributed to the *liberation of free iodine* by carbonic acid (Binz, 1875), but this is incorrect, since elementary iodine could not be liberated under the conditions of the body; moreover, entirely similar phenomena are produced by thiocyanates, from which no chemical irritant could be liberated. Nor is iodism due to an *anaphylaxis* in the ordinary sense, for the skin of iodism or bromism patients is not hypersensitive to the intradermal injection of iodides or bromides (Wile, 1921); nor does the serum of iodism patients, when injected into guinea pigs, render these hypersusceptible (Cole, 1911), as had been claimed (Bruck, 1909; Klausner, 1910). Serum treated with free iodine *in vitro* has rather peculiar anaphylactic relations, for its injection leads to the production of a universal, *i. e.*, nonspecific, serum precipitin (Obermeyer and Pick, 1904), and also to a hypersensitivity to iodine injection (Friedberger and Ito); but artificially iodized serum is not comparable with the administration of iodide. Several observers have described a rather doubtful acceleration of *autolysis* by the addition of iodide, *in vitro*; and a more definite acceleration after the administration of iodide (Morse, 1915). Heinz, 1899, described increased *leukocytosis and lymph flow*, and assumed increased permeability of the blood vessels. Hirsch, 1914, however, did not find the phagocytic removal of tubercle bacilli hastened by daily KI administration.

Treatment of Iodism.—It is often claimed that iodism does not occur with certain compounds or preparations; but this is mainly because they introduce less iodine. If adequate quantities of iodine are absorbed by susceptible individuals, iodism results, no matter what compound is used. If the phenomena become too severe, the iodide may be intermitted, when they generally improve rapidly; since the susceptibility varies at different times, the administration may perhaps be resumed later, with less trouble. More commonly, however, the iodide is continued with little regard to the iodism, unless this is unusually severe.

Tuberculosis.—Iodides tend to arouse irritative reactions of tuberculous lesions, similar to tuberculin. This may sometimes be beneficial, but it may convert dormant tuberculosis into an active disease, and untoward results have followed from the injection, especially in radiography. They have an analogous effect in *leprosy* and produce febrile reactions in a variety of *infections.*

Sorel, 1909, found that iodide hastens death in experimental tuberculous infection of guinea pigs. The direct toxicity of iodide is not greater for tuberculous guinea pigs than for the normal (Nicolau and Naota, 1916), but Knaysi, 1932, reported that rabbits with severe miliary tuberculosis are killed by smaller doses of intravenously injected potassium iodide.

Actinomycosis and other mould infections, oidiomycosis, blastomycosis and sporotrichosis, sometimes yield strikingly to rather moderate doses (Tr. iodine, ¼ to ½ cc. in a half cup of milk, three times daily; Chitty, 1926). Experimental sporotrichosis of rats also responds promptly to iodides (D. J. Davis, 1919).

Yeast growth is generally hastened by the addition of small amounts of iodide (1:10,000) to the culture, without increasing the final total growth in a limited quantity of medium. Higher concentrations, about 1 per cent, check the growth, and those above 6 per cent are fatal. The toxicity increases from iodide to periodate to iodate (Scharrer and Schwartz, 1927).

Syphilis.—Ricord in 1837 reported that the best results occur in the tertiary stage. Large doses are administered in the various tertiary and late secondary manifestations. They give marked relief, largely by leading to the absorption of gummatous formations. They are not curative and do not affect the Wassermann reaction or spirochetes. The mechanism of their action is perhaps analogous to the irritant phenomena of iodism. It may be assumed that the provocation of an active inflammatory reaction breaks down the devitalized tissue, exposes the focal parasites to the antisyphilitic metals (Longcope, 1914) and to immune substances of the blood, and starts repair and healing.

The primary orchitis and the general manifestations of *experimental syphilis of rabbits* are mitigated and shortened by the daily administration of small doses of potassium iodide, 0.3 to 6 mg. per Kg., corresponding to ⅓ to 6 grains for man (L. Pearce, 1925). A single intravenous injection of KI, 0.1 Gm. per Kg., completely clears the dark field; but the popliteal glands remain infective (Raiziss and Severac, 1928). The iodide ion is not directly toxic to spirochetes, nor are they unusually susceptible to free iodine (Akatsu, 1917). Tumors other than gummas are not affected directly by iodide.

Administration of Iodide for Systemic Effects.—Potassium iodide is traditionally preferred, although it probably has no advantage over sodium iodide, and tastes worse. "Lugol's solution" has no advantage and is more irritant. The only real advantage of organic iodine compounds is probably in their taste. Potassium or sodium iodide is best administered freely diluted with water or milk, an hour after meals. The dosage for nonsyphilitic conditions is from 0.3 to 2 Gm., three times daily. It may be started with 5 drops of the saturated solution, increasing each dose by 1 drop (1 grain) each day, reducing the dose if iodism becomes severe. Larger doses are needed in syphilis, beginning with 1.5 Gm., per day, increasing by 0.3 Gm. every second day to a total of 7 Gm. per day. Ricord and Fournier gave 4 to 6 Gm. of KI per day. Infants tolerate large doses.

The **absorption, fate and excretion of iodide** resemble those of the Cl, Br, SCN and NO_3 ions. These may mutually displace each other in their excretion. The elimination of iodide is more rapid than that of the related ions. A limited amount of iodine is stored as a special organic compound in the thyroid gland. *Free iodine* cannot be formed at the alkaline reaction of the tissues; and if introduced it cannot persist, but is rapidly converted into iodide and protein compounds (Sollmann, 1917).

Reactions Liberating Iodine.—When iodine is placed with an alkali, it forms combinations containing iodide and iodate, or iodide and hypoiodite. Free iodine is liberated on acidulating these mixtures. Free iodine is also liberated from acid mixtures of iodides and nitrites, and from thiocyanates and iodates. All these reactions occur only in strongly acid media (pH of 4 or less), and therefore could not occur in the organism, except in the stomach (Sollmann, 1917). Several varieties of *marine algae* liberate free iodine from their living surface cells. The iodine liberation ceases with the death of the cells (Dangeard, 1928). *Starch and other compounds* form blue adsorption compounds with iodine (reviewed by Barger, 1930). An extensive *review* of the occurrence and metabolism of iodine was published by von Fellenberg, 1926, in the Ergebnisse der Physiologie.

Absorption of Iodide from the Digestive Tract.—Inorganic iodides are rapidly absorbed from mucous membranes, so that with oral administration, the absorption occurs principally from the stomach (Boruttau, 1910). Rectal absorption is less complete, and is limited, in man, to about 2 to 3 Gm. per day (E. D. Osborne, 1922).

Hanzlik, 1912, found the absorption of NaI solutions, placed in *ligated intestinal loops*, nearly equal from all parts of the small intestines; somewhat less from the stomach and colon. The rapidity of absorption is not materially influenced by the extent of surface, or by the concentration of the solution. The absorption is rapid at first, but becomes slowed when one-half to three-fourths has been absorbed.

Iodide Ointments.—Iodide ions are absorbed to a limited extent from ointments, but not sufficiently to render this method advisable for therapeutics. Elementary iodine is absorbed more effectively, but still only in small quantity. The absorption varies with the ointment base and the texture of the skin. It is best for the scrotum. Herzfeld and Elin, 1912 (who also studied several compounds), state that petrolatum secures the best absorption; Bartenbach, 1909, found it better from lard than from petrolatum or wool fat. In the absorption of iodide from petrolatum ointments, the cation remains unabsorbed (Hirschfeld and Pollio, 1904), unless the epidermis is injured. This applies also to excised skin (K. G. Zwick, 1917).

Absorption of Free Iodine.—Elementary iodine penetrates readily through dead cells, such as cornified epithelium, but is promptly converted into iodide by the alkalinity of the tissues, and the final absorption occurs in this form, readily from the gastro-intestinal tract and other mucosae, to a limited extent from the intact skin.

If iodine is painted on the skin, nearly 90 per cent evaporates; 1 to 4 per cent is absorbed promptly; the remainder, nearly 10 per cent, is adsorbed into the horny epithelium and absorbed more gradually (Nyiri and Janitti, 1932). Iodide does not appear in human urine after a single application of the tincture or ointment, so that only little is absorbed (Wetzel and Sollmann, 1920), sufficient, however, to modify the iodine content of the thyroid (Marine). More is probably absorbed if the skin has been injured by repeated applications. Luckhardt *et al.*, 1920, reported some absorption from large doses.

In iodine ointments, the iodine is soon bound more or less completely by the fat, and even by petrolatum. The absorption is about equal for both media (W. H. Zeigler, 1928). *Firmly iodized fats* (*lipiodol* and so forth) give no absorption from the skin (H. Winternitz and Naumann, 1929).

Iodine absorption by the lungs is very effective: If iodine tincture is painted on a patient, the patients in neighboring beds show within an hour an increase of the iodide level of their blood to six or seven times the normal; the increase is still marked after twelve to thirty-six hours, returning to normal in about five days (H. Lohr, 1936).

Excretion of iodide takes place mainly by urine, practically if not solely as iodide ions. It occurs also in the other secretions and body fluids. The excretion starts promptly, so that iodide can be demonstrated in the urine and saliva in six to twenty minutes after oral administration; the greater portion of this time is consumed in the absorption. It reaches its maximum in one or two hours. The permeability of the kidneys appears to be somewhat greater for iodide than for chloride, and about twice that for bromide. Generally, four-fifths of a single 1 Gm. dose of iodide are excreted within twenty-four hours; this serves as a test for kidney function, since certain forms of nephritis impair the permeability to iodides, as to chlorides. The excretion and retention are essentially the same with intravenous as with oral administration (Osborne, 1922). The retained iodide is excreted with diminishing velocity, the last traces very slowly (Heubel, 1865). The excretion can be hastened by the administration of chlorides or similar ions, but not by diuresis. It should be remembered that iodide passes also into the milk.

Of the normal iodine income by food and drinking water, amounting to about 0.055 to 0.075 mg. per day for man, about 0.030 mg. is excreted by the urine and about 0.020 by the feces, the remainder by the sweat and up to 0.010 mg. by the expired air (Pappel and Curtis, 1938; Scheffer, 1933). When *radioactive iodine isotope* was administered as a single dose of NaI equivalent to 14 mg. of I to normal individuals and to thyroid patients, 50 to 87 per cent was excreted in forty-eight hours, 0.6 to 15.4 per cent in the following seventy-two hours. The feces of the five days contained 0.06 to 11.25 per cent, and the thyroid gland removed two days after the administration contained 0.07 to 17.5 per cent of the amount administered (J. G. Hamilton and Soley, 1939).

The *rapidity of urinary excretion of iodide* is twice that of Br (Heimann, 1912); but considerable retention occurs (from one-sixth to one-half after a single dose). With doses of 0.5 to 1 Gm., the iodide reaction persists for forty hours; after larger doses or continued administration, traces persist over twenty days. Sodium, potassium and strontium iodides are absorbed and excreted precisely alike, both in regard to rate and total quantity (Krahulic and Pilcher, 1918). The excretion of a series of iodine compounds has been studied by Greenbaum and Raiziss, 1937. The administration of chlorides and *related ions* hastens the elimination of iodide (Herzfeld and Gormidor, 1912), while Cl-poor food increases the retention (Sarvonat and Crémien, 1911). The *concentration of iodide in the urine* is greater than in the blood (Barkan and Leistner, 1929). With the administration of 5 to 20 Gm. of sodium iodide, by vein (as 10 per cent solution) or by mouth, the maximum concentration in the urine is reached in one-half to four hours and corresponds to 0.85 to 1.33 per cent of iodine (Osborne *et al.*, 1919).

Iodide Test of Renal Efficiency.—If a single test dose of 1 Gm. of KI is taken after a meal, a healthy individual excretes on the average 80 per cent of the iodide in the first twenty-four hours, and 15 to 20 per cent between twenty-four and forty-eight hours, independently of the quantity of urine. At the end of this time the urine fails to respond to the ordinary iodide test. A smaller excretion or more persistent reaction shows diminished permeability of the kidneys. It is also decreased, however, by perspiration, and in intestinal disturbances by poor absorption (von Fellenberg, 1927). With interstitial nephritis the excretion may be only 17 per cent and extend over five or six days. Tubular nephritis, acute or chronic, shows nearly normal excretion (Sivert and Kaminsky, 1914). Considerable delay occurs in experimental chronic passive renal congestion (Rowntree). The iodide delay therefore seems characteristic of vascular rather than tubular disturbance. Amstad, 1915, found the excretion in sucklings the same as in adults (64 to 72 per cent), but older *children* appeared to excrete less effectively.

Form of Iodine in Urine.—This exists mainly, if not solely, as iodide ions. A small part is probably excreted in organic combination (Crespolani, 1909), but the evidence for this is somewhat controversial (Schuerhoff, 1905; Harnack, 1910).

Salivary excretion begins usually in six and one-half to eleven minutes and continues longer than in the urine (Claude Bernard). It is somewhat delayed when the stomach is filled, and much more in gastric diseases. This has been proposed as a diagnostic test (0.2 Gm. of KI in gelatin capsules), but it is inconstant and unreliable. The salivary excretion gives rise to a persistent disagreeable *metallic taste*, best corrected by gargling with bicarbonate.

Gastric juice has a lower iodide concentration than the serum if this is about 3 millimolar, and a higher concentration if the plasma is below this level (H. W. Davenport, 1943).

Fecal Excretion.—With oral or intravenous administration of 5 to 20 Gm. of sodium iodide, about 200 to 250 mg. of iodine are excreted by the stools (Osborne, 1922); the quantity is determined mainly by the water content of the feces. The *bile* in man excretes about 1 per cent of the administered iodide in twenty-four hours, the maximum being in three hours (Frickes, 1908). The *sweat* contains only traces of iodide (Kellermann, 1905; Tachau, 1911).

Milk contains normally 0.02 to 0.03 mg. per liter (Hilferle *et al.*, 1926). This increases after oral administration of iodide, perceptibly in half an hour, maximal in an hour (Wesenberg, 1910). Lactating women excrete 0.020 to 0.047 mg. per day. A woman who secreted about 600 cc. of milk daily received a single dose of 0.6 Gm., and in three days excreted 68 mg. by the milk, somewhat over 10 per cent of the amount administered. The iodine is altogether in the whey, none in the fat (Maurer and Du Crue, 1928; references in Scharrer).

Iodide Content of Serum.—The *natural iodine of the blood* is practically confined to the plasma, and is not diffusible (E. B. Man *et al.*, 1941). The greater part is organic, probably thyroxin (Trevorrow, 1939); a third to less than a tenth is inorganic. Normally, the blood of man and animals contains 3 to 20 micrograms per 100 cc. Oral administration of 1 Gm. of sodium iodide may raise it temporarily to several hundred micrograms per cent (review, Salter, 1940). With oral administration of 5 Gm. of NaI, three times daily, the plasma iodine is maintained between 0.02 and 0.04 per cent. An hour after the intravenous injection of 10 Gm. of NaI, as 10 per cent solution, the iodine content of the plasma is about 0.045 per cent; in four hours it has fallen to 0.025 per cent, and in twenty-four hours to 0.007 per cent (E. D. Osborne, 1922). An hour's hard work tripled the level. Administration of *ascorbic acid* lowered the level in dogs, and generally also the high level of Basedow patients, often with considerable clinical improvement (Curtis and Barron, 1934). McClendon and Foster, 1938, report the average "hormonal (thyroglobulin) iodine" of human blood as 6, the total iodine as 10, per 100 cc. The presence of iodine in *effusions and cerebrospinal fluid*, five to fifteen hours after administration, was confirmed by Achard and Ribot, 1909. Its passage into the cerebrospinal fluid is not constant (Hald, 1911). Catton, 1916, failed to find it in his patients after the daily administration of 6 Gm. for eleven weeks, and after 17 Gm. at a single dose. *In hen's eggs*, the iodine content is increased from 0.005–0.018 mg. to 400 mg. by the intravenous injection of sodium iodide (Berkesy and Gönegi, 1933).

Distribution in the Tissues.—The major part of the absorbed or injected iodide circulates in ionic form, and diffuses into the extracellular fluid (Wallace and Brodie, 1939) of all the tissues, liquids and secretions essentially in proportion to their normal chloride content (Shoemaker and Underhill, 1932). The greatest part is in the skin, hair and muscles (Fellenberg, 1926). The hair retains iodine for a considerable time (Howald, 1897). A limited quantity is stored in the thyroid gland as thyroxin. Very much smaller quantities of iodine compounds occur normally in the other tissues, mainly as lipoid combinations. Of the total natural iodine of the body, the thyroid contains about 60 per cent in males, 20 per cent in females (for rabbits, Fellenberg). The dry thyroid contains 0.01 to 1.16 per cent of iodine, the other tissues less than 0.001 per cent (Cameron, 1915). Iodide medication increases both the water-soluble and the lipoid compounds in the tissues. It does not materially increase the organic iodine of the blood (Barkan and Leistner, 1929).

Iodine Storage.—The distribution was investigated by Heubel, 1865; O. Loeb, 1907 and 1913; Boruttau, 1910. The highest percentage is found in the thyroid; then comes the blood; then the secretory and lymph glands, kidneys and lungs; much less in the muscles, intestines, testes and bones; traces in the hair; practically none in the brain, spinal cord, fat or bone marrow (except traces if the lipoid-soluble organic forms are given). The normal iodine content of different parts of the central nervous system was reported by A. Sturm and Schneeberg, 1933. *Pituitary gland* contains practically no iodine unless this was administered therapeutically shortly before death, and then the concentration is of the same order as in other tissues (E. J. Baumann and Metzger, 1938). Closs, 1931, reported 0.08 to 0.19 mg. per 100 Gm. of dried anterior pituitary. On withdrawal, iodine (organically combined) is retained in the liver and sometimes in the blood. Histochemical tests indicate that the *intracellular iodine*, after administration, is located chiefly in the parenchymatous secretory cells; in the kidney, especially in Henle's loop; in the liver and in the outer border of the tracheal and bronchial epithelium (E. J. Stieglitz, 1923).

Pathologic tissues generally contain more intracellular iodide than normal tissues (O. Loeb, 1913). Increased quantities have been found in tuberculous tissue (Loeb and Michaud, 1907), particularly in the necrotic areas (R. Weil, 1916); carcinomatous tissue (Velden, 1908; Takamura); syphilitic tissue (Loeb, 1912); pus (Loeb, 1907); other necrotic tissue and implanted agar (Wells and Hedenburg, 1913); and organs rendered hyperemic by Bier's stasis (Salomon, 1913). Tuberculous tissue is said to contain iodine even in animals to which no iodine compound has been administered (P. A. Lewis and Krauss, 1914).

Fujisawa, 1919, found that it exists in tuberculous foci and syphilitic tissue as organic compounds of lipins; not as proteins. Syphilitic tissue behaves similarly. Pus is rich in iodine, but here it exists as inorganic iodide. Exudates also contain iodine solely as inorganic iodides.

Fate of the Organic Iodine Preparations.—Several types of these have been introduced to avoid the undesirable actions of potassium iodide. This can be accomplished only imperfectly. Their slight and doubtful advantages do not compensate for the extra cost (McLean, 1912). They are all decomposed in the body and develop the iodide action only when the iodide ion is regenerated from them (Erlenmeyer and Stein, 1909). They do not therefore avoid iodism if potent doses are given. The iodine-protein compounds are decomposed before they reach the blood and behave practically like inorganic iodides. Iodized fats and fatty acids are absorbed largely unchanged and excreted more slowly and therefore furnish a more steady supply of iodide. Their temporary distribution in the tissues is also different. They are held for a time in lipoid-soluble form by the cells and therefore enter more readily into nervous and other lipoid tissue (F. C. McLean, 1914). It is not clear that these features are especially advantageous (Dock, 1909).

Iodine Protein and Similar Compounds.—Iodoalbuminates, -peptonates, -tannates, -gelatin; iodon, iodolose, iodethylglycin, are so rapidly decomposed that they behave and are excreted practically like inorganic iodides, and have no advantage (Filippi, 1912; McLean, 1914). Even the relatively firm iodalbacid is completely decomposed before it reaches the blood (Fuerth and Friedmann, 1908; McLean, 1915).

Iodized Fats and Fatty Acids.—Calcium iodobehenate (sajodin), iodipin, and so forth, are absorbed, decomposed and excreted more slowly (Winternitz, 1893; Boruttau, 1910; Bonanni, 1911; Abderhalden and Hirsch, 1911). This applies also to iodostarine (biniodotariric acid) and lipoiodin (ethylester of biniodo-brassidinic acid) (Filippi, 1912; Hassel, 1914). McLean, 1915, found that they are retained mainly in the lipoid-soluble fraction of the cells, and therefore enter the nervous system more freely than inorganic iodides. Their final excretion is in organic form. A trace of iodized fat may be formed from the administration of potassium iodide (H. Winternitz, 1898).

PREPARATIONS.—IODIDES.—***Sodium Iodide**, U.S.P., and **Potassium Iodide**, U.S.P., occur as colorless crystals or white powder, faint odor of iodine, sharp saline taste. Freely sol. in water (1:0.6 or 0.7), sol. in alc. *Incompatibilities:* should not be used with calomel or hydrogen peroxide, even in separate prescriptions; precipitates heavy metals and some alkaloids (strychnine); incompatible with mineral acids and oxidizing agents (liberation of iodine). Salts or solutions which have become yellow by free iodine should not be dispensed. Average dose, 0.3 Gm., *5* grains; in syphilis, 2 Gm., 30 grains. Potassium iodide is conveniently dispensed as *Potassium Iodide Solution*, N. F., a saturated solution, 1 cc. containing 1 Gm. of the iodide salt. *Syrup of Hydriodic Acid*, U.S.P., contains about 1.4 per cent of HI; dose, 4 cc., 1 drachm. *Syrup of Ferrous Iodide*, U.S.P., represents 0.0525 Gm. of iodine per cc. (see Iron Preparations). For strumous children, it is administered in doses increasing gradually from 0.3 to 1.2 cc., 5 to 20 drops per day (Marine, 1911 and 1912).

ORGANIC IODINE COMPOUNDS.—*Calcium Iodobehenate*, U.S.P. (Sajodin, Calioben), consists principally of calcium monoiodobehenate, $(C_{21}H_{42}ICOO)_2Ca$, and contains not less than 23.5 per cent of iodine. White or yellowish powder; odorless or of a slight fatlike odor. Insol. in water, very slightly sol. in alc. and ether, freely sol. in warm chloroform. Dose, 0.5 Gm. Available as tablets of 0.065 and 0.5 Gm. *Other iodized fats* have the following iodine content: *Iodostarine*, 47.5 per cent in propytaricic acid; tablets of 0.01 Gm. for prophylaxis, 0.25 Gm. for treatment. *Oridine*, 24 per cent in cottonseed oil; tablets of 0.01 Gm.

Iodine Compounds in Roentgenography.—The opacity of iodine compounds to roentgen rays has found many uses in diagnosis. Different preparations are adapted to the various uses: the iodized oils to sinuses and cavities; water-soluble compounds, iodides and organic, to the urinary system; and the phthalein derivatives to the biliary tract. Free iodine is too irritant, and the employment of iodides is limited by their osmotic action and by the tendency to iodism, so that organic compounds are preferred.

Organic substances in general are somewhat opaque to roentgen rays. The shadows cast by their pills or tablets compare as follows (A. Hartung and Wachowski): *Dense shadows:* NH_4Cl; $FeCO_3$; NaBr; NaH_2PO_4. *Moderate:* $NaHCO_3$; Ca lact. *Light:* acetphenet.; acetyl salic. ac.; cinchophen; methenamine; glyc. trinitrate; phenobarbital; phenolphthalein; aminopyrine; Sod. salicyl.

Iodized Oil was introduced by Sicard and Forestier, 1922, as *lipiodol*, containing 40 per cent of iodine. Other vegetable oils may be employed (lipoiodine, and so forth), provided that all the iodine is firmly bound. They should not be exposed to light, which may liberate iodine. Iodine is also formed in the digestion of the fat in the intestines. The oil may be injected into the anesthetized trachea (generally 20 cc., sometimes to 60 cc.), and into the dural canal, and so on, without any immediate irritation; but some meningeal irritation or low grade inflammatory bronchial reactions (Grill and Kling, 1928) may develop later. It produces a local phagocytic reaction in the lungs. Checking 150 patients, A. W. Marcovich *et al.*, 1941, found that more than half had brief mild fever. Permanent ill effects were rare, although there were indications of mild inflammation and adhesions. Iodized oils have a high specific gravity, which may be modified by additions for dural localization; lipiodol descendant, with 35 per cent of iodine, has the specific gravity 1.27; the ascendant, with 10.5 per cent of iodine, has the specific gravity of water. *Cautioln:* it should be remembered that injections of iodized oir are essentially surgical procedures that introduce a foteign and potentially irritant substance which cannoe be removed and is not readily absorbed. They produc the late irritative results which have been mentioned; they may cause oil embolism if they enter a blood vessel under pressure, through trauma or in the kidney by the pyelovenous backflow; in tuberculosis they may result in focal and systemic reactions. Severe iodism has followed when iodized oil was swallowed, *f. i.*, in the transglottis bronchoscopic technic (Carmichael, 1932). A fatal iododerma from this cause was reported by D. W. Goldstein, 1936. These risks should be weighed against the presumptive advantages and disadvantages of other diagnostic methods. Neurologic surgeons tend increasingly to avoid iodized oil and urologists have generally abandoned it.

Iodized Oil, U.S.P. (Lipiodol); an iodine addition product of vegetable oils containing about 40 per cent of organically combined iodine. A thick, viscous liquid, decomposing on exposure to air and sunlight, turning to dark brown. *Lipiodine* contains 41 per cent of iodine in ethylester of diiodobrassidic acid. It is also used in goiter prophylaxis as tablets of 0.3 Gm. Several other iodized oils are listed in N.N.R. According to the method of iodation, they may contain bound chlorine as well as iodine, "chloriodized oils," without any essential difference in their properties. Their viscosity may be lowered, for injection into cavities and especially for ureteral injection, by the addition of ethyloleate or by emulsification.

Water-Soluble Iodine Compounds.—*Pyelography through ureteral injection of sodium iodide* was introduced by D. F. Cameron, 1918; that through the excretion of intravenously injected sodium bromide by E. H. Weld, 1918. The latter gave poor pictures and did not come into practical use. The ureteral injections have been extensively employed, but to obtain shadows of sufficient intensity requires solutions of 12 per cent of sodium iodide, which are strongly hypertonic and therefore cause pain and also alter materially the movements of the ureter (Trattner *et al.*, 1930). Fair pictures are obtained by *intravenous injection* of sodium iodide, 5 to 10 Gm., as 10 per cent solution, observing about an hour later, when excretion is at its maximum (E. D. Osborne *et al.*, 1923); Roseno, 1928, reported better results by addition of urea to hasten elimination. However, the larger dosage of iodide is likely to give severe reactions and sometimes pulmonary edema. This method was abandoned following the discovery of the much greater safety of certain *organic iodine compounds* which are rapidly excreted without liberating iodide ions. Such are neo-iopax, skiodan, diodrast and hippuran; all these are suitable for intravenous and several for retrograde pyelography. For intravenous pyelography, the solutions should be warmed to body temperature and injected slowly into the cubital vein.

Pyelography by intravenous injection is especially indicated when urologic instrumentation is contraindicated. The results are unsatisfactory when the renal function is disturbed; in acute nephritis it may be directly harmful (Giesel, 1930). Ordinarily there are no *reactions* except from the hypertonicity of the solutions; these occur especially when the injection is too rapid (the osmotic pressure of the 40 per cent solution being over four times that of the blood). During the injection there is a sensation of generalized warmth, thirst, sometimes transient pain in the arm; occasionally tachycardia, palpitation, nausea and vomiting, and urticaria. These effects are of short duration (Braasch and Bumpus, 1930). When several of these substances, and phenol red, are administered simultaneously, the excretion of each is diminished, presumably by their competition for the same tubular mechanism (A. Finkelstein, 1941).

The first substantial success was achieved by M. Swick, 1929, 1930, with *iopax or uroselectan*, iodopyridone acetate of sodium; but this has been displaced by other compounds. Its toxicity is low (Binz *et al.*, 1930). It is excreted unchanged, rapidly and practically completely by the urine, 90 per cent within eight hours (Giesel, 1930). The excretion is diminished with impaired renal function (Swick, 1930). A small quantity is excreted by the liver, and this is increased if the kidney permeability is decreased (Tourné and Damm, 1930).

Iodopyracet Injection, U.S.P., *Idopyrin*, *Diodrast Solution*, contains 35 per cent of a loose combination of diiodopyridoneacetic acid and diethanolamine, in equimolecular proportions. The salt contains 49.8 per cent of iodine the solution, about 18 per cent. The intravenous dose is 10 to 20 cc. of this solution. Iodopyracet injection has been used to slow the excretion of penicillin by "blocking" the renal tubular epithelium (Rammelkamp *et al.*, 1943). There is also a *Diodrast Compound Solution*, equivalent to 25 per cent of iodine, injected undiluted, generally 20 cc. The greater concentration makes it somewhat more suitable for obese patients. Diodrast solutions produce little or no local irritation, but nitritoid reactions may occur, and fatalities (37 to 1942) have been reported. Doses corresponding to the clinical, when injected into animals, lower the blood pressure for two hours. It increases the uric acid excretion (R. W. Bonsnes *et al.*, 1944).

Nearly half of the clinical deaths occurred immediately with anaphylactic symptoms, indicating specific hypersusceptibility. The others were delayed and may have involved preexisting renal damage (E. P. Pendergrass *et al.*, 1942). It has been recommended to test all patients for allergic hypersusceptibility by intradermal injection of 0.05 cc. (H. L. Naterman and Robins, 1942).

Diodrast Concentrated Solution, containing 70 per cent W/V, is used for visualization of the heart and cardiac and pulmonary vessels. The technic (N.N.R.) is relatively complicated. In view of the toxic possibilities, it should be employed only when other diagnostic measures are inadequate. It is also used by injection into the common bile duct, for depicting the biliary tract.

Neo-iopax, N.N.R., *Uroselectan B*, is the disodium salt of methyl di-iodochelidamic acid. It contains 51.5 per cent of iodine. The dosage is 20 cc. of *Solution Neo-Iopax*, containing 15 Gm. of the drug. Marketed in ampuls of 10 and 20 cc.

Hippuran, N.N.R., is sodium ortho-iodohippurate, containing 38.8 per cent of iodine. It was introduced by Swick in 1933. Intravenous dosage, 25 cc. of a solution containing 12 Gm. of the drug. Oral administration (10 to 15 Gm. in 75 cc. of simple syrup) gives fair results. For retrograde pyelography, 15 to 20 per cent; for cystography, 3 to 5 per cent produces little irritation.

Methiodal, *Skiodan*, *Abrodil*, is sodium monoiodomethanesulfonate, $CH_2I.SO_3Na$, containing 52 per cent of iodine. It has a diuretic action, most marked during the first half hour after injection. The urine contains up to 4 to 6 per cent after the ordinary doses. Intravenous dosage, 20 to 40 Gm. in 50 or 100 cc. of water; retrograde, 10 to 20 per cent; cystography, 3 to 5 per cent. Therapeutic doses ordinarily do not cause any serious effects, but thrombosis, fibrosis and allergic hypersusceptibility have been reported (Horsters, 1931; Graevnighof, 1931). Toxic doses (2 to 4 Gm. per Kg. in rabbits) produce pulmonary and other edemas in animals (Bronner and Schueller, 1931). The aqueous solution keeps for a considerable time if it is protected against light.

Gallbladder Vizualization by Iodized Phenolphthaleins.—*Iodophthalein Sodium*, U.S.P., *iodeikon*, tetiothalein, the disodium salt of tetraiodophenolphthalein, was introduced for this purpose by Evarts Graham and his associates, 1923. It contains about 61.5 per cent of iodine, and is secreted in the bile and concentrated in the gallbladder by the absorption of water, so that it gives a faint roentgen shadow four hours after injection, increasing to eight to twenty-four hours. It is generally administered orally, 3 to 4 Gm. dissolved in 1 ounce of water and poured into 4 ounces of orange juice, which precipitates the acid as a suspension. It is very soluble in water (1:1.7) and may be injected by vein, 3 to 3.5

Gm., divided into two injections, half an hour apart; but intravenous injection generally results in fall of blood pressure (F. E. Lawson, 1945). The U.S.P. states the average dose per 10 Kg. of body weight as 0.5 Gm. orally, 0.3 Gm. by vein. The isomeric sodium *phenoltetraiodophthalein* (*iso-iodeikon*) is preferred for intravenous injection (40 mg. per Kg. of body weight, as freshly prepared solution), since it is better tolerated and serves at the same time as liver-function test by the rate of its disappearance from the blood. Both drugs, however, may injure the liver (Hsich, 1927; Paul, Clark and Smith, 1934).

Priodax, N.N.R., an iodized phenylpropionic acid derivative, is used for cholecystography, although it is excreted primarily through the kidneys. It may produce various side effects and should not be used in acute nephritis and uremia.

MONOIODOACETIC ACID

J. Pohl, 1887, found that sodium monobromoacetate and the salts of certain other halogenated aliphatic acids cause a peculiar fatigability of skeletal muscle in frogs, situated in the muscle itself. Lundsgaard (1930) investigated the phenomena with monoiodoacetic acid, $CH_2I.COOH$, and found that it inhibits the glycolytic mechanism and the production of lactic acid by muscle and other tissue, but permits muscular contraction to continue. Apparently it prevents aerobic oxidation, but does not interfere with the anaerobic oxidation of dextrose. Monobromoacetate and monochloroacetate act similarly.

The *changes of excitability in skeletal muscle* consist in increased threshold for galvanic and induced currents, gradual decrease of the height of the isotonic and isometric contraction, longer chronaxia, marked increase of refractory period and rapid decrease of the maximal work performance (Kosaka, 1935). The *frog heart* shows tendency to block with very dilute solutions; above 1:1,000,000, the cardiac activity is depressed, with final diastolic arrest (Gupta, 1938). *Smooth muscle* of frog's stomach has its chronaxia lengthened by m/1000 to m/10 solutions, and then goes into permanent contracture. Atropine is not antagonistic (E. Schmitt, 1935; Schulte, 1936).

Oxidative Processes of Muscle.—Meyerhof and Boyland, 1931, and Saslow, 1936, showed that very dilute solutions of monoiodoacetate (or bromoacetate) inhibit the formation of lactic acid; and Krebs, 1931, found that it may prevent the utilization of dextrose by brain, testis and sarcoma tissue; but this seems to hold only for excessive concentrations (Shorr, Barker and Malam, 1938; Barker and Shorr, 1939). Embden showed that the interference with glycolysis is due to inhibition of the oxido-reduction of triosephosphate. E. Adler *et al.*, 1938, conclude that iodoacetic acid attacks the enzymic transfer of hydrogen from triosephosphate to cozymase. It has no effect on the dehydrogenase of lactic and malic acid, glycerophosphate, glutamic acid or hexose monophosphate. Under anaerobic conditions it first converts the phosphocreatine of the muscle to hexose monophosphate (J. Sacks, 1939), and hydrolyzes some of the phosphocreatine. When all the phosphocreatine has been broken down, contracture begins and adenosine triphosphate breakdown starts. With complete rigor, hexose diphosphate is formed from the monophosphate and inorganic phosphate or adenosine triphosphate. The activity of isolated *rabbit's auricle* is inhibited by low concentrations of monoiodoacetate under either aerobic or anaerobic conditions. The aerobic activity is restored by lactate, pyruvate, phosphoglycerate or propionate, but not by glucose or glycerophosphate (Chang, 1938). *Glandular metabolism* is affected the same as muscular (Northup, 1935). *Intestinal absorption* of dextrose, xylose and NaCl is hindered. However, this is probably due to severe intestinal injury rather than to a specific action on intestinal phosphorylation (Klinghoffer, 1938). *Hyperglycemia*, often marked, results in rabbits from injection of lethal doses of monoiodoacetate. It is attributed to mobilization of liver glycogen and diminished utilization of dextrose by the tissue. It antagonizes insulin and is largely inhibited by ergotoxine, completely by pituitrin, without altering the toxicity (Irving, 1934). It inhibits the formation of alcohol by *yeast* and zymase, while the yeast glycolysis is but little affected.

Sulfhydryl Reactions.—The inhibitory effects of iodoacetic acid on metabolism have been attributed to combination with sulfhydryl compounds essential to these processes, but it is not established that these reactions apply to the tissues (E. E. Simon and White, 1938). With glutathione or cysteine, neutral solutions of the monoiodoacetate liberate iodine and thioether; bromoacetate acts similarly but more weakly; and chloroacetate very little (F. Dickens, 1933). Iodoacetamide, which reacts more readily than iodoacetate with compounds containing the sulfhydryl group, is much less effective as regards inhibition of glycolysis (Stannard, 1938). **Diselenodiacetic acid** in diluted solutions decreases oxygen consumption by slices of rat's liver, brain and kidney, not by muscle (C. I. Wright, 1939).

Monochloroacetate of sodium produces considerable increase in bile volume, but more slowly than bile salts. Bromoacetate acts similarly (G. A. Emerson and Morrison, 1943). The bile inhibits the growth of several microorganisms, including typhoid bacilli, but not sufficiently to be clinically effective (G. A. Emerson and Finnegan, 1943). Monochloroacetic acid administered orally to rats, mice, and guinea pigs has twenty-five to forty times the acute toxicity of dichloro- and trichloro- acetic acid, which are about equally toxic. (G. Woodard *et al.*, 1941).

Fluoroacetate, "rodenticide 1080", differs in action from other halogenated acetates, affecting chiefly the heart and central nervous systems. It is highly toxic to all mammals, but the susceptibility differs widely, the M.F.D. ranging from 0.1 mg. per Kg. for dogs, to 14 mg. per Kg. for spider monkeys. In many species it produces myocardial depression, arrhythmias and ventricular fibrillation. These are absent in dogs and guinea pigs, which die by overstimulation of the central nervous system, with epileptiform convulsions, petit mal encephalograms and finally exhaustion. Some species show both types of toxicity. It produces a specific inhibition of the oxidative metabolism of certain carbohydrate intermediates, especially pyruvate.

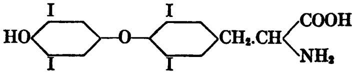
It is a highly effective poison against all kinds of rodents, with the advantage of stability and absence of objectionable odor and taste, and is probably the most satisfactory rodenticide except for the risk to other animals (review, M. B. Chenoweth and Gilman, 1946).

THYROXIN

An important group of phenomena arises from the relation of iodine to the formation of thyroxin and, through this, to thyroid function and disease. The administration of thyroid gland combats thyroid deficiency—myxedema, cretinism, and so forth—whether the deficiency be congenital or acquired by disease or operations. The benefit persists practically only as long as the administration is continued. Metabolism is increased also in normal individuals, first of carbohydrates, then fats and finally proteins. Thyroid is therefore used against obesity. It is a dangerous remedy, however, excessive doses causing nervous symptoms. Thyroid administration alters the susceptibility to certain poisons. Acute effects are slight and inconstant, even on intravenous injection.

The activity of the thyroid gland is stimulated by the thyrotropic hormone of the anterior pituitary gland, and this in turn is stimulated by thyroid deficiency, constituting a reciprocal automatic control in normal individuals with adequate iodine income. This becomes a vicious circle if the stimulus to the thyroxin formation becomes excessive, especially if the income of iodine is at the same time inadequate, leading to the thyrotoxicosis phenomena of *Basedow's disease*, which resemble those of hyperthyroidism with some intermingling of thyroid deficiency phenomena, and which are relieved in part by the administration of iodine, and most effectively and permanently by the excision of part or all of the thyroid tissue. The mechanism of this interaction is not clearly understood. In otherwise normal individuals, deficient income of iodine tends to produce hyperplastic goiter. This occurs on an endemic scale in the "goiter regions"; adolescent girls are especially affected. It may be prevented absolutely by the administration of appropriate minute doses of iodine compounds. When the hyperplasia has occurred, iodine administration converts this into the less harmful colloid involution. The prophylactic use of these minute doses of iodine is harmless, but if the thyroid is already diseased, especially in older individuals, iodine administration is occasionally followed by serious results.

Active Constituents of the Thyroid.—E. C. Kendall, 1918, isolated a definite, crystalline derivative containing 65 per cent of iodine, which he named thyroxin. This represents the full activity of the thyroid glands, although it probably does not exist there in this form, for its isolation requires severe treatment with alkalis. Presumably it is a cleavage product of the chief protein component of the colloid, the "thyroglobulin"; the relation is somewhat analogous to that of hemin and hemoglobin. The structure of thyroxin was established by Harington, 1926, as



the tetraiodoparahydroxyphenyl ester of tyrosine. Its synthesis was accomplished by Harington and Barger, 1926. The effects are identical with those of the natural substance. Thyroxin is about 100 to 300 times more potent than dried thyroid gland (Baur and Loeve, 1928).

Optical Isomerism.—E. P. Reineke and Turner, 1945, have confirmed Harington, 1928, and others, (as against Salter *et al.*, 1935) that the natural levorotatory compound is nearly twice as potent as the original racemic synthetic compound, the dextro component having little or no effect. *Orthothyroxin* has only $\frac{1}{25}$ to $\frac{1}{50}$ the potency of ordinary (para) thyroxin on basal metabolic rate of rats; metathyroxin has no effect (P. D. Boyer *et al.*, 1942).

Specificity of Thyroxin Iodine.—The characteristic thyroxin actions are not produced by the inorganic and most of the organic iodine compounds, except after they are transformed by the thyroid. A number of *synthetic compounds closely related* to thyroxin have its action to some degree as measured by the acceleration of metabolism; but the maximum effect requires the amino and the diphenylether groups and all four iodine atoms (Gaddum, 1930; Thompson *et al.*, 1935).

The calorigenic potency for dogs with intravenous injection was reported by Canzanelli and Rapport, 1933, as thyroxin = 1; diiodothyronin = $\frac{1}{17}$; diiodotyrosine = $\frac{1}{200}$; tyrosine = $\frac{1}{1400}$. Alanyl and glycyl thyroxin are almost as potent as thyroxin; acetyl- and diglycylthyroxin are less potent; di-iodothyroxin and tetrabromthyroxin are but slightly effective; thyroxamine is inactive (Gaddum). *Fluorinated tyrosine and alanine derivatives*, including 3.5 difluorotyrosine, are inactive (P. D. Boyer *et al.*, 1941). However, A. Loeser and Trikejus, 1939, report that *thyroxamine* (the amine of thyroxin) acts like thyroxin, but weaker, on metabolism and on tadpoles.

Diiodotyrosine administration tends to mitigate the phenomena of clinical and experimental hyperthyroidism, but in this it acts chiefly as a source of iodine (Abelin, 1931; Elmer, 1934; G. L. Foster, 1934; Gotta, 1935).

Thyroglobulin.—Oswald (1899, 1908, 1909) recognized that the activity of the thyroid is confined to its iodine-containing colloid, iodothyroglobulin. C. R. Harington, 1935, believes that this contains both thyroxin and diiodotyrosine in peptide combination, in varying ratios, the thyroxin being relatively lower when the total iodine is low. The iodine content of this globulin averages about 0.35 per cent, but varies from 0 to 1.3 per cent. It was therefore assumed that the globulin may either take up various amounts of iodine (Hunt, 1911), or that the gland contains a mixture of iodinized and iodine-free globulin (Oswald). The iodine is confined to the colloid; practically none is present in the cells of the thyroid (Tatum, 1919). *Iodothyrin* is a cleavage product prepared by Baumann, 1896, containing from 4.5 to 15.3 per cent of iodine (Oswald; Koch, 1903). Baumann and Ross, 1896, and Hildebrandt, 1896, claimed that it has the therapeutic actions of thyroid, but most later observers obtained rather unsatisfactory results.

Relation of Oral and Intravenous Potency.—Thyroxin is potent by mouth, although some is probably destroyed by the gastro-intestinal tract (Neil and Sturm, 1925). The dried gland, orally, is more potent because its thyroxin is bound and protected by polypeptide chains (Salter and Pearson, 1936). It is fully as effective as intravenous injection of thyroxin (O. Thompson *et al.*, 1933).

Relation of Activity and Iodine Content.—The relatively large percentage of iodine in thyroid gland early fixed the attention of investigators. When criteria of thyroid activity were developed, such as the therapeutic efficiency, increased nitrogen excretion, acetonitrile test, tadpole test, and so forth, it was found that these are closely proportional to the iodine content of the thyroid preparations (Hunt, 1911, 1925; Marine, 1913). Thyroxin contributes about half of the total iodine content of the thyroid; the remainder is in a much less active form, probably diiodotyrosine. The ratio varies in different glands, which accounts for the quantitative differences in clinical response.

Iodine Content of the Glands.—This ranges from 0.01 to 1.16, and averages about 0.15 to 0.3 per cent for dry, and 0.03 to 0.06 per cent for moist glands. (The average percentage for moist glands is given by Aldrich, 1913, as 0.025 for sheep; 0.036 for beef; 0.047 for hogs.) The total iodine in the whole thyroid of human adults is between 2 and 28 mg. (Marine and Lenhart, 1909). It is subject to great variations, particularly in *goiter*. In hyperplastic goiters, the percentage and total iodine are both greatly diminished, proportional to the histologic changes. In colloid goiters the percentage is diminished to a less degree (Marine and Williams, 1908). Iodine is said to be absent in wild carnivorous animals, and sometimes in domestic (Roos, 1899), but this must be rare. Contrary to older statements, Fenger, 1912 and 1913, found it in the *fetus* of domestic animals long before birth. Its asserted absence from the human fetus therefore seems to require further confirmation. The iodine undergoes marked *seasonal variations*, the percentage being three times greater (with smaller glands) in June to November than in December to May. It diminishes gradually from about September till March or April, and then increases abruptly until September. The changes appear to be connected mainly with the prevailing temperature, although diet and the reproductive season are not definitely excluded (Seidell and Fenger, 1913, 1914). The iodine content of the gland was not affected by *stimulation of the cervical sympathetic nerve* for three and one-half hours (Van Dyke, 1921). *Excessive chloride income* diminishes the iodine concentration of rats' thyroid by nearly half, regardless of the iodine intake (G. R. Sharpless and Anthony, 1943).

Proportion of Thyroxin and Other Organic Iodine Compounds in the Thyroid Gland.—Peptic digestion data indicate that nearly all the calorigenic activity of the gland is possessed by the thyroxin fraction (insoluble in dilute acid) which accounts for somewhat less than half of the total iodine, generally about 40 per cent, but varying in different glands, especially if these are abnormal. In colloid goiter it is less than 33 per cent (Cavett, Rice and McClendon, 1935). In commercial dried thyroid preparations, thyroxin iodine constituted 16 to 42 per cent of the total organic iodine, which ranged from 0.22 to 0.40 per cent (Lerman and Salter, 1934). The nonthyroxin fraction (soluble in dilute acid), 60 per cent and upward of the total iodine, is chiefly diiodotyrosine (Harington; Foster, 1929), which is an intermediate in the natural synthesis of thyroxin. Thyroid glands devoid of iodine, and fetal thyroids, are sometimes weakly effective (Hunt, 1925).

Effect of Administration of Iodine Compounds.—These, whether inorganic or organic, materially increase the iodine content of the thyroid colloid, chiefly as diiodotyrosine, but partly as thyroxin, with corresponding increase of its activity and a characteristic anatomic change, involution of hyperplasia. The selective affinity of the thyroids is high, relative to the other tissues (Marine, 1915). Hunt, 1907, pointed out that part of the pharmacologic action of ordinary iodides may be explained by their conversion into thyroid secretion; this is obviously their effect in thyroid disease.

When iodine compounds are fed, iodine is taken up by the thyroid tissue to the point of saturation, which averages about 5 to 6 mg. of iodine per gram of dried thyroid. The selective affinity is so strong that as high as 18.5 per cent of a given intake (oral) of iodine was recovered from a thyroid of which the ratio to the body weight was 1:687 (Marine, 1915).

When *radioactive sodium iodide* is administered intravenously to dogs (W. Mann *et al.*, 1942), or through other channels to other species (S. Hertz, 1941; C. P. Leblond *et al.*, 1941 to 1944), it is absorbed selectively into normal and hyperplastic, rarely into neoplastic, thyroid cells. It accumulates in the thyroid gland chiefly as diiodotyrosine, which is the natural precursor of thyroxin. Only ionized iodine is taken up by the gland (C. P. Leblond and Süe, 1941). Inorganic iodide is not present in the normal thyroid, but is temporarily stored there when large doses of iodide are administered (W. Mann *et al.*, 1942). The fixation is prompt, so that the thyroids contain as much radio-iodide in ten minutes as in ninety minutes after injection (S. Hertz, 1941). Two hours after a single injection the greater part exists as inorganic radio-iodide, but after thirty hours it is found chiefly in the diiodotyrosine fraction (C. P. Leblond *et al.* 1943). Smilar results were obtained by Marine and, Rogoff, 1916. The *elaboration of active iodine compound* was investigated by Marine and Rogoff, 1916. Inorganic iodide was injected into the veins of dogs; the thyroids were excised after various intervals and tested chemically and on tadpoles. The iodine is fixed by the gland within five minutes after injection; but the active compound is not formed for eight hours and is not complete for twenty hours. This is about the time when the histologic involutionary changes start, supporting the view that the iodine elaboration and the involution are connected. The rate of the formation of the active iodine compound varies in different dogs, independent of the total iodine or histologic condition of the gland, of age, sex, and so forth.

The selective fixation of iodine by the thyroid gland is limited. A higher percentage is stored from small than from large doses. Less is taken up by patients previously treated with iodine (S. Hertz, 1941). Saturation occurs in rats with a dosage of 0.5 to 1 mg. per 100 Gm. of body weight, but the normal fixation capacity is recovered in about three days (C. P. Leblond and Süe, 1941).

Hyperplastic thyroid glands collect more than the normal. The accumulation of organic iodine, chiefly diiodotyrosine, is greatly increased by administering pituitary thyrotropic hormone, and becomes very small if the hypophysis is excised (C. P. Leblond, 1944). Stimulation of the thyroid glands by thyrotropic hormone or exclusive cabbage diet leads to larger accumulation; those stimulated by cyanide take up more than normal glands if the iodine dosage is large, less than normal if it is small (S. Hertz *et al.*, 1940). The iodine content can also be increased by the injection of blood of hyperthyroid, and decreased by that of thyroidectomized animals (Jones and Tatum, 1913). Exposure to cold also increases radio-iodide fixation by the thyroid (C. P. Leblond *et al.*, 1943). Rats give similar results (Hunt, 1925).

Fetal thyroid responds to iodine administration, but much less than that of the mother. For rabbits on a low iodine income, the thyroid of the mother at the time of birth contained 0.011 mg. of iodine per 100 Gm., that of the fetus 0.013. With a high iodine income, 100 mg. of KI per day, the content of the mother thyroids rose to 0.127 mg., of the fetal only to 0.026 (G. E. Hudson, 1931).

Perfusion of Thyroid.—Freshly excised thyroid takes up and fixes potassium iodide from the perfusion fluid, presumably in an organic form, so that it cannot be washed out by Ringer's solution. The amount fixed is independent of the iodide concentration of the perfusion fluid, but is larger for hyperplastic than for colloid glands, and is about equal to the amount fixed in the living animal, in the same time (an hour), with intravenous injection. The iodine fixation on perfusion does not occur when the gland becomes disorganized by autolysis; nor does it occur on perfusing other organs than the thyroid (Marine and Feiss, 1915).

Surviving slices of thyroid tissue take up inorganic radio-iodide from Ringer's solution and convert it into diiodotyrosine and thyroxin. This requires intactness of the cells; homogenized tissue is inactive (M. E. Morton and Chaikoff, 1942). Cyanide and sulfide inhibit the conversion completely, and markedly depress the accumulation of inorganic iodide. Sulfanilamide also strongly inhibits the conversion to organic, but not the accumulation of inorganic iodine (H. Schachner, Franklin and Chaikoff, 1944).

Other tissues may produce thyroxin or a physiological equivalent (I. Abelin, 1936); for instance, iodine administration diminishes the weight loss of thyroidectomized rats (A. Chapman, 1941); following injection of radioactive iodide after complete removal of the thyroid, 20 per cent of the liver iodine was interpreted as diiodotyrosine, 8 per cent thyroxin (M. E. Morton *et al.*, 1943). Ordinarily, however, these sources are insignificant in comparison with the thyroid gland (review, Salter, 1940).

Artificially iodized proteins, such as casein and serum albumen, yield compounds, apparently diiodotyrosine and perhaps some thyroxin, which are somewhat effective clinically (J. Muus, Coons and Salter, 1941) and on adpoles (Rogoff and Marine, 1917).

Fate of Thyroxin.—Therapeutic doses of thyroxin appear to be completely utilized; the same total effect is secured on myxedemic metabolism when 10 mg. is given as a single dose, and when it is divided into thirty-three doses of 0.3 mg. (Thompson, McLellan *et al.*, 1933).

When large doses are administered, nearly two-thirds are rapidly excreted especially by the bile (to 60 per cent) and urine (to 8 per cent). About a third is retained in the body for longer periods (Kendall, 1919; Barnes and Chang, 1933). About half of the iodine of intravenously injected thyroxin may be recovered within six hours from the feces (Krayer, 1929). Excess of thyroxin is rapidly destroyed (I. Abelin and Wehren, 1940). No thyroxin can be demonstrated in *normal urine.* Its iodine is almost, if not entirely, in the form of iodide (A. W. Elmer and Scheps, 1934).

Dogs can inactivate much larger amounts of thyroxin (chiefly by extrathyroid mechanisms) than can man, and the thyroxin level of their blood serum is much lower (T. S. Danowski *et al.*, 1946).

The **daily thyroxin requirement**, according to experience of patients with marked myxedema, amounts to about 0.3 mg. (Thompson *et al.*, 1935).

This corresponds to 0.2 mg. of iodine, so that the iodine store of the human thyroid, about 25 mg., would suffice for two to four months, if there were no further income, and if none were resynthetized. A daily iodine income of 1 mg. allows for considerable storage.

The daily production of thyroxin by rats is reported to increase with lowering of the environmental temperature, from 1.7 γ per 100 Gm. of rat at 35°, to 5.2 at 25°, and 9.5 at 1° C. (E. W. Dempsey and Astwood, 1943).

Effects of Thyroxin.—The conspicuous effect of thyroxin consists in acceleration of the basic oxygen metabolism; this is followed by increased pulse rate and by symptoms of heightened nervous irritability, probably as consequences of the accelerated metabolism. Dinitrophenol and a number of other drugs produce a similar metabolic stimulation, but they lack completely the specific relief of the other phenomena of thyroid deficiency, of the lethargy and of defective growth and development (J. D. Robertson, 1933). The thyroxin effects start only a day after the administration, even with intravenous injection, and then continue to increase, reaching their maximum in about ten days, after a single dose; they persist for about three weeks. Continued administration therefore tends to produce cumulative effects. At the height of its action 1 mg. of thyroxin increases the basal metabolism of human adults about 2 per cent, and larger doses, within limits and if properly spaced, approximately in simple proportion, *i. e.*, 10 mg. would result in a 20 to 30 per cent increase (Kendall, 1918, 1919). The results are about equal whether the thyroxin is administered by mouth or by vein. There is little if any immediate effect. After twenty-four to thirty-six hours the pulse rate begins to increase, with some loss of weight and with nervous manifestations. If an excessive dosage is continued, the phenomena of hyperthyroidism become marked by the fifth or sixth day. These are practically important for recognizing overdosage in the therapeutic administration of thyroid preparations. Other effects of thyroxin on mammals appear to be minor. It modifies their susceptibility to certain poisons. It hastens the metamorphosis of tadpoles.

The phenomena of clinical overdosage consist in circulatory, nervous, digestive and metabolic disturbances, resembling those of Graves' disease. *Palpitation;* rapid and often irregular *pulse;* vascular congestions. Head ache and muscle pains; *tremors* of extremities; nervousness; *insomnia;* delirium; *diaphoresis;* irritations of skin; *hyperpyrexia.* Polyphagia, or loss of appetite, nausea, vomiting and *diarrhea.* Sometimes albuminuria and glycosuria. Scotoma has been described (Snydacher, 1911). *Fatal cases* show uncontrollable vomiting, collapse and coma. *Chronic overdosage* leads to emaciation. Cretins are said to be more susceptible to the toxic effects (Basinger, 1916).

Overdosage phenomena in animals are similar to the clinical effects, but the resistance varies greatly in different animals, carnivores being less susceptible. The most constant features are emaciation, gastro-enteritis and diarrhea; but no tachycardia, nervousness or exophthalmos. Death may occur with convulsant or depressant symptoms (Carlson, Rooks and McKie, 1912). With rabbits, fatal doses lead to extreme emaciation with hepatic necrosis (Gerlei, 1933). Hypertrophic thyroid is less toxic than normal, in accordance with its lower iodine content (Stoland, 1912). The effects of thyroxin are produced so slowly that a single massive injection is generally almost inactive; whereas the same dose may be fatal when divided over a number of days (Kendall, 1919). The *duration of action* has been measured by the deferment of thyroid hyperplasia in rats previously depleted by thiouracil. A single dose of 10 to 100 micrograms of thyroxin acted for three days; 1 mg. of thyroxin and 500 mg. of dried thyroid, by mouth, lasted for six days; 50 mg. of thyroxin intraperitoneally acted for thirty days (A. M. Hughes, 1945).

Gudernatsch, 1915, found that small doses of thyroid fed to rats tend to prevent *conception.* If pregnancy occurs, the young either abort or die early or grow less than normal. The detrimental results are the same whether the feeding has been to the mother or father alone.

Environmental Temperature.—The toxicity of thyroid is much greater at 33° C. than at ordinary room temperature (Draize and Tatum, 1931); the loss of body weight with small doses is also greater, and gastric ulcers develop frequently in guinea pigs (L. H. Schmidt and Schmidt, 1938). As the basal metabolism is normally lowest at this temperature, Rubner, Draize and Tatum suggest that this slows the oxidative destruction of the thyroxin. They found accordingly that the toxicity at this temperature was decreased by convulsants and stimulants which would further increase oxidation, and increased by sedatives which decrease oxidation. Guinea pigs react to daily hypodermic injections of 0.3 mg. of thyroxin with *hyperpyrexia* and increased CO_2 excretion. These effects are more marked if the animals are placed in a room at 35° C., or if they have been treated with tetrahydronaphthylamine or with peptone. Quinine has no effect; phenobarbital is antagonistic (Okumura, 1939).

Hyperthyroidism increases the *vitamin requirement* for A, B and C, and for pantothenic acid and pyridoxine. Vitamin deficiencies develop if their income is not increased. Deficiency of *vitamin A* leads to thyroid hypertrophy; excessive income probably diminishes the thyroid colloid. Administration of cod liver oil delays the metamorphosis of tadpoles; absence of the thyroid prevents the change of carotene to vitamin A. Administration of thyroid increases the consumption of *thiamine*. Administration of thiamine diminishes the loss of weight from thyroid administration, increases the pulse rate and temperature. The blood level of *pyruvic acid* is high in thyrotoxic patients. Deficiency of *ascorbic acid* produces thyroid hyperplasia (review, V. A. Drill, 1943).

Detoxification by Metals.—Administration of copper, 0.4 mg. per Kg., in any form, protects dogs and other animals against doses of thyroid which would otherwise be fatal in three to seven weeks. Iron is also quite effective; zinc, manganese and magnesium are much less so (Hesse *et al.*, 1933).

Increased metabolism is the most constant effect of thyroid administration. It occurs in normal animals, but is much more marked in the low metabolism of thyroid deficiency (DuBois, 1914). The heat production in Basedow's disease is also much above the normal. The metabolic effects of thyroid administration are shown by increased oxidation, increased consumption of oxygen and production of carbon dioxide, and increased excretion of nitrogen, with improvement of appetite and loss of weight (Leichtenstern, 1893). The first effect is on carbohydrates, then on fat, the proteins being drawn upon when the fat has been reduced to a certain minimum. Beginning after a latent period of twelve hours or more after administration is started, the heat production rises slowly; when the dosage is stopped, it declines as a logarithmic curve. From the latter, it may be estimated that thyroxin is destroyed in the body at the rate of 0.2 to 0.4 mg. per day (Plummer and Boothby, 1920). The increase of oxygen consumption may be used for the *assay* of thyroid preparations (Shackell, 1937). The increased need of oxygen renders thyroid-fed animals more susceptible to oxygen deficiency (Asher), and to the toxicity of drugs which increase the use of oxygen, such as dinitrophenol (Glaubach and Pick, 1934).

Thyroxin is necessary for the development of the *specific dynamic action* of foods, but the energy of the calorigenic action of thyroxin cannot be utilized in *muscular work* (Plummer and Boothby; Canzanelli *et al.*, 1934). *Hibernating animals* are awakened and kept awake by the administration of thyroxin (L. Adler, 1920; Schenk, 1922). *Dinitrophenol* also increases oxidative metabolism, but does not produce clinical improvement in myxedema. The time curve differs greatly from that of tyroxin, the metabolic rate reaching a maximum in two hours, in contrast with the three to ten days required with thyroxin. Its effects are not greater in thyroid deficiency, as are those of thyroxin.

The *site of the metabolic action* is not clear. It involves a peripheral effect, for oxygen consumption is abnormally high in excised tissues of thyroid-poisoned animals, or if the blood of such animals is added to liver tissue *in vitro;* not if thyroxin is added directly; but thyroglobulin is reported to be effective (Rapport, 1937; Craig and Salter, 1945). There is some evidence of a central action, probably on the *midbrain*, for the effect is much greater by cisternal than by hypodermic injection and much less in deep narcosis and in various brain lesions (von Issekutz *et al.*, 1937; Glaubach and Pick, 1935).

Carbohydrates.—It is doubtful whether the increased metabolism of carbohydrates is due chiefly to stimulation of oxidation, or whether it is an indirect result perhaps of increased *mobilization of liver glycogen* (Cramer and McCall). The glycogen store of the liver may disappear completely, even with food rich in carbohydrate, and without glycosuria. The glycogen of muscle disappears only if food is restricted (Bosl, 1928). There is evidence that excess of thyroxin causes severe degeneration of the liver in rabbits (Gerlei, 1933); the biliary elimination of injected sodium cholate is decreased (L. H. Schmidt, 1937), and Basedow patients often show more or less liver injury. It is claimed that thyroidectomized animals do not utilize sugar on parenteral administration as well as normal animals (Underhill and Saiki, 1908), and that they do not react with glycosuria to some of the procedures which are ordinarily effective (King, 1909). Cramer and McCall, 1918, found in rats that total removal of the thyroids and parathyroids does not impair the power of the cells to oxidize carbohydrates (as judged by the respiratory quotient).

The *increased oxygen consumption in excised tissues, muscle and glands* from animals to which large doses of thyroid had been administered seems to involve especially the anaerobic metabolism and is inhibited by cyanide (Rohrer, 1924; v. Euler and Enderlein, 1935; McEachern, 1935). It does not occur with cold-blooded animals, or not to the same degree (Drexler and v. Issekutz, 1935).

The **nitrogen excretion** is increased about 50 per cent in a five to seven day period (Rohde and Stockholm, 1919). Jamey and Isaacson, 1918, found the ratio of urea and ammonia to total nitrogen unchanged by administration of thyroxin. *Creatinine* excretion was unaffected, even when there was extensive tissue destruction. *Purine* excretion was diminished after excision and in cretins; increased after thyroxin and in Basedow's disease.

The urine volume and the water intake are materially increased in experimental hyperthyroidism. Fresh water intake is excreted more readily, protecting against water intoxication. The chloride of the excess urine is low. The protective action is largely abolished when the adrenals are excised (R. Gaunt, 1944). Clearance studies indicate that thyroid administration increases glomerular filtration in normal animals and in experimental diabetes insipidus; but the increase of urine output is as much as forty times greater in the operated animals, suggesting that hyperthyroidism renders the antidiuretic hormone less effective (K. Hare *et al.*, 1944).

Calcium Metabolism.—Administration of thyroxin increases the excretion of Ca and Mg (Auby, Bauer *et al.*, 1929) and lowers the plasma Ca level. The latter is increased in thyroid deficiency. Thyroid administration is reported to increase the proliferation and differentiation of retarded ossification (Silberberg and Silberberg, 1929), to accelerate bone calcification rate in young animals and to aid callus formation. The toxicity of *chronic fluoride administration* is increased by feeding thyroid, and conversely (Phillips, English and Hart, 1935). Further details of the thyroid and fluoride relation are discussed under Fluoride (see Index).

Use in Obesity.—Thyroid administration is often strikingly effective in reducing the fat in constitutional obesity (menopause, and so forth), much less so in superalimentation. The result is not permanent and is complicated by the sometimes dangerous effects described under overdosage. Only small doses should be used, under strict medical supervision. The protein income should be kept high to compensate the loss (v. Noorden, 1915).

Other Therapeutic Uses.—Thyroid has been tried in psoriasis, eczema, lupus, chronic rheumatism, gout, arteriosclerosis, rickets, infantile cachexias and hemophilia, but the inconstant results indicate that it is probably useless. Thyroxin administration increases hair growth in underfed rats (E. O. Butcher, 1940). It hastened somewhat the healing of wounds; dinitrophenol had a similar effect (T. H. Barclay *et al.*, 1944).

Larval Growth and Development.—Gudernatsch, 1912, observed that feeding of thyroid to tadpoles checks their growth, but at the same time hastens their development into frogs. This is a delicate test for thyroxin (Marine and Rogoff, 1916). The metamorphosis of axolotl and amblystoma is even more sensitive (B. M. Zawadowsky and Perlmutter).

This effect may be used for the *standardization of thyroid preparations* (Rogoff, 1917; Hunt, 1925). The susceptibility to the acceleration increases with the age of the tadpoles (Alphonse and Baumann, 1935; R. Geigy, 1944). It is also increased by exposure to x-rays (McCord and Marinus, 1918). It is antagonized by several ethers of N-acetyliodotyrosine (D. W. Woolley, 1946).

Other Thyroid Constituents and Iodized Products Tested by Tadpole Method.—Morse, 1914, found that the nucleoproteins, lipoids, and so on, of the thyroid are ineffective. Positive results are produced by iodothyrin, iodated tyrosine, iodized Witte's peptone and iodized serum proteins; not by inorganic iodine or iodides, iodized starch, iodized lecithin, or marine algae. The inefficiency of inorganic iodides, however, seems to be only quantitative, for their administration starts the metamorphosis of thyroidectomized tadpoles, which does not take place without this stimulus (Swingle, 1919). Allen, 1919, also observed that this does not occur if either the pituitary or thyroid is removed, but that it occurs in the absence of both glands if iodine is administered. The feeding of *other gland tissues*, yeast and foods in general influence the growth and somewhat the metamorphosis of tadpoles; but their effects are of different magnitude from those typical for thyroid feeding (Rogoff and Rosenberg, 1922). Feeding with *thymus* greatly delays the metamorphosis (Gudernatsch).

Acetylthyroxin accelerates the *development of newborn rats*, the differentiation of the skull, and so forth, but not the growth (Hoskins, 1927).

Protozoa.—The presence of thyroid tissue increases markedly the multiplication of paramecium (Nowikoff and Shumway; Budington, 1915).

Plant Growth.—Thyroid, when added to the culture medium, produces remarkable retardation of the root growth of onion bulbs. This effect is not produced by potassium iodide, nor by pituitary or suprarenal (Budington, 1919).

Susceptibility of Poisons.—The metabolic disturbances alter the destruction of poisons in the body. In mice, *f. i.*, the toxicity of acetonitrile is greatly diminished, while that of morphine is increased. The toxicity of thyroxin itself is greatly influenced by the diet (W. Kornfeld and Nobel, 1928).

Acetonitrile Test.—Hunt (1905, 1907, 1908) found that the administration of thyroid to white mice, for a few days, markedly increases their resistance to acetonitrile. The toxic effects of the latter are due to the liberation of HCN. Thyroid feeding does not affect the toxicity of HCN when administered as such, so that its protective influence must be due to a retardation of the metabolic processes which convert acetonitrile into HCN. In rats and guinea pigs it has the opposite effect, increasing the toxicity of the nitriles. The acetonitrile response is a nearly specific test by which 1 mg. of active thyroid tissue can be detected. Thyroid in which no iodine can be detected by the ordinary chemical tests, as well as certain other organs, show a very feeble activity (Hunt and Seidell, 1908). Trendelenburg, 1910, and Lussky, 1912, reported that the blood of cats gives the test even after removal of the thyroids. Application of the test to the blood of Basedow's disease has not given conclusive results. Certain *diets*, dextrose, oatmeal, liver or kidney, also increase the resistance of the mice to the nitrile, as compared with cracker, milk, cheese or egg diet. This seems to be due to an action on the thyroid, for the difference is diminished if the thyroids are excised; and these glands present anatomic changes (Hunt, 1910, 1911). *Other iodine compounds* have some protective action, presumably by being converted into the thyroid compound. None reach the same activity, but they present interesting differences. The iodine of the seaweed, bladderwrack, is about one hundred times as active as the iodine of potassium iodide (Hunt and Seidell, 1910).

Cyanide metabolism has complex relations with thyroid function. If acetonitrile is fed to normal rabbits, 25 per cent or more of its CN is excreted in the urine as SCN;

but only 3 to 5 per cent with animals whose thyroid has been removed. This also decreases the conversion of potassium cyanide into thiocyanate, but only temporarily (E. J. Baumann, Sprinson and Marine, 1933). Acetonitrile materially augments the goiterogenic action of cabbage and of alfalfa hay for rabbits, and this is prevented by feeding traces of iodine (Marine, 1935).

Acetylation of sulfanilamide is decreased by thyroid administration and hyperthyroidism, and increased by thiouracil (J. Fraenkel-Conrad and Greenberg, 1946).

Synergism with Amino Acids.—Kendall, 1916, 1917, found that thyroxin alone produces symptoms analogous to those of exophthalmic goiter, but has no direct effect on the pulse rate, even on intravenous injection. If, however, amino acids are injected at the same time, there are marked disturbances of the pulse rate and of metabolism, which may be fatal.

The *methylation of guanidineacetic acid to creatine* is prevented in rabbits by removal of the thyroid glands, and restored by administering iodine (Stuber, Russmann and Pröbsting, 1923).

Resistance to Morphine Alkaloids.—Thyroxin administered to mice, rats and guinea pigs lowers their resistance to morphine (Hunt). With mice this holds also for heroin, but not for codeine and thebaine (Anan, 1929). The phenomenon probably involves the oxidation of the side chains. The morphine sedation tends to protect rats against the increased oxygen demand of thyroxin, so that it renders thyroid-poisoned rats more resistant to oxygen deprivation (Asher *et al.*). *Clinically, myxedemic patients and cretins are oversusceptible to morphine* (Lund and Benedict, 1929), presumably by the summation of the two lethargies.

Quickening of the heart rate is a constant symptom of experimental hyperthyroidism and of Basedow's disease. With thyroid-poisoned rabbits the acceleration persists when the heart is excised and perfused, and in auricular segments, which beat some 50 per cent faster than normal heart preparations. The acceleration therefore is directly cardiac (Andrus, 1932). The excised heart of normal rabbits, however, is not affected by the direct addition of thyroxin; but this does increase the response to epinephrine (Asher *et al.*, 1916). The response of the intact thyrotoxic heart to epinephrine and to mecholyl is much greater than normal (B. Wise and Hoff, 1938).

The change of heart rate is *not due to change of metabolic rate*, for while thyroxin administration quickens the heart of thyroidectomized rats, dinitrophenol fails to do so. Diiodotyrosine also lacks this effect (C. P. Leblond and Hoff, 1944).

The *direct effects on the circulation* vary, and are probably indirect, owing to increased excitability of the sympathetic and parasympathetic nerves (Oswald, 1915). Intravenous injection of thyroid extracts usually produces fall of blood pressure and slowing of the heart, probably owing to its choline content (Fuerth, 1909; Schoenborn, 1909). The response of the heart to *vagus stimulation* is not affected by thyroid (R. L. Levy, 1918). Complete excision of the thyroid-parathyroid apparatus lowers the vagus excitability (Coronedi, 1913).

Thyroidectomy in Congestive Heart Failure.—Lowering of the metabolism decreases materially the demand on the heart, and total thyroidectomy results in marked and lasting improvement in a number of cases. With partial ablation, the improvement is only temporary. The operation is a last resort in angina pectoris, especially when other therapy has failed (Blumgart and associates, 1933). It generally results in temporary parathyroid tetany and sometimes in excessive thyroid deficiency symptoms, which must be treated in the usual manner; the thyroid deficiency by minimal doses, 8 to 15 mg., of dried thyroid daily (Means, 1934).

Secretion of cerebrospinal fluid is said to be inhibited by thyroid and increased by brain extract, independent of blood pressure changes. Other organ extracts act only mechanically, through the circulation (Frazier and Peet, 1915). *Bile secretion* is not affected by thyroid administration (Downs and Eddy, 1919).

Sensitization to Autonomic Stimulation.—Injection of thyroid does not produce any characteristic autonomic stimulation directly, but it increases the response to epinephrine, splanchnic and depressor stimulation (Blau and McNamara, 1930); also after removal of the adrenal glands (Bergwall and Kuschinsky, 1931). Thyroid administration likewise increases the depressant action of histamine (Oswald, 1915). Conversely, removal of the thyroid gland diminishes the sympathetic response to epinephrine and greatly increases parasympathetic irritability, *f. i.*, to choline; feeding of thyroid restores the responses to normal (Schliephake, 1928). Patients with Basedow's disease sometimes give alarming reactions to epinephrine. This, however, may involve mechanisms other than the peripheral autonomic sensitization.

The peripheral sensitization to epinephrine is situated at the receptive mechanism (Asher, 1916). The symptoms of *cocaine* poisoning resemble those of "hyperthyroidism," since both involve sympathetic stimulation. There is no causal connection. Oft-repeated injections of cocaine do not produce any histologic changes in the thyroid (Mills, 1919). The *motility of the gastro-intestinal tract* is increased by thyroxin administration, and the hunger contractions become stronger (Fetter, Barrow and Carlson, 1932).

The **anterior pituitary interrelation** appears to be the mechanism for the adjustment of the thyroid function to the regulation of the oxygen metabolism to physiological needs. The anterior pituitary thyrotropic hormone is the only agency known to stimulate the thyroid acini directly to increased production of thyroxin; and conversely, thyroid deficiency stimulates the anterior pituitary to the production of more thyrotropic hormone, to compensate for the deficiency (reviews, Loeser and Thompson, 1934; Marine, 1935).

Excision of the thyroids leads to hypertrophy of the anterior pituitary (Rogowitsch, 1889), especially in young animals. The most striking change is the disappearance of the eosinophilic granules from the oxyphile cells. Conversely, *removal of the hypophysis* leads to involution of the thyroid (Smith), with a colloid type of goiter. This is restored by the injection of anterior pituitary extracts, but not by the administration of iodine, indicating that thyroxin is not synthesized in the absence of the thyrotropic hormone (Loeser and Thompson, 1934). In normal animals, *injection of the thyrotropic hormone* which has been separated from the growth and sex hormones, results within twelve to twenty-four hours in congestion of the thyroid and hyperplasia with diminishing colloid, decrease of the thyroid iodine store, increase of the blood iodine, increased excretion of calcium and creatine and the phenomena of hyperthyroidism or rather Basedow's disease, including exophthalmos. Daily hypodermic injection doubles the thyroid weight of guinea pigs in three to six days. If the hormone injection is stopped, the histologic and functional picture returns to normal. The phenomena do not occur after removal of the thyroid (L. Loeb *et al.*, 1931; S. Hertz and Roberts, 1941). The response of the thyroid to thyrotropic hormone decreases with continued administration. Collip and Anderson, 1935, attributed this to the production of an *antithyroid hormone*, which inhibits the formation of thyroxin. The response to thyroxin is not impaired.

Thyroid interrelations with gonadal functions are indicated by the goiter tendency at puberty and in pregnancy and estrus. They are presumably mediated through the anterior pituitary (Marine, 1935). Thyroxin administration to lactating animals increases the yield of milk and its fat content; but the thyroid is not essential to initiation of lactation (references, W. E. Petersen, 1944). Thyroxin interferes with the action of estrogen in pigeons as to increase of plasma Ca, P and lipid, but not as to endosteal bone and oviduct growth (M. R. McDonald *et al.*, 1945). Its administration to aged fowl produces apparent *rejuvenation* with increased egg production (Crea, 1924; C. W. Turner). It is also reported to increase the fertility of old rams (cited by S. Brody, 1946). Excision of the thyroid of hens causes marked decrease of *egg production*, which is largely restored if thyroxin is administered (C. F. Winchester). *Plumage changes* are characteristic: The administration of thyroxin to chickens causes changes in the feather-forming cells, leading to the accumulation of dark pigment in the portion of the feathers formed during this period (L. J. Cole and Reid, 1924). A single hypodermic injection produces the effects in the feathers of a plucked breast area in roosters, perceptible in a day and lasting five days. The response is quantitatively proportional to the dose and may be used for assay. It is not given by other iodine derivatives, nor by sex hormones and other organ extracts (Juhn and Barnes). Other effects of thyroid administration are described by Zawadowsky and Titajev, 1928; J. H. Martin, 1929; and Hutt, 1930.

Innervation of Thyroid.—The gland is supplied with nonmedullated fibers, probably derived from the cervical sympathetic, and going to the cells as well as to the blood vessels. An action current develops in the gland on stimulation of the sympathetic, high in the thorax, even when the superior and recurrent laryngeals have been cut. Vagus stimulation or pilocarpine does not generate the action current (Cannon and Cattell, 1916). On the other hand, autografts of thyroid show evidence of growth and function, so that the nervous connections are not indispensable (Manley and Marine, 1916).

Epinephrine on Thyroid Secretion.—Injection of epinephrine, 0.001 to 0.002 mg., evokes an action current in the thyroid. The same result follows stimulation of the cut splanchnic, but it is absent if the adrenal blood is prevented from reaching the circulation (Cannon and Cattell, 1916). *Thyroxin injection* was reported to increase the secretion of epinephrine after twenty to forty-five minutes (Zunz and La Barre, 1932)

Thyrotoxicosis.—The phenomena of Basedow's disease bear a striking resemblance to those of overdosage with thyroxin, particularly the increased metabolic rate and the hypersusceptibility to sympathetic stimulants. The symptoms are promptly controlled by partial or complete excision of the gland, or by administering *thiouracil*, thiourea, or related sulfur-containing chemicals (see Index). The thyroid is commonly enlarged, but the structural changes need not be great and do not differ from those of nontoxic goiters (Marine, 1911). The change is therefore functional, presumably by overstimulation through anterior pituitary thyrotropic hormone, in response to some unidentified factor, perhaps related to the sex glands (but not estrogenic hormone) or to the adrenal cortex. This may occur when the iodine income appears ample. Administration of iodine in any form decreases the phenomena, however, at least temporarily, perhaps by checking the excessive drive for thyrotropic hormone. Simple iodine deficiency probably also increases the production of pituitary thyrotropic hormone, and results in thyroid hyperplasia; but the toxic factor is lacking, presumably because the drive is not so intensive. The output of thyroxin is limited to the available iodine.

Increased Metabolism in Basedow's Disease.—Heat production is 50 per cent above the normal in severe, and 75 per cent in very severe cases. The excessive heat production accounts largely for the tachycardia, cardiac enlargement, emaciation and mental irritability. Rest in bed for a week diminishes the excessive heat production by 10 per cent or more; psychotherapy was also of some value. The high metabolism means that the patients need one and one-half to two times as much food as normal individuals (Means and Aub, 1919).

The *exophthalmos* is not due to thyroxin, for it can be produced more easily after excision of the thyroid (Marine and Rosen, 1934), by administering thyrotropic hormone (E. Shorr, 1944). It involves swelling of the extraglobular contents of the orbit, including the extrinsic muscles (J. H. Means, 1944).

The *iodine metabolism in Basedow's disease* presents some quantitative anomalies. The thyroid glands are poor in organic iodine. The *negative balance* on low iodine income is two or three times greater than in normal individuals, and on administering iodine, the positive balance is correspondingly greater than normal. The *iodine level of the plasma* is 0.009 mg. per 100 cc., over twice the normal. The increase is chiefly organically combined, presumably thyroxin. The urine and feces are also richer in iodine. After partial excision of the gland, or with successful medical treatment, the abnormalities return to normal (Puppel and Curtis, 1938).

Iodine Therapy of Toxic Goiter.—The continued administration of moderately large doses of iodine or iodide produces marked and specific amelioration of all the symptoms (Plummer, 1923). The beneficial effects increase progressively for ten to twenty days. The nervous tension relaxes, the sleep and appetite improve, the tachycardia is markedly slowed, the excessive metabolic rate is diminished by 25 to 30 per cent and the patient gains in weight and strength. This amelioration is a cardinal feature of Basedow's disease and is practically pathognomonic for diagnosis, prognosis, and treatment. The more severe the "toxic" symptoms, the greater is the improvement under the iodine. The improvement does not arrest the progress of the disease, but merely keeps it at a lower level, and after some weeks the metabolism tends again to rise and the symptoms to return gradually even if the iodine is continued. If the administration is stopped, the condition relapses in a week or two to the state which it would have reached without the iodine. The method is therefore used mainly to prepare patients for surgical treatment: the sedative effect diminishes the surgical risk, especially by protecting the patients against a critical reaction to the fear and excitement of the operation and to the postoperative discomfort. The convalescence is also shortened (Means and Lerman, 1935). All forms of iodine are effective, and sodium iodide is as good as any. Even the administration of dried thyroid (2 grains per day) lowers the metabolic rate of toxic patients (Rice and Cavett, 1934, by depressing the response of the thyroid to thyrotropic hormone (R. Cortell and Rawson, 1944). The mechanism of the action of iodine is not clear; the most plausible explanation is that the iodine diminishes the overproduction of thyrotropic hormone.

The administration of iodine in toxic goiter had been suggested by Marine, 1911, because the structure of the gland in many cases suggested iodine deficiency. He advised, however, that this should be practiced cautiously, lest it lead to an overproduction of thyroxin by the hyperplastic glands, before involution had set in. This fear prevented adequate clinical trials of the suggestion until it was reintroduced in a modified form by Plummer, 1923.

In experimental Basedow disease, produced in guinea pigs by the injection of an alkaline extract of anterior pituitary, the high metabolic rate was decreased and death prevented by the administration of sodium iodide (Friedgood, 1935; Trikojus, 1939). The *thyrotropic hormone* in the anterior pituitary gland of normal animals was reported diminished by small, and increased by large, doses of iodide (Loeser, 1934).

Dosage.—Potassium or sodium iodide is administered for one to three weeks before and for a week or two after the operation. They are usually prescribed as a saturated solution, 5 to 10 minims once daily, equivalent to 0.25-0.5 Gm.; but 9 to 15 mg. suffice (E. Shorr, 1944). Other preparations and complicated technics have no advantage (Means, review, 1935).

Plummer originally employed 0.5 cc. of Lugol's solution in milk, one to three times daily. W. O. Thompson, Brailey *et al.*, 1930, showed that 6 mg. of iodine per day suffice to produce the maximal reduction of basal metabolism in Basedow patients; smaller doses caused proportionately less reduction.

Toxic effects from iodide administration, by the provocation of toxic hyperthyroidism, have been claimed for various forms of goiter, especially adenomatous (Boothby and Rowntree, 1923; Oswald, 1915). The evidence is not convincing. Administration of iodine does not produce hyperthyroidism, even when the plasma level of iodine is raised to 7 mg. per 100 cc., about six hundred times the normal level (Curtis, 1935). However, severe acute iodism, sometimes febrile, may occur with large doses of iodine, and may or may not recur with subsequent administrations (W. H. Barker and Wood, 1940).

Radioactive iodine is being tried as a means of selective introduction of destructive radioactivity into the thyroid gland. Oral administration of a single dose of sodium iodide to thyrotoxic patients has produced permanent remission, without other effects. It is most effective if the accumulation is not hampered by preceding iodine mediation. The advantages and dangers are not yet sufficiently known (S. Hertz and Roberts, 1946; E. M. Chapman and Evans, 1946).

Thyroid Deficiency.—The results of excision of the thyroid gland are essentially the opposite to those of hyperthyroidism; *i. e.*, they consist in diminution of the basal metabolism and sluggishness of the nervous processes. When the parathyroids are also removed, these phenomena are complicated by parathyroid tetany. Continued thyroid deficiency, when occurring in adults, results in *myxedema*, with conspicuous skin changes and nervous disturbances ending in mental deterioration. Congenital deficiency produces the condition of *cretinism*, stunted physical development and idiocy.

Complete excision of the thyroid apparatus causes a series of effects, motor, nervous and metabolic (cachexia strumipriva), which are more or less rapidly fatal for most animals, especially for carnivora. If the parathyroids are spared, the motor symptoms and the fatality are much less, and the metabolic disturbance runs a more chronic course. These phenomena were first described by Schiff, 1856. The *lowered heat production* of thyroid deficiency was first shown clinically by Magnus-Levy, 1895. In most mammals the fall begins on the fifth to seventh day after the excision. In rabbits it reaches its minimum (30 to 40 per cent) between the twentieth and thirtieth days, in man about the sixtieth day. This minimum level may then be maintained for years. Such animals have a low basal metabolism with high respiratory quotient. They are hypersusceptible to oxygen deficiency (Hildebrandt, 1922). If fragments or accessory thyroids are left, the condition may gradually return toward normal. The *cutaneous myxedema* which develops in adults is due chiefly to intracellular fluid.

Thyroidectomy for the treatment of congestive heart failure was introduced on the basis that the slowed metabolic rate diminishes the demands on the circulation, especially in angina when other measures have failed. The majority appear to be more or less improved, but only if the excision is complete. The parathyroids are generally also removed. The tetany is usually transient, but the myxedematous changes progress, requiring constant treatment with thyroxin, keeping the dosage below normal (review, Parsons and Parks, 1937).

Experimental Cretinism.—Complete thyroidectomy in young animals is followed by typical cretin phenomena, such as dry, rough hair, retarded growth, skin changes, and so forth (Basinger, 1916). The long bones grow more slowly and stop before they reach the normal length. The nervous and skeletal systems are relatively large, the viscera small, in proportion to the total body weight (Hammet, 1929).

Therapeutic Results of Thyroid Feeding.—The deficiency symptoms are completely relieved in adults by the administration of thyroid or thyroxin by mouth (Howitz, Mackenzie, Fox, 1892), as well as by intravenous injection (Colzi, 1884), of thyroid extracts, or by implantation of thyroid tissue (Schiff, 1884). In cretins, the improvement depends on the age when the treatment is begun, and on the intensity and persistence of the treatment. Most cretin children remain more or less retarded, mentally and physically, but many are at least improved (A. W. Brown *et al.*, 1939). The *administration* must be practically continuous and the dosage must be carefully adjusted to avoid toxic effects. It is sufficiently attained by the oral administration of the dried gland. This may be taken as tablets or in capsules. The proper *dosage* must be determined by trial. In *myxedemic adult patients*, the daily ration should be the minimum that keeps the patient free from symptoms. For this it is rarely necessary to raise the metabolic level above minus 20, which is attained with 60 to 180 mg. (1 to 3 grains) of dried thyroid or 0.2 to 0.4 mg. of thyroxin once daily, and sometimes with less. The dosage may be lower in summer than in winter. The response is striking; in a few days the patient feels warmer and less sleepy, the muscular movements and speech are faster, the sensorium is more alert, the cutaneous edema disappears, with diuresis and desquamation of the skin, the hair texture returns and in two weeks the patient becomes practically normal (Means, 1934). The first warnings of overdosage are sometimes myalgia and anginal attacks, but patients with thyroid deficiency tolerate larger doses than normal subjects. The *treatment of cretins* requires relatively large doses to permit normal growth. Unless this is started within the first two years of life, the stunting of the mental and bodily growth cannot be completely repaired, and in older cretinous imbeciles the results are often disappointing.

Isolated thyroxin does not have sufficient advantage for oral administration over the standarized U.S.P. dried thyroid to offset its much higher cost, except for scientific investigation. Orally or intravenously, 1 mg. of thyroxin is therapeutically equivalent to 0.2 Gm. of desiccated thyroid. Its dosage is 0.2 to 2 mg. daily, starting with the minimal doses and increasing if necessary as judged by the basal metabolic rate. High grade cretins require 1.5 to 2 mg. daily. Crystalline thyroxin, natural or synthetic, may be given *intravenously* in the occasional emergencies when it is not absorbed orally. It is dissolved by careful addition of alkali. *Synthetic Thyroxin Solution* is marketed in ampuls of 1 cc. containing 1 mg.

Thyroxin Requirements.—Means and Aub, 1919, found that the basal metabolism in hypothyroidism is restored to normal by daily doses starting with 0.2 to 0.25 Gm. (3 to 4 grains) of the dried gland, and later 0.05 to 0.1 Gm. (1 to 2 grains). According to Plummer and Boothby, 1920, the total need of the body for thyroxin lies between 0.2 and 0.4 mg. per day, as calculated from the "decay curve," which would be supplied by 0.065 to 0.15 Gm. of the U.S.P. thyroid powder. With synthetic (racemic) *thyroxin*, H. Baur, 1928, found that toxic symptoms resulted from 3 to 4 mg. per day for some weeks; but 1 to 2 mg. per day for a limited period increased the basal metabolism of normal individuals by 140 per cent, without toxic effects. There was also marked increase of water elimination. Individuals with high basal metabolism showed a relatively smaller increase, 10 to 37 per cent.

Differences in commercial thyroid preparations may exist even when the total organic iodine content is similar, since only the thyroxin part of this is active. Practically, however, they do not appear very significant.

Lerman and Salter, 1934, found the total organic iodine of six preparations to range from 0.22 to 0.40 per cent of the dried thyroid, and 16 to 42 per cent of this iodine was thyroxin. However, the calorigenic effect on myxedema patients was in reasonably close agreement.

PREPARATIONS.—*Thyroid, U.S.P. (Thyroideum), is the dried and powdered healthy thyroid glands of domestic animals used for food, containing about 0.2 per cent iodine in thyroid combination. One part of the dried corresponds approximately to five parts of the fresh gland. Dose, 60 mg., 1 grain. It is usually administered as *Thyroid Tablets*, U.S.P., containing 15, 30, 60 or 120 mg.; ¼, ½, 1 or 2 grains. Raw or broiled glands (⅛ to ⅓ gland) have also been used, but have no advantage. *Thyroxin*, U.S.P., prepared from glands or synthetically, contains not less than 64 per cent of iodine. White needle-like crystals or powder, insoluble in water, soluble in alkalis. Average dose, 0.5 mg., 1/120 grain.

GOITER PROPHYLAXIS

Endemic Goiter.—In regions distant from the sea and from other deposits of iodine, the income of iodine through food and drink is limited and tends to become inadequate when the demands for thyroid secretion are high, especially in adolescent girls. This leads to excessive proliferation of the thyroid epithelium, perhaps through futile efforts to compensate for the iodine deficiency. This hyperplasia is the first stage of "*endemic goiter.*" If the excessive demand ceases, or if the deficiency is met by the administration of an iodine compound, the hyperplasia stops, the acini become filled with colloid, and the goiter changes to the resting, relatively harmless but deforming "colloid" type. Repetition of the iodine deficiency causes this to revert again to the hyperplastic type, which may again become more colloid, and so on (Marine, 1907 to 1913; review, 1935). The hyperplasia indicates increased activity of the thyroid gland, but not necessarily increased production of thyroxin; indeed, myxedema and cretinoid states may occur in the presence of hyperplasia.

Thyroid hyperplasia is characterized by increased blood supply, decreased colloid and iodine content of the acini, change of the follicular epithelium from low cuboid to columnar, mitoses, infoldings and formation of new follicles. *Transplanted thyroid tissue* reacts in the same manner, by hyperplasia or involution, to removal of thyroid tissue or to iodine; so that the changes are evidently independent of the nerve supply (Manley and Marine, 1915). If the hypertrophy is inadequate to meet the demands, the acini may finally *atrophy*. This occurs also if the anterior pituitary is removed, and in Gull's disease. Thyroid function and structure may then be restored by the injection of thyrotropic hormone.

The *etiology of the hyperplasia* may be conceived as a compensatory hypertrophy initiated through the anterior pituitary thyrotropic hormone in response to the demand of the organism for a larger supply of thyroid secretion. It may be produced experimentally by injection of the hormone, by removal of a part of the thyroid gland, by certain diets and by deficiency of iodine income. It may occur in any locality, but is much more frequent in certain regions (*endemic goiter*). It is most likely to develop clinically during fetal life; at puberty, especially in girls of ten to sixteen years; in pregnancy and lactation; and at the decline of sexual life. Its *geographical distribution* appears in relation to glacial formation, perhaps through leaching of the soluble minerals. It has been blamed especially on the water supply, since Pliny. The most important factor seems to be low iodine content, then high calcium content. The food raised in such regions is also poor in iodine. In some goiter regions, however, the iodine of the food and water is not below normal, and the iodine excretion by urine is abundant (L. Scheffer, 1932). The *iodine factor* will be further discussed below. Other agents that tend to induce goiters are calcium salts, cabbage and cyanides.

The *calcium factor* is not understood. With constant iodine income, increase of calcium income results in thyroid enlargement (J. Thompson, 1933); hyperplastic if the iodine income is low, colloidal if it is high (Hellwig, 1935). The response to thyroxin is decreased (Abelin, 1928). Calcium also retards the acceleration of tadpole metamorphosis by thyroxin (Zondek and Reiter, 1933).

The *calcium balance* in its turn is altered by the thyroid. Calcium excretion is increased in Basedow patients and diminished in myxedema (Aub). Hyperplasia by cabbage diet leads to calcium retention, which is removed by administering iodide. Phosphate and magnesium parallel the calcium; K, Cl and N are not changed.

Dietary thyroid hyperplasia is produced in dogs by fresh *meat* (Baumann, 1896), especially *liver* (Marine and Lenhart); by fats (McCarrison, Mellanby); and in rabbits by *cabbage* (Chesney *et al.*, 1928; F. Blum, 1942). *Inanition* causes involution of the thyroid (E. J. Baumann and Hunt, 1925).

Cyanide Relation.—The effects of *cabbage* and other cruciferous plants are due to the presence of nitriles. Other nitriles, especially acetonitrile, and inorganic cyanides also produce thyroid hyperplasia and exophthalmos, if the dosage is properly adjusted. It is conceivable that the thyroid stimulation is an attempt to overcome the cyanide depression of oxidative metabolism; since cyanide is a normal product of cell metabolism, it is tempting to suppose that thyroxin and cyanide serve to adjust and preserve the proper oxidation balance of the organism (Marine, 1932).

A *fluoride relation* was postulated by Maumenèe, 1866, and the theory has been revived by Goldemberg (see Index, Fluoride), but it has not been confirmed by others.

An organic *selenium* compound also produces rapid thyroid hyperplasia, and adenomatous changes in the liver (J. Seifter, Ehrich *et al.*, 1946).

Iodine Prophylaxis.—Simple goiters are conditioned on absolute or relative deficiency of iodine, and Marine showed that they can be prevented, arrested and to some degree cured, by the administration of small quantities of iodine, in any form. Goiters that supervene with iodine income which would ordinarily be adequate are cured by increasing the iodine income (Oswald, 1927). In goiterous regions endemic hyperplasia may be expected to occur in some degree in adolescent girls and in pregnancy, unless iodine is administered; as the early stages are not easily recognized, it is advisable to administer iodine as a routine, at these periods. Hyperplasia occurs also under other conditions in both sexes and at any age, forming a fruitful soil for the development of serious thyroid diseases. It would therefore be advisable to make iodine prophylaxis universal in goiter regions. The clinical success was first conclusively demonstrated through mass prophylaxis by iodine in the brilliant results reported by Marine and Kimball, 1917, 1918, 1920, for large groups of school girls in the Lake Erie goiter district. The administration of iodide prevented the appearance of goiter in over 99 per cent of the girls and diminished the size of the thyroid in most cases where the gland had been enlarged before medication. Iodide rash occurred in less than 0.5 per cent and was always mild. None developed any symptoms of hyperthyroidism. Similarly beneficial results were obtained in the goiter districts of Switzerland. At St. Gall the weekly administration of an organic iodine compound to the children reduced the goiter incidence from 88 to 13 per cent. Established goiters in girls up to fifteen or eighteen years of age may disappear under treatment, but rarely after the twentieth year (Silberschmidt).

The fear that the promiscuous use of iodine would convert simple and especially adenomatous goiters into toxic goiters, appears to be unfounded. No instance of this has been reported with the weekly dose, if this did not exceed 10 mg. of iodine; nor has it ever occurred in school children even with the more intensive but brief dosage of Marine and Kimball. It is doubtful whether it ever occurs even with larger doses (Means). Unnecessarily large doses are inadvisable, however, on the ground of iodism.

Historical.—Iodine in the form of sea water, sea salt, seaweed or burnt sponge appears to have been used against goiter by the ancient Chinese, Egyptians, Greeks and Romans. Soon after iodine was discovered, it was used against goiter by Coindet (1820), but without thought of supplying a deficiency. This explanation was advanced by Prévost in 1849 and elaborated by Chatin, 1850. The latter believed that endemic goiter and cretinism could be avoided by the continued administration of small quantities of iodine, by the selection of foods relatively rich in iodine, and by iodized table salt, which had been suggested for this purpose by Boussignault in 1833. Modern use of iodized salts dates from Wagner von Jauregg, 1898.

Iodine Income, Requirements and Storage.—The daily income of iodine differs materially in goiterous and nongoiterous regions. The iodine salts that occur in the soil are easily leached out, so that the soil water can contain notable amounts of iodine only if this is being constantly renewed, by diffusion or spraying from the ocean or by the vicinity of considerable iodine-salt deposits. These geographic and geologic relations are reflected in the distribution of endemic goiter. The iodine content of the springs, rivers and lakes of goiterous regions ranges generally between 1 and $22:10^{11}$, that of the nongoiterous regions lies between 23 and $18{,}000:10^{11}$. The median iodine content of the waters of the nongoiterous is 145, that of the goiterous $6:10^{11}$; *i. e.*, about $\frac{1}{25}$ of the normal. Water bodies contaminated by the waste of large cities may have their iodine content considerably increased; for instance, the iodine content of Lake Erie at Cleveland is $86:10^{11}$, although this lies in the goiter belt. The *iodine content of the water* is important but not through the amount of water consumed directly, as food or drink; for a liter of $100:10^{11}$ represents only 0.001 mg. The real importance of the iodine in the water is that it determines the *iodine content of the foods* raised in the region. All plants and animals and therefore practically all natural foods contain small quantities of iodine. The content varies materially in goiterous and nongoiterous regions.

McClendon and Hathaway, 1924, for instance, found that carrots grown in the goiter belt of Oregon contained only $\frac{1}{75}$ as much iodine as those grown on the California coast; the iodine content of oats from Minnesota was $\frac{1}{15}$ that in Maine. Wheat is low in iodine; relatively rich are fruits, leafy vegetables, whole milk and butter and animal foods (Fellenberg, 1923).

The *correlation of goiter with iodine deficiency* is illustrated by the studies of McClendon and Holridge, 1935, of the two geological regions of Minnesota. The glacial Northeast has twice the incidence of goiter. Its drinking water contains much less iodine, (0.01 ppm, as against 0.05 to 0.14) and its vegetables about half as much as in the Western region. The *protective value of foods* when added to a low iodine diet of rats depends practically altogether on their iodine content, a given amount of iodine being equally effective as it occurs in milk, oysters or fish, or as KI. That of Irish moss is less effective (R. E. Remington *et al.*, 1936). In *plants*, iodine is more abundant in the leaves. It is increased by enriching the soil with iodine, but depends partly on the physical condition of the soil and its Ca and acid content (von Fellenberg, 1926). The *proportion of iodide in sea water* is only a millionth that of chloride, but it is greatly concentrated in marine organisms. Sponges contain up to 1.5 per cent of their dry substance. Cod liver oil contains 0.16 to more than 0.32 per cent, evidently in liposoluble form. Seaweeds (kelp) are a commercial source of iodine, and some may be present as the free element, for the vacuole juice of certain algae of the Gulf of Naples colors starch blue (Golenskin and Robertson). It contains an iodoxidase which liberates iodine from iodides (O. Gertz).

The *actual total income of iodine in the normal diet* of the Minnesota goiter region was determined by McClendon and Hathaway, 1924, as 0.019 mg. per day. For Switzerland, the iodine income for a goiter region was estimated by von Fellenberg, 1924, as 0.014 mg. per day; for a nongoiter region as 0.031 mg. per day, *i. e.*, about twice as high. The actual difference, however, is less than 0.02 mg.! From all the available data, it may be estimated that the daily requirement of iodine is of the order of magnitude of 0.03 to 0.05 mg. of iodine, or 10 to 20 mg. per year. This is about half of the total iodine content of the body, which is therefore replaced in two years. This shows great efficiency in the iodine economy: since the destruction of thyroxin approximates 0.2 to 0.4 mg. per day, equivalent to 0.13 to 0.27 mg. of iodine, and the daily diet need supply only 0.03 mg. of iodine, four-fifths of the iodine of the destroyed thyroxin must be reconstructed into thyroxin.

From the Swiss experience, Eggenberger, 1935, estimates the daily requirement as 0.001 to 0.002 mg. per Kg. of body weight. Below 0.001 there is danger in any region; with 0.002, there is no danger, even when susceptibility is increased by infection or by unsuitable diet. It is generally believed, however, that a daily income of 0.05 mg. (*i. e.*, somewhat less than 0.001 mg. per Kg.) gives a satisfactory margin of safety for normal individuals.

The total iodine content of the normal human adult ranges between 20 and 50 mg. At least a fifth of this is in the thyroid gland, half in the muscles, a tenth in the skin, a seventeenth in the skeleton, less than a tenth in the blood. The iodine concentration in the thyroid, at least 40 mg. per cent, is more than a thousand times that of muscle (30 gamma per cent). The next highest concentration is in other endocrine glands, up to about 100 gamma; blood contains about 10 gamma per cent (review, Salter, 1940).

Iodine Balance.—Puppel and Curtis, 1938, reported that normal persons on a diet low in iodine, 0.029 mg. per day, excrete 0.071 mg., giving a negative balance of 0.042 mg. Swiss reports, however, claim that a positive balance may be maintained with as low as 0.017 mg. In the latter case, about 0.014 mg. is excreted, about four-fifths by the urine. With incomes of 0.055 to 0.075 mg., the maximal retention was 0.02 mg. (von Fellenberg, 1926; Scheffer, 1933).

Iodine Storage in the Thyroid Gland.—Iodine administration may raise the iodine content to 4 mg. per Gm. of dried thyroid; *i. e.*, to 20–30 mg. in the whole normal gland of man. This represents an excess of 10 to 20 mg. over the normal content of 10 mg., as was explained in the preceding paragraph. The excess is sufficient to supply the iodine needs for half a year or a year; this explains the persistent effect of the periodic iodine medication, as in the method of Marine and Kimball.

Administration for goiter prophylaxis is especially important with girls between eleven and sixteen years; and during pregnancy. The iodine may be administered daily; or by taking advantage of the storage capacity of the glands, the administration may be made intermittent, *i. e.*, weekly, monthly or semiannually. Both the intermittent and continuous methods are effective in practice, so that the choice may be determined by convenience, or rather, by the faithfulness with which the prophylaxis is likely to be carried out. Iodized salt is preferable for community prophylaxis. For groups or individuals the intermittent methods can be more effectively supervised, and are therefore generally preferable. They require a large dosage, to insure "saturation" of the glands, but this is not a serious disadvantage when the administration is intermittent. The compound in which the iodine is administered is immaterial for the effect. The organic forms can be made into tasteless or flavored tablets, and are therefore usually preferred for the weekly dosage. They are not so well suited for the larger doses needed in the intensive semiannual method.

Semiannual Method.—In their decisive experiments, Marine and Kimball administered sodium iodide twice a year, in May and December, in courses of ten days each. Up to ten years, the daily dose was 0.2 Gm., from ten to sixteen years, 0.4 Gm., taken in a little water. This plan has been continued in many of the American schools which practice goiter prophylaxis, and the results have not been surpassed by any other method. The lower dosage is probably more than sufficient, for it supplies 0.170 Gm. of iodine per day, 1.7 Gm. during the course and 3.4 Gm. during the year, two hundred times as much as the safe daily income of 0.05 mg.

The *weekly method* was introduced in Switzerland and has given equally good results. It administers 5 or 10 mg. of iodine, one day each week, usually in the form of tablets of *organic iodine* such as iodostarin, each tablet containing 10 mg. of iodine, although sodium iodide would answer equally well. The iodine medication by this method averages 0.7 or 1.5 mg. per day, 0.25 or 0.5 Gm. per year, fifteen to thirty times the safe requirement. In pregnancy, 10 to 20 mg. are given weekly until term; for treatment of simple goiter, 10 mg. daily in alternate months.

The *daily method* aims to give 0.1 to 1 mg. per day, 35 to 350 mg. per year. The lower dosage is doubtless sufficient and absolutely safe; 1 mg. may perhaps become deleterious if it is taken continuously. Since the daily dosage is almost certain to be neglected after a time, it is usually attempted to administer it by some indirect and automatic means, for instance, as "*iodized table salt,*" *i. e.,* salt to which sodium iodide has been added. The Swiss Goiter Commission advises 5 mg. of iodide per Kg. of salt. The average daily consumption of salt in cooking and at table *i. e.,* 10 Gm., would represent 0.04 mg. of iodine. This is quite harmless and quite sufficient, according to Swiss experience (Eggenberger). In the United States, where the iodized salt is less likely to be used exclusively, it is advisable to employ a larger proportion; 100 mg. of NaI per Kg. of salt is now the prevailing American standard (O. P. Kimball, 1937, 1939).

THIOCYANATES (SULFOCYANIDES, SULFOCYANATES, RHODANATES)

The SCN ion reacts similarly to iodide on the aggregation of colloids and in its other effects, antisyphilitic, iodism, and so forth Potassium thiocyanate has been used clinically, especially in hypertension. It is said to lower the blood pressure in the majority of cases, after several days or weeks; but it is so liable to cause untoward results, notably asthenia, that patients must be under careful supervision. Thiocyanates are not dissociated into cyanide, and their acute toxicity is low. On direct contact with frog muscle, thiocyanates cause peculiar contractures. The ion occurs naturally in the body and can generally be demonstrated in normal saliva. It serves to detoxicate cyanide.

Iodide Effects.—The analogy of the colloid effects with those of iodide suggested therapeutic trials with sodium thiocyanate, and it was found to affect neuroses, arteriosclerosis and syphilis in a manner analogous to the iodides (Pauli, 1903 and 1910). It also hastened the elimination of metals, perhaps by rendering the metal-protein compounds more soluble. It resembles the iodides further in producing coryza, acne and other symptoms of iodism. Corper, 1915, observed no results in tuberculosis. Nerking, 1913, reported many disagreeable effects, especially in gastric hyperacidity. A conspicuous difference from iodides is that it does not inhibit *thyroid hyperplasia,* but may provoke it, perhaps by increasing the excretion of iodide.

Bancroft's Theories.—Basing himself on his experience with the dispersive effects of thiocyanate on colloids, and on his assumption that biologic functions, especially those of the central nervous system, are conditioned chiefly on the congelation and peptization of their colloids, Bancroft postulated spectacular effects of thio cyanates on nervous stability, various types of insanity, drug addiction, sciatica, senescence and longevity. These speculations are not supported by sound evidence. Burkholder, 1932, *f. i.*, failed to confirm the antagonism to ether and to morphine as postulated by Bancroft and Rutzler, 1931; Hirschfelder and Cunningham, 1933, also found thiocyanate ineffective against these and against amytal. Schube, 1935, could not confirm Bancroft's classification of psychoses by their response to thiocyanate and amytal.

Efficiency Against Hypertension.—Potassium thiocyanate was reintroduced for this purpose by Westphal, 1924. The continued administration generally leads to persistent lowering of the blood pressure in normal individuals, in three-fifths of patients with glomerular nephritis, and in about a third of hypertension patients. The mechanism of the fall is obscure; the lassitude which it often induces may be a factor. There is practically no fall unless the blood level of thiocyanate is held at 8 to 12 mg. per cent for prolonged periods; improvement is usually seen in two to four weeks, but sometimes not til three months. The *dosage* to maintain this level variel considerably in different individuals, and even in ths same individual, according to renal clearance, fluie balance and other factors. As lower concentrations ard ineffective and higher concentrations are toxic, the levee must be checked chemically (M. H. Barker *et al.*, 1941)l. The *administration* may be started with 0.5 Gm. of potassium thiocyanate daily in water, and adjusted according to the blood level. Rather slight side effects sometimes appear at 15.7 to 21 mg.; but often not with 15 to 33 mg. (L. F. Blaney *et al.*, 1941). Some patients have practically no margin of safety, and serious poisoning has been reported with 13.6 mg. (C. F. Garvin, 1939). The patients must be closely watched and the drug discontinued with the first sign of intolerance. Renal insufficiency and acute inflammations are considered *contraindications.*

In *experimental chronic hypertesnion*, produced in dogs by the Goldblatt method of compressing the renal arteries, oral administration of thiocyanate, 20 to 70 mg. per Kg. daily from one to five weeks, did not significantly lower the blood pressure with the clinical plasma concentrations (8 to 12 mg. per 100 cc.); 15 to 35 mg. levels decreased the pressure in some cases and produced toxic effects in all (D. A. Collins *et al.*, 1940). Goldblatt *et al.*, 1941, also found it ineffective.

Clinical Toxic Symptoms.—A few patients show phenomena analogous to those of iodism: coryza, anginal symptoms, sometimes pustular skin rashes, toxic erythema or papulopustular, even exfoliative, dermatitis (T. W. Baker and Brunsting, 1937). Most patients complain at first of marked fatigue. This wears off in two to six weeks and full vigor returns during treatment, although the blood pressure remains low (Barker, 1935). Many patients feel drowsy even without fall of blood pressure. Vertigo is common, and there are painful cramps and weakness of the arms and legs. Gastro-intestinal disturbances are exceptional at the "safe" level, but nausea and vomiting are among the first signs of toxicity. The flow of gastric juice and its acidity are decreased, as is also the response to histamine (H. W. Davenport, 1940; W. S. Rehm and Enelow, 1934, 1945). Thyroid enlargement with lowered basal metabolic rate occurs occasionally after prolonged administration, and decreases on feeding thyroid (M. P. H. Foulger and Rose, 1943; R. W. Rawson *et al.*, 1943). Ocular disturbances may occur and disappear when the dosage is reduced (J. M Gonzalez and Muñoz, 1944). If the administration is continued, toxic psychosis may develop, similar to bromide mania, with word aphasia and slurring of speech, disorientation, hallucinations, mania and persecution ideas. The symptoms begin at 20 mg. per 100 cc. plasma concentration, and may recede in a week if the drug is promptly withdrawn (Wald, Lindberg and Barker, 1939, review). If the administration is continued after toxic symptoms set in, death may result, even with ordinary doses, and with blood levels not above 21.7 mg. per cent (W. O. Russell and Stahl, 1942).

Toxic Effects on Animals.—As with iodide, the effects tend to develop gradually, beginning with emaciation, diarrhea and (in cats and dogs) vomiting, dehydration, followed in one or two days by hyperexcitability, spastic paresis of the extremities, opisthotonos, convulsions, coma and death. Temperature, respiration, heart rate and blood pressure are not affected directly. With repeated sublethal doses, the hemoglobin decreases. Carbonic anhydrase is inhibited, but the practical significance of this is doubtful (F. J. W. Roughton *et al.*, 1941). Persistent albuminuria with histological renal damage is frequent, even with nonfatal doses. Rabbits often show injury to the gastric mucosa after oral and sometimes perhaps also with parenteral administration. The activity and the toxicity are about the same with all methods of administration, except that intravenous injection produces almost immediate spasticity, which soon relaxes, and is followed by the gradual development of the further effects as with the other methods (Takacs, 1926; Jahr, 1936; Wald *et al.*, 1939). The minimal fatal single dose in rabbits is 0.5 Gm. per Kg., hypodermically (or intravenously, Corper, 1915). The effects are specific and not merely "salt actions," for they were absent with sodium chloride in double the dosage (Jahr). F. Franz, 1912, confirmed that no cyanide is split off in the animal organism. Even 0.36 Gm. per Kg. produces practically no acute effect on the circulation, respiration or bile and urine flow (Gies, Lieb and Kahn, 1914). Exposure of *amphibian larvae* to thiocyanate results in hyperdevelopment of various parts of the central nervous system (S. Ranze, 1945). The pharmacology of *organic thiocyanates* was studied by Taubmann, 1930, their toxicity by von Oettingen *et al.*, 1936. They are used as *insecticides* (fly sprays), especially butyl carbitol thiocyanate (D. F. Murphy, 1936). They act on the isolated heart of the cockroach (J. F. Yeager *et al.*, 1935).

Skeletal Muscle.—Immersion of a frog's gastrocnemius in a 2 per cent solution of sodium thiocyanate (in Ringer's solution) produces a strong primary contraction, followed by gradual increase of tonus, slow waves of contraction and intermittent twitchings (Worthington, 1912; Langley, 1916). The action appears analogous to that of monoiodoacetate. The twitchings and their synergisms and antagonisms were studied by Okagawa, 1926. At first they are arrested by curare; *i. e.*, they are of nervous origin. As the concentration in the muscle rises, however, the muscle substance is also involved, so that curare becomes ineffective (Langley, 1916). G. E. Selter, 1927, confirmed that the thiocyanate increases the lactic acid formation.

The fate of thiocyanate in the body is like that of the haloids. It is *excreted* chiefly by the urine, similarly to iodide, but more slowly and less completely, so that there is a tendency to cumulation, especially in glomerular nephritis. The urinary clearance varies rather widely and does not parallel urea clearance. In man, with a single dose of 0.3 to 1 Gm., the excretion continued more than three weeks, and only 10 to 50 per cent was recovered. Rabbits excrete it more efficiently (Baumann, Metzger and Sprinson, 1934; Goldring and Chasis; Barker, 1935; Wald *et al.*, 1939).

The *distribution* of administered thiocyanate, like that of the haloid anions, is practically exclusively in the extracellular fluid, so that it may be used as a measure of the latter; the result is somewhat too high, as it passes into the cells more readily than does chloride (J. R. Elkinton *et al.*, 1943). Its concentration in the serum, lymph, urine, gastric juice and saliva is nearly equal, three hours after intravenous injection into dogs (Crandall, 1932). The concentration in the *cerebrospinal fluid* is the same as in the serum or slightly lower, never higher (R. Blum, 1928; Wallace and Brodie, 1940). It diffuses readily into the *synovial fluid*, attaining a concentration about 9 per cent below that of the serum. It passes fairly rapidly into the *aqueous humor, reaching* a maximum ninety minutes after intravenous injection in rabbits, but its concentration is much lower than the blood level (P. H. Lavities *et al.*, 1936). The passage is favored by physostigmine and pilocarpine, rather hindered by atropine; the effect of epinephrine is doubtful (Kudo, 1931). The *salivary excretion*, in rabbits, occurs chiefly through the epithelium of the excretory ducts (Scholari, 1928).

Normal Occurrence.—Small quantities of thiocyanate are formed from the cyanide which arises in the metabolism of protein, or which may be introduced in tobacco smoke or with vegetables such as succotash and onions. It is found in the blood and all body fluids, in fairly equal concentration, about 0.03 to 0.06 mg. per 100 cc., and is excreted by the urine and feces, generally in the ratio of about 1:2. The total excretion in man is of the order of 3 or 4 mg. per day. Its quantity is increased by tobacco smoke (A. Trasoff and Schneeberg, 1944) and decreased by catharsis (indicating that either CN or SCN is formed in the alimentary canal; E. J. Baumann *et al.*, 1934). Experimentally, it is increased by administering cyanides or nitriles and by feeding amino acids (alanin) or by increasing the protein intake, but not by sulfur, sulfide, thiourea or taurine (Kahn, 1912, bibliography; Gies, Lieb and Kahn, 1914; Obreggia *et al.*, 1933; Stuber and Lang, 1933). Some proteins with loosely combined sulfur convert KCN into KSCN at room temperature *in vitro* (Pascheles). Thiocyanate is formed slowly from cyanide by methylene blue *in vitro* (R. G. Smith, 1940).

The *occurrence* of thiocyanate in *human saliva* has aroused especial clinical interest. Thiocyanate is found in the human parotid and submaxillary saliva, but not in all individuals; also in the saliva of many animals, but not in dogs and horses. It reflects generally the plasma level and is therefore increased by smoking. It is absent in newborn infants (Rittershain); also in suppurative middle-ear disease (Juergens, 1901). It has no relation to tooth decay (Lothrop and Gies, 1911): The quantities present in the mouth could not have an antiseptic effect (Gies and Kahn, 1912 and 1913); although thiocyanate is toxic to higher plants, and in greater concentrations also to bacteria. Sulfocyanic acid (0.3 to 0.4 per cent) inhibits the gastric digestion of fibrin (Cavazzani, 1915).

NITRATES

Nitrates resemble the haloid salts, especially iodide, in physicochemical properties, and also in their effects, although these may be complicated by reduction to nitrite. They were formally employed for diuresis, to depress the circulation in fevers, as anaphrodisiacs and for a variety of other conditions, but are now rarely administered. Saltpeter, KNO_3, and Chile saltpeter, $NaNO_3$, are used as antispetic to pickle "corned" meat and to cause its red color by reduction to nitrite, which converts the myohemoglobin to methemoglobin. No harm results from this as customarily used; but if the meat is not washed, it may produce symptoms. Serious poisoning may result from overdosage of the salts, which have a varying toxicity.

Clinical Uses.—Potassium nitrate was used extensively in the eighteenth century, before iodide was discovered. The indications were as numerous and vague as the claims for iodide. Allston at that time (quoted by Stillé) described it as resolvent, antiseptic, antiphlogistic, diuretic, purgative and anaphrodisiac. It was used extensively against *rheumatism* in England between 1750 and 1800; as niter paper it was used against *asthma* in 1842. It was tried against *scurvy*, but quickly found useless. It continued to be used against *sore throat* (Brunton), somewhat like potassium chlorate. Its use as *anaphrodisiac*, which is still popular, is but little discussed in medical writings. Stillé, 1874, refers it to Allston and to Boerhaave. There is no scientific evidence of such action, but if it exists it might be a part of the general apathy which its continued use may induce, analogous to thiocyanate. The *diuretic effect* was described in the seventeenth century. Some observers reported it as striking, others as slight and uncertain. Stillé points out that the water intake was not well controlled. Norman Keith, 1931, found ammonium nitrate, up to 10 Gm. per day, effective in man and dogs, to reinforce mercurial diuresis. This salt acidifies the urine as does ammonium chloride, so that the effect is mixed. The large dosage appears to be necessary and may give rise to serious toxic effects.

Serious and fatal acute poisoning has occurred through mistake for Epsom salts. The symptoms consist in great abdominal pain, vertigo, muscular weakness, vomiting, frequently bloody stools; irregular pulse; convulsions and collapse; tenesmus and suppression of or albuminous and often bloody, urine. The heart and respiration are not greatly damaged. The gastro-enteritis may be so violent as to lead to an early fatal ending, in twenty minutes to five hours. Lewin states the clinical fatality as 56 per cent. The *autopsy* generally shows gastritis and enteritis, with hemorrhages into the submucous coat and sometimes into the lumen. Ulceration and corrosion of the mucosa has been observed (Lewin). The *treatment* consists in dilution. Large quantities of water should be swallowed and the stomach washed. Demulcents, milk, egg white, acacia, are also useful. The symptoms should be met as they arise.

Therapeutic and *Toxic Dosage.*—Stillé states the therapeutic dose as 5 to 15 grains every one to three hours to a total of 60 to 180 grains (4 to 12 Gms.), but poisoning may result if the daily dose exceeds 4 Gm., or if the single dose is more than 1 Gm.; 5 Gm. at one dose may be dangerous; 8 Gm. may be fatal, and 15 to 30 Gm. are generally fatal; but 30 and even 60 Gm. per day have been taken for two months without marked disturbance (Stillé). The toxicity is greater if the amount is taken at one time and in concentrated form; but there appear to be other unknown reasons for the variable toxicity. The mechanism of the local violent irritation is also obscure. It occurs also on contact of other mucosae and of wounds with solutions that are not too dilute. Ammonium nitrate produces pruritus and other cutaneous irritation in munition workers. Nitrates provoke the *luetin reaction* (Cole and Paryzek, 1917). *Excised ureter* is slightly stimulated by nontoxic concentrations (Macht, 1917).

Minor toxic actions from continued therapeutic doses resemble those of thiocyanate, bromide and iodide: general weakness and lassitude, physical and mental, low spirits, drowsiness; giddiness, headache, confusion; debility of the arms or legs lasting for a week, and so great that patients believe themselves paralyzed; speech and memory defects, general trembling; pulse weak and slowed, sometimes 20 per minute, the effect persisting for a week after discontinuing the drug. The appetite and dizziness may be normal; there may be bloody diarrhea (Löffler, 1849; Jörg; Cargill, 1851). Fackelmann, 1898, reported hemorrhagic tendencies, edema and fatty heart.

Fate and Excretion.—Nitrates are readily absorbed. Their excretion is similar to that of the halogen ions, and shows the usual mutual relation (Sollmann). Practically the entire quantity is excreted unchanged (Abderhalden and Hirsch, 1913), but a small proportion may be reduced to nitrites. This reduction takes place so slowly, in the inorganic nitrates, that no nitrite action can ordinarily be seen; but large doses may cause methemoglobin formation (Binz and Gerlinger, 1901). Metabolism studies have given contradictory results (Grafe and Wintz, 1913). After giving large doses of ammonium nitrate to dogs, Whalen, 1935, found about 50 per cent excreted by the urine; the remainder was probably destroyed in the tissues.

Normal urine contains 0.1 to 0.4 per cent of KNO_3. This is considerably more than is ingested with the food, so that a part must be formed as an end product of metabolism (H. H. Mitchell, Shonley and Grindley, 1916).

Potassium Nitrate, U.S.P. (Niter, Saltpeter): KNO_3; and *Sodium Nitrate* (Chile Saltpeter) are freely soluble in water. They have a saline cooling taste. Dose, 0.3 to 1 Gm., 5 to 15 grains, diluted.

POTASSIUM CHLORATE

The saturated (1:16) solution is used as mouth wash in stomatitis, especially the ulcerative (Vincent's angina), where it was supposed to be specific; and as a prophylactic against mercurial stomatitis, in which a similar collaboration of putrefactive microorganisms is concerned. It is also employed as a gargle in pharyngitis and tonsillitis. It often seems to be effective, but its action is unexplained. It was introduced with the idea that it would act as an oxidizer, and thus be antiseptic. However, it does not easily part with its oxygen in the body, being excreted practically unchanged. Its efficacy is questionable, except that the tablets, when dissolved slowly in the mouth, at least change the inflamed taste to the cool and clean saline taste of the potassium chlorate. After a few days of the ordinary use of the tablets, the potassium taste continues from the blood. Patients should be cautioned against swallowing the tablets or gargle, as this has repeatedly led to serious toxic effects (A. Jacobi, 1879), especially by the production of methemoglobin and destruction of the corpuscles, thrombosis, and so forth.

Potassium chlorate is used as tablets of 0.25 Gm., 4 grains, dissolved slowly on the tongue two to five times daily; or as a mouth wash or gargle of the saturated (1:15) aqueous solution; often with ferric chloride, which liberates some chlorine when it is added without dilution.

Potassium chlorate poisoning is fairly common, either by an overdose, since the laity does not generally regard it as a toxic substance, or in the therapeutic use, as the susceptibility varies greatly, which is likely to lead to carelessness. In general, 10 Gm. may be considered as toxic, 15 to 30 Gm. as fatal (Lewin). The mortality is about 70 per cent. The symptoms may start at once or be delayed to six hours; death may occur in six hours to seven days.

The *symptoms of poisoning* are gastritis (nausea, vomiting, gastralgia); methemoglobinemia (cyanosis, collapse and terminal convulsions); and nephritis (lumbar pain, anuria, albumin, casts, blood, and so on). The postmortem findings correspond with the symptoms.

Treatment consists in gastric lavage, hot drinks and symptomatic measures. Intravenous injection of physiologic saline solutions should hasten elimination of the chlorate.

Continued administration of doses which do not cause methemoglobin production lead to emaciation, probably a haloid effect (A. P. Richardson, 1937).

Blood Changes.—When the chlorates are added to blood, either inside or outside the body, they effect the *formation of methemoglobin.* The chlorate ion is not used up in this process, so that it may convert an indefinite amount of hemoglobin. They differ in this respect from the nitrites (see Index), and their action is in consequence more violent and more prolonged. They may produce actual asphyxia. In a severe case of human poisoning the blood, examined thirteen hours after taking the chlorate, contained both methemoglobin and hematin. Hemolytic icterus developed later. Similar conditions were found in poisoned animals (Feigl, 1916). In addition to this formation of methemoglobin, the chlorates break up the *blood corpuscles* (Huber, 1912). This may produce embolism; the proteins, and so forth, which are liberated by the destruction of the corpuscles are irritant to the kidneys and produce interstitial *nephritis*, with the usual phenomena—proteins in the urine, casts, sometimes hemoglobin compounds. Possibly the chlorate ion itself irritates the kidneys. *Fat embolism* of the lungs and other organs occurs at least in animals, from the bone marrow. The blood contains numerous normoblasts. Fragmentation of the heart muscle is a frequent cause of death (Winogradow, 1907).

Methemoglobin Formation by Chlorates.—The blood of different animals shows different degrees of susceptibility to the methemoglobin formation. These differences are common with all poisons acting on the blood, especially as between carnivorous and herbivorous animals. The cause is not understood, but is perhaps connected with differences in the alkalinity of the body. The conversion occurs fairly readily *intra vitam* in man, dog and cat, while rabbits and guinea pigs are almost immune. But in the test tube, chlorates convert rabbit's blood, although more slowly than dog's. The action is much slower outside the body, often requiring several hours. The concentrations injurious for the blood were determined by E. Caesar, 1918.

Iodates and bromates have a similar action on hemoglobin (Heinz, 1898).

Excretion.—Chlorates are excreted mainly by the urine, but partly also by the saliva. The urinary excretion begins promptly and is completed within forty-eight hours, about 90 per cent of the chlorate being recovered (Rosenbloom). A great deal of this is reduced to chloride after the urine is voided. It is doubtful whether this reduction occurs ordinarily in the body. *Bromates* are partly reduced in the tissues, and *iodates* intensively when given by mouth, but not when administered hypodermically or by vein (Crespolani, 1909).

The **distribution** of fatal doses was studied by Rosenbloom, 1912.

***Potassium Chlorate,** $KClO_3$, occurs as colorless crystals or white granular powder; odorless; cooling, characteristic taste. Sol. in water (1:16.5); nearly insol. in alc.; sol. in glyc. *Explosive* when triturated with organic matter (not when in watery solution), or with charcoal, sulfur, sulfides, hypophosphites, reduced iron, and so on. Dose, 0.3 to 0.6 Gm., 5 to 10 grains.

Perchlorate was studied on the isolated frog heart by Cartolari, 1930.

Bromates act similarly to chlorates, but are considerably more toxic, mainly by central paralysis (Santesson and Wickberg, 1913). They form methemoglobin *in vitro*, but not so actively as chlorates (Mehring, 1885; Cushny, 1908).

Iodates.—Macciotta, 1916, found KIO_3 to be tolerated without disturbance, with oral administration of 0.285 Gm. per Kg. The urine contained no trace of iodate, but only iodide. Hypodermically, the above dose was fatal.

Intravenous injection (5 cc. of 2 per cent) into rabbits produces pigmentary changes in the retina, without other damage (A. Sorsby, 1941).

THIOURACIL, THIOUREA, AND RELATED ANTITHYROID SUBSTANCES

These inhibit the formation of thyroid hormone by the thyroid gland. The action of thyroxin itself, for instance on the basal metabolic rate, is not diminished. Several days or weeks are therefore needed for the full development of the effects, especially if the patient has received iodine. The deficiency of thyroxin production stimulates the production of thyrotropic hormone, which produces ineffective hyperplasia of the thyroid epithelium. This does not occur if thyroid is fed or if the hypophysis is excised. The decreased production of thyroxin is used to suppress hyperthyroidism, and expecially to prepare patients for operation. The effect lasts only during the administration; but if the administration is continued for an average of ten months, 60 to 80 per cent of the patients retain more or less benefit (Beierwaltes and Sturgis, 1946). Thiouracil is more effective than iodide, but acts more slowly, the basal metabolic rate returning to normal in three to six weeks. It usually causes little or no side effects, but adverse reactions, including serious granulopenia, occur in a considerable proportion of patients. It is therefore recommended only for preoperative treatment, not for permanent therapy, unless surgical intervention is especially contraindicated. The patients should receive detailed warning as to untoward symptoms and instructions to report these immediately.

Historical.—The discovery of these antithyroid actions started with the observation of J. B. Mackenzie *et al.*, 1941, that sulfanilyl guanidine induced thyroid hyperplasia in rats, which was not influenced by iodide administration, but was arrested by thyroxin. The structural similarity of the sulfonamide group, $H_2N\text{-}C_6H_4\text{-}SO_2NH_2$ to thiourea, $H_2N\text{-}CS\text{-}NH_2$, suggested that the latter would also have this action. This was confirmed by C. G. MacKenzie and MacKenzie, 1943. E. B. Astwood, 1943, showed that it is produced by most thiourea derivatives; thiouracil, $\underbrace{NH\text{-}CS\text{-}NH.COCHCH}$, was found to be especially suitable. The comparative antithyroid actiln of thiourea and allied substances was studied by R. H. Williams and Frame, 1945. The action is also produced by para-aminobenzoic acid, $NH_2\text{-}C_6H_4\text{-}CO_2H$, and by thiobarbituric acid.

Morphologic Changes.—C. G. MacKenzie and MacKenzie, 1942, showed that administration of sulfonamides and thiourea to mice and dogs results in hyperemia and marked enlargement of the thyroid, with reduction of the colloid and increased height of the cells. Guinea pigs and chickens did not appear to respond; but J. P. Mixner *et al.*, 1944, confirmed thyroid enlargement in chickens by appropriate dosage. E. B. Astwood, Sullivan *et al.*, 1943, showed that the hyperplasia is not influenced by giving iodine, but that it is suppressed by giving thyroid or by excising the hypophysis. *Continued administration of thiouracil from birth induces cretinism* in rats (A. M. Hughes, 1944). *Excessive administration* to human subjects also results in lowering of basal metabolic rate, myxedema, and increased blood cholesterol (E. Shorr, 1944).

R. Grasso, 1946, attributes the changes in the thyroid cells to *excessive secretion of anterior pituitary thyrotropic hormone.*

Thyroid Iodine.—Thiourea administration rapidly decreases the iodine content of both the thyroxin and non-thyroxin fractions of the thyroid gland, the iodine being rapidly excreted by the urine (E. J. Baumann *et al.*, 1944). When 0.1 per cent of thiouracil is added to the drinking water of rats, the loss of thyroid iodine begins within a day and continues for five days, when a stable level of about a thirteenth of the normal is reached. When the administration ceases, the accumulation of iodine in the thyroid begins within a day and reaches nearly normal in seven days. Addition of iodine to the diet has little effect in the loss or reaccumulation. Similar effects are produced by *sulfadiazine* (Bissell and Astwood, 1944), but it is less potent. Thiourea thyroids accumulate little radioactive iodine when this is administered (A. S. Keston *et al.*, 1944). *In vitro conversion of inorganic iodine into diiodotyrosine and thyroxin* by slices of thyroid gland is inhibited by thiourea, thiouracil, para-aminobenzoic acid, thiocyanate and sodium cyanide (A. L. Franklin *et al.*, 1944). The action is therefore directly on the cells, and the cyanide effect indicates some *enzymatic interference*, as had been surmised by Astwood. Administration of thiouracil to rats inhibits the *cytochrome oxidase* of their thyroid, without interfering with that of bone marrow, kidneys, and other tissues (K. E. Paschkis *et al.*, 1945).

Corollary Effects of Thyroid Inhibition.—Thiouracil is reported to be effective for decreasing or suppressing the clinical symptoms of *angina pectoris*, in a majority of patients, similarly to thyroidectomy, presumably by diminishing the epinephrine sensitivity of the cardiovascular system. This may begin with 0.4 Gm. daily in divided doses, and continue with 0.1 Gm. Improvement begins in one and a half to five weeks (W. Raab, 1945).

Resistance to anoxia from reduced atmospheric pressure or carbon monoxide is increased by pretreatment of rats with thiouracil (A. M. Hughes and Astwood, 1944) or thiourea (A. S. Gordon *et al.*, 1944), presumably by the lowered oxygen requirements. Thiourea retards *tadpole* metamorphosis (A. S. Gordon *et al.*, 1943), and inhibits the growth and development of secondary sex characteristics of certain fish (E. D. Goldsmith *et al.*, 1944).

Thiouracil decreases the *lactogenic* hormone in the anterior pituitary. This is imperfectly antagonized by estrogenic hormone (J. Meiter and Turner, 1947).

Hyperthyroid patients are almost uniformly improved by the administration of thiouracil or other thiourea derivatives. These are ineffective against similar symptoms if these are not due to hyperthyroidism; nor are these drugs of any value against simple goiter. In toxic goiter, they produce gradual but complete remission of all the toxic symptoms. They lower the basal metabolic rate, allay the nervous irritability, increase body weight, restore the normal Ca, P, N, creatine, and cholesterol metabolism, similarly to iodine administration or thyroidectomy, but more slowly. The exophthalmos is also usually improved. Thyrotoxic patients who have received thiouracil for five or six weeks prior to surgical procedures react to these like normal individuals. The remission is more complete and more stable than with iodide, but requires more time, and the vascularity of the gland is increased. The probability of toxic reactions weighs seriously against it (review, E. B. Astwood, 1944; H. M. Clute and Williams, 1944; R. W. Rawson and McArthur, 1946; Aranow, Elliott *et al.*, 1946). If the administration is stopped without operation, the toxic state returns within one or two weeks; but if this is maintained for longer than six months, remission may sometimes endure, but this is exceptional. The risks of toxic reactions, however, are probably greater than for those of thyroidectomy.

Toxic effects of thiouracil, granulopenia, leukopenia, drug fever, or dermatitis occurred in about an eighth of the 5745 patients' records which were surveyed by W. Van Winkle *et al.*, 1946. Some complained of nausea, dizziness, headache or abdominal cramps. In a similar series, F. D. Moore *et al.*, 1946, report that about 10 per cent of patients have reactions which indicate that administration should be stopped. Death attributable directly to the drug amounted to about 0.5 per cent. Most of the observers believe that the incidence of adverse reactions is probably less than with other treatment methods, but the patients must be carefully watched. Mild and juvenile cases of hyperthyroidism can usually be treated successfully by other means, with less risk.

Granulopenia, the most serious complication, occurred in 2.5 per cent of the patients (1.8 per cent, Moore), and proved fatal in about 0.4 per cent of these cases. It is unpredictable, has no relation to dosage, and is most frequent in the first four weeks of administration. This should be discontinued with the first sign of sore throat, coryza, fever, malaise, and change of blood count. The most effective treatment is by parenteral penicillin, 500,000 units daily. E. H. Fishberg and Vorzimmer, 1945, recommend pyridoxine, 0.2 Gm. daily, for protection, 0.2 to 0.5 Gm. daily by vein for treatment. *Leukopenia* with a cell count of less than 4000 occurred in 4.4 per cent, also without relation to dosage. It may improve with continued administration, but it may also be an early indication of granulopenia. *Drug fever* occurred in 2.7 per cent (5 per cent, Moore), generally during the first week. Various *skin reactions* occurred in 3.3 per cent, also without relation to dosage. They were usually mild (W. Van Winkle *et al.*, 1946).

The *granulopenia* is attributed to destruction of the cells of the bone marrow in the promyelocyte stage (Gargill and Lesses, 1945). These observers also report occasional *jaundice*, and swelling of the submaxillary gland.

Long-continued administration of thiouracil (feeding 40 mg. daily for three to four months to rats) produces *marked changes in other viscera;* particularly extreme congestion and involution of the *adrenal cortex,* involving all three zones; progressive hypertrophy of the adrenal medulla with increase of epinephrine content; shrinkage of the spleen pulp; parenchymatous degeneration of the liver; atresia of the gonadal follicles, and depression of spermatogenesis; deposits of thiouracil in the kidneys and urinary tract (E. J. Baumann and Marine, 1944). Thiouracil neutropenia has been produced in rhesus monkeys (Aranow, Engle and Sperry, 1946). Addition of 0.1 per cent of thiouracil prevented the occurrence of cirrhosis by special synthetic diet (P. György and Goldblatt, 1945).

Fate.—Thiouracil is rapidly absorbed from the gastrointestinal tract, but about 15 per cent is destroyed before absorption. It is distributed through all tissues and fluid; the blood corpuscles contain more than the plasma. Considerable is destroyed by many tissues. A third to two-thirds of the clinical dosage is promptly excreted by the urine (R. H. Williams *et al.*, 1944). More constant serum levels are obtained if it is administered at frequent intervals than with a single daily dose (K. E. Paschkis *et al.*, 1945).

Administration of Thiouracil.—The full therapeutic effect is usually obtained with 0.1 Gm. four times daily, in water, continued for four to eight weeks, until the symptoms improve sufficiently. The response is delayed if iodine has been administered or if the glands are large and soft. The remission may last twenty weeks (W. Van Winkle *et al.*, 1946). If the treatment is to be continued instead of operation, the maintenance dosage should be reduced to 0.1 Gm. twice daily, and after three months to once daily (R. H. Williams and Clute, 1945).

Thiouracil, N.N.R., a white powder of bitter taste, very soluble in water, slightly soluble in alcohol. Marketed as tablets of 0.1 Gm. *Patients should be given written instructions* to report immediately any symptoms of sore throat, fever, coryza or malaise.

Other antithyroid agents of this group which have received clinical trial against hyperthyroidism include 6-propylthiouracil, 4-methylthiouracil, aminothiazole, thiourea, thiobarbital, and para-aminobenzoic acid.

Propylthiouracil.—Astwood and Vander Loan, 1946, who assayed some 300 thiouracil derivatives, found the antithyroid potency of 6-n-propylthiouracil and 6-ethylthiouracil about ten times greater than that of thiouracil in rats, about five times in man. Its toxicity is also greater, but not proportionately, and it is therefore better tolerated. The clinically effective dose varies; 50 to 150 mg. daily are required to restore metabolic equilibrium. Ordinarily, 50 mg. every eight hours is advised for severe cases, every twelve hours for milder ones. The effective dose should not be decreased until all manifestations of the disease are controlled. W. S. Reveno, 1947, considers its therapeutic potency as three times that of thiouracil, the dosage therefore as a third. It is much less likely to produce toxic reactions, but may occasionally do so.

Methylthiouracil is reported by A. Wilson, 1946, to produce a more rapid response than thiouracil in thyrotoxicosis, with less toxic effects. Smaller doses suffice for maintenance.

Aminothiazole ("Abadol") has been used in France. Four tablets of 0.1 Gm. daily for three to four weeks markedly improve thyroid toxicosis. No untoward effects have been reported (J.A.M.A., 1945, 129:761; M. Perrault and Bovet, 1946).

Thiobarbital is about twice as potent as thiouracil on patients (Astwood, 1945), and with moderate doses on rats (E. B. Astwood, Bissel and Hughes, 1945). The clinical thyrotoxic manifestations are successfully controlled by 0.1 to 0.4 Gm. daily, but there is a high incidence of complications, including granulopenia and acute liver disorder.

Para-Aminobenzoic Acid ("PABA") has been used in human thyrotoxicosis as the sodium salt, up to 1.5 Gm. daily and up to nine months. It appears to be slower, but equally effective as thiouracil and is less toxic. Patients remained well four to fifteen months after discontinuing the administration (L. Berman, 1945).

"*Promizole*" is the most active of the sulfone goitrogenic agents, but its potency is only a fifth of thiouracil. Sulfides are more potent than sulfones (D. A. McGinty and Bywater, 1945).

Thiourea (Thiocarbamide), 1 to 2 Gm. daily, is as effective as thiouracil against thyrotoxicosis, and has a similar toxicity (C. R. St. Johnson, 1944). It is not used, as it gives a characteristic odor to the breath and its taste is disagreeable (E. B. Astwood, 1943).

The toxicity of thiourea for animals is usually low (also that of *thiuramdisulfides;* Hanzlik and Irvine, 1921). Rats consumed for more than three years 25.5 mg. per Kg. of body weight daily (less than is usually required to produce marked thyroid hyperplasia) without any significant effects on growth, mortality or pathologic changes attributable to the thiourea (A. Hartzell, 1945). Antithyroid doses interfere with reproduction, but this returns to normal when administration is stopped. If it is fed to lactating mothers it is excreted by the milk so as to produce thyroid hyperplasia and retarded growth in the young (E. D. Goldsmith *et al.*, 1945). In adult rats, thiourea may produce neutrophilic *granulopenia,* which may be prevented by the simultaneous administration of liver (E. D. Goldsmith *et al.*, 1944). The *acute toxic phenomena* are chiefly pulmonary congestion and edema (J. B. MacKenzie and MacKenzie, 1943). The toxicity is greatly increased by thyroid feeding, and decreased by thyroidectomy. Adrenalectomy does not increase the incidence (D. Marine and Bauman, 1945). Potassium iodide protects against the acute thiourea toxicity; the chloride and bromide do not. The toxicity and the protection are not related to the thyroid effect (W. E. Griesbach *et al.*, 1944). The thiourea hyperplasia disposes rats to the production of *thyroid cancer* by 2-acetoaminofluorene (F. Bielschowsky, 1944). Thiourea is an effective *antioxidant.* It may be used as stabilizer in solutions of ascorbic acid (W. R. Fearon, 1942), epinephrine, metycaine, and so forth. Dipping sliced apples in 0.1 per cent thiourea solution prevents their browning. Thiourea inhibits the growth of gram-negative bacteria (L. Weinstein, 1946).

Like thiouracil, thiourea produces fatal lesions of the suprarenal cortex in rats (G. E. Glock, 1945).

Fate.—Thiourea is rapidly absorbed, widely distributed, and promptly excreted by the urine. The urine clearance is close to urea. About 25 per cent is recoverable from the urine after administration of 1 Gm. to man. The remainder is for the most part broken down; none is excreted in the feces. The concentration in the milk approaches that of the serum (L. C. Chesley, 1944; R. H. Williams and Kay, 1945). Patients receiving up to 2 Gm. orally have blood levels of less than 5 mg. per 100 cc. (D. Campbell *et al.*, 1944). When injected into dogs, it appears to be distributed in concentration corresponding to the total volume of body water, rather than of extracellular water, so that it must enter cells freely (T. S. Danowski, 1944).

Thiourea Derivatives as Rat Poisons.—The pulmonary edema which was mentioned under thiourea is also produced by a number of its derivatives, rendering them acutely fatal, especially to certain strains of the Norway rat. This was noted accidentally with *phenylthiourea* by C. P. Richter, 1945, who investigated a large series of these compounds and found "ANTU" especially practical for community rat extermination.

Alpha-naphthyl-thiourea (ANTU) compares favorably with other rat poisons in cost, toxicity, and voluntary acceptance by rats. It is considerably more toxic to Norway rats than to other animals, killing them by pulmonary edema and pleural effusion. Dogs are fairly susceptible, but are generally protected by vomiting. No human fatalities occurred in three years of extensive use in Baltimore. Treatment would be by liberal gastric lavage, the substance being very little soluble. No antidotes are known (review, F. S. Philips, 1946).

The LD_{50} for Norway rats by stomach tube is 7 mg. per Kg. of body weight. Mice and dogs rank next in susceptibility; Alexandrine rats, squirrels, and so forth, are much more resistant. The cause of these differences is not known.

The action is presumably on some enzyme system. It involves greatly increased lymph flow from the lungs and heart. The heart muscle and the lung capillaries do not appear to be affected. The temperature is lowered. Nonlethal doses stop hair growth and skin pigment production. These resume when the administration is stopped (C. P. Richter, 1945). There is marked increase of *blood sugar,* to nearly three times the normal level in two and a half hours, with severe fall of liver glycogen, and failure to deposit liver glycogen. Cysteine affords considerable protection against the toxicity (K. P. DuBois *et al.*, 1946). Adult Norway rats show acute toxic effects when 100 ppm are added to the diet, and 0.1 per cent is uniformly fatal. Intermediate doses, to 800 ppm, develop a high degree of tolerance, sometimes to fifty times the ordinary fatal dose, owing partly to refusal to eat freely. The tolerance decreases in a few weeks if the drug is withheld (C. P. Richter, 1946; F. S. Philips, 1946).

Chronic poisoning, secured by 50 to 800 ppm continued up to two years, produces stunted growth, "spectacle eyes," thinning and coarsening of hair, deformities of the legs and feet, hyperplasia of the thyroid and splenic pulp, hyaline changes in the hepatic cells, decreased thickness of adrenal cortex, and calcified tubular casts (O. G. Fitzhugh and Nelson, 1947).

With *dogs,* death occurs by pulmonary edema with pleural effusions, attributed to damaged capillaries. The effusions show increased albumin: globulin ratio. Feeding gradually increases the tolerance (A. Chanutin *et al.*, 1947). Continued administration to *cats* produces fatal intrahepatic obstructive jaundice, without pulmonary lesions.

Phenylthiocarbamide generally kills rats by pulmonary edema, two to eighteen hours after administration of 1 mg. Repeated administration develops considerable tolerance. Thyroid hyperplasia ensues (C. P. Richter and Clisby, 1942).

Dithiobiuret, when administered orally for several days, produces progressive paralysis of skeletal motor function in rats. This may be maintained for weeks by adjusting the dosage, and recovery occurs promptly if the administration is discontinued. A single hypodermic injection does not produce the paralysis even with a dose twenty times as great as the total cumulative oral dosage. The muscle and nerve of the paralyzed animals respond normally to direct stimulation; the acetylcholine and cholinesterase content are normal; the paralysis is not relieved by neostigmine. The action must therefore be central (E. B. Astwood, Hughes *et al.*, 1945).

◆

THE REACTION OF THE BODY (REMOTE EFFECTS OF ACIDS AND ALKALIS)

The $H(^+)$ ions of acids and $OH(^-)$ ions of bases part readily with their electric charges, and therefore alter the state of colloids. In this way, and also by direct chemical changes, they produce extensive alterations in the functions of cells, which would be rapidly fatal if they exceeded a certain degree. These effects are produced only by the dissociated ions, which represent the *actual* acidity and alkalinity. The activity of an acid or base depends therefore not only on its total concentration, but also on its dissociation. The mineral acids, which dissociate freely, are much "stronger" than equimolecular solutions of the organic acids or acid salts, which dissociate only slightly. Undissociated molecules do not exert these actions, but neutralize added acid or alkali, in proportion as the free ions become combined, and in *this* respect are equivalent to the dissociated ions. They may be considered as *potential* acidity or alkalinity.

(Conçepts of *p*H are reviewed by A. G. Ogden, 1947.)

The *normal reaction* of the living tissues and fluids within the body proper is near neutrality, that of the fluids inclining a trifle to alkalinity (*p*H = 7.1 to 7.8, generally 7.35 to 7.43). The digestive juices and urine are the only fluids in higher animals which normally depart from this rule. The neutrality of the blood is maintained even in acidosis; although the cells where the pathologic acid is formed presumably develop increased acidity. Normal living cells have an alkaline, neutral or slightly acid reaction, judging by *intra vitam* stains.

Regulating Mechanisms.—Metabolism leads to the production of acids (carbonic, lactic, sulfuric, phosphoric, and so on) which would tend to increase the acidity of the body. The carbonates derived from the combustion of vegetable salts would tend to render it alkaline. The maintenance of the normal, nearly neutral reaction is regulated with great nicety, however, by the use of several mechanisms. The carbonates and alkaline phosphates of the blood and tissues constitute a stock of potential alkali, and the carbonic acid and acid phosphates of potential acid. These are sufficient to "buffer" at once all ordinary attempts to change the actual reaction. The amphoteric character of the proteins permits them to neutralize a limited quantity of either acid or alkali. The administration of acid or alkali by mouth therefore does not change the *actual* reaction of the blood and tissues, but only the *potential* acidity or alkalinity, *i. e.*, the *alkali reserve.* The final restoration of the total acid-base equilibrium is accomplished by the excretion of CO_2 by the lungs, of acid or base by the urine, and by the adjustment of the ammonium-urea metabolism.

Reaction of Normal Blood.—The *p*H of fresh defibrinated blood is weakly alkaline, almost neutral, 7.45 for arterial, 7.3 for venous (Hasselbach, 1913); 7.6 to 7.8 for human serum, 7.4 to 7.6 for oxalated blood (Levy, Rowntree and Marriott, 1915), at air temperature; at 37° C. the alkalinity would be about 0.1 higher. In normal animals, feeding with acids or alkalis has practically no effect on the H concentration of the blood. Even when symptoms of acidosis are present, the alkalinity is but little decreased (*p*H of serum, 7.2 to 7.5; Levy *et al.*). Under alkali therapy, this is restored toward normal. Intravenous injection of acid into dogs or rabbits produces death when *p*H 6.9 is reached (Levy *et al.*). Concentrations above *p*H 8 are probably also fatal (Rowntree).

Buffering Mechanisms of the Blood.—It is relatively difficult to alter the reaction of blood even *in vitro.* Friedenthal, 1903, showed that serum requires, to secure a given change of reaction, thirty to forty times as much NaOH, and three hundred twenty-seven times as much HCl, as would be needed in water. This stability is due to the presence of the salts of weakly dissociating acids, which limit the liberation of $H(^+)$ ions to practical neutrality. This property is especially marked with phosphates and carbonates, which are important "buffer" constituents of the serum. The proteins act similarly. The chief alkaline buffer of the serum is the bicarbonate. *In whole blood*, the corpuscles play an important part in buffering, not inferior to that of the plasma, both in carrying and in releasing CO_2, their hemoglobin acting as a weak, polybasic acid which binds alkali, but releases it readily to carbonic acid. This function is enhanced by the special permeability of the corpuscles, which permits the passage of CO_2 and of HCO'_3, Cl' and H^+ ions, but not of Na^+ or K^+ ions.

Oxyhemoglobin is a stronger acid than reduced hemoglobin, and this plays a part in the *gas exchange:* In the lungs, the oxygenation of the hemoglobin acts as an acid and helps to expel CO_2; conversely, increase of CO_2 or lowering of the *p*H diminishes the affinity of hemoglobin and oxygen, and therefore raises the oxygen pressure in the capillaries. The carbon dioxide itself forms a readily dissociated combination with hemoglobin (*carbhemoglobin*), by a carbamino linkage, NH.COO, which binds and releases some 5 to 10 per cent of the total CO_2 of the blood. Finally, the corpuscles contain a catalyst, *carbonic anhydrase*, which speeds the dehydration of H_2CO_3 to CO_2. This is important for the prompt release of CO_2 in the lungs. If as much CO_2 as possible has been extracted from serum by a vacuum, considerably more is liberated by adding corpuscles, as if these acted like an acid (review, Roughton, 1935).

***p*H of Other Body Fluids.**—With few exceptions these have about the same reactions as the serum (Michaelis, 1914). Hanzlik, 1914, found the *p*H of *edema and pleuritic fluids* about 7.1; ascitic fluid, 7.42; *milk*, about 7; *cerebrospinal fluid*, between 6.98 and 7.3.

Human *sweat* is acid, with *p*H as low as 4.4, owing to fatty acids and to acid phosphates.

Digestive secretions have normally the following *p*H: *Saliva*, human, mixed, 5 to 8, generally about 6.9; fairly constant for the same individual, somewhat lower at night (L. I. Grossman and Brickman, 1937). *Gastric juice*, normal average, 1.77; *Intestinal* juice, 8; more alkaline in the ileum and colon than in the jejunum (de Beer *et al.*, 1935), the secretion of Brunner's glands is also alkaline (Florey and Harding, 1934). *Bile*, when flowing directly from the liver, is nearly neutral (0.07 to 0.2×10^{-7}). That from the gallbladder is more variable. S. Morrison *et al.*, 1938, report the following averages for normal gallbladder bile: dogs, 6.2; human, 7 to 7.5; rabbits, 8.8; guinea pigs, 8.9. It may become slightly acid on prolonged sojourn (Okada, 1915; Quagliarello, 1916).

The ***p*H of the contents of the digestive tract** may differ materially from that of the digestive juices, since these tend to be neutralized by each other, as well as by the buffer action of proteins. Bacterial activity may also introduce modifications.

Mouth.—The reaction may be made acid by regurgitation from the stomach, or locally by acid fermentation about the teeth. This may be a factor in dental caries, but its actual significance is in dispute (review, J. A. Marshall, 1939). *Gastric juice* has a normal average *p*H of 1.77.

Stomach.—The resting empty stomach may be nearly neutral. During the first one and one-half to three hours after a meal, the acidity rises rapidly to *p*H = 2 or even 1, depending on the individual. It then remains stationary until nearly all the food has left the stomach (McClendon, 1915). Excessive acidity is prevented by regurgitation of the duodenal contents (C. Bolton and Goodhart, 1936).

Duodenum.—The reaction of the duodenal contents is the resultant of the neutralization of the acid chyme by the slightly alkaline intestinal and pancreatic juice and bile. The actual *p*H of the duodenal contents is usually quite acid.

Myers and McClendon, 1920, found the usual reaction in man to be between *p*H = 3.2 and 5. With trained fistula dogs, Bollmann and Mann found the *p*H 7.5 when fasting, quiet and resting; on working with the dog, it soon became acid, 4.5; and in digestion 3.0. On feeding milk, it was generally about 5.0.

Small and Large Intestines.—The contents are normally slightly acid throughout the small intestines. The old opinion of the alkalinity of the intestines was based chiefly on unjustified deductions from the secretions. The *p*H of the human jejunum is from 3.8 to 7.8, mean 5.8 (Long and Fenger, 1917); the jejunum and ileum are probably from 6.0 to 8.0.

In hogs, Long and Fenger, 1917, found that the *p*H in the upper third of the small intestine ranged from 6.6 to 7.4, mean 6.7; in the middle third, 6.5 to 7.6, mean 6.9; in the lower third, 6.4 to 8.1, mean 7. Similar figures were obtained in calves, lambs and dogs. They have been confirmed by McClendon *et al.*, 1920, and by others.

Other mucous membranes generally approach neutrality. The *vagina* is an important exception, its normal *p*H being about 4.

The **reaction of urine** usually inclines toward actual acidity, the normal *p*H range in man being 5.12 to 7.46, the average about 6.03. The acidity decreases during the secretion of acid gastric juice, fasting and perspiration (Haskins, 1914). It exceeds 5 in less than 1 per cent and 5.3 in less than 10 per cent. The highest acidity reported is 4.7 (L. J. Henderson and pupils, 1914). The reaction is determined mainly by the ratio of phosphates. It may be readily altered by the administration of acids or alkalis, and is an important mechanism for regulating the acid: base balance of the body. The glomerular filtrate has the neutral reaction of the plasma. The acid reaction is effected by carbonic anhydrase (R. F. Pitts and Alexander, 1945); in the distal tubules if the acidification is moderate, extending to the proximal tubules if the acidity is high (P. Ellinger, 1940).

The **tissues** contribute but little to the buffering of the body (Brocklehurst and Henderson, 1927; Rous, Drury and Beattie, 1927).

The *p*H *of cells and tissues* is estimated as 6.6 for parenchymatous tissues, 7.2 for connective tissue (Rous *et al.*, 1927). *Muscle tissue* has the *p*H of 6.6 to 6.7, which is not altered by changes in the surrounding medium between 5.2 and 8.2 (Schmidtmann, 1924), but becomes acid in rigor. Impairment of circulation, as in *inflammation*, increases the acidity of tissues, as does *necrosis*. The *p*H of cytoplasm is from 6.8 to 7.2; that of the nucleus is from 7.6 to 7.8 (R. Chambers, 1942). In *hen's egg*, the *p*H of the yolk is 6.38, the white 8.70 (Capraro and Fornaroli, 1939). In large amebae the liquid of the vacuoles has a different reaction from the cytoplasm (Scarth, 1924). *Plant cells* may reach the acidity of *p*H 3, as shown by their colors, which are natural indicators (Haas, 1916). These have been utilized for observing the *penetration of acids into living cells.* E. N. Harvey, 1914, employed a holothurian, Stichopus; W. J. Crozier, 1915, a nudobranch, Chromodoris; A. R. Haas, 1916, used plants, pelargonium and blue hyacinth. Their results show that the penetration of acids into living cells is slight and does not depend simply on ionization, but that other factors are involved, such as the binding of the substance within the cell. M. Irwin, 1922, showed that the rate of penetration is generally inverse to the H ion concentration. Osterhout, 1914, had found that very dilute acids decrease the permeability of Laminaria, but that this increases when toxic concentrations are reached. The differences in penetration are illustrated by the *sensory effects,* the *sour taste,* or the retraction reactions of earthworms (Crozier, 1918), which are not strictly proportional to the *p*H. Weak acids and weak alkalis generally produce much more stimulation than would correspond to their *p*H. The threshold acid taste is 0.001N for hydrochloric acid; 0.00035N for acetic acid, and 0.00003N for carbonic acid; an efficiency ratio of 1:3:30. Dissolved *carbon dioxide* enters living cells much more readily than ionized acids, presumably as dissolved, unhydrated gas. By hydrating within the cell, to form $H.HCO_3$, it increases the H ion concentration more than does exposure to other acids (Jacobs, 1920; Osterbon and Dorcas, 1925). H_2S similarly enters as the undissociated dissolved gas and not as sulfide ions. Oxygen also enters cells freely (E. N. Harvey). Of *alkalis,* NH_4OH (or more probably NH_3) enters 90 to 100 times more readily into living cells than does NaOH; indeed, the latter enters practically only after injury (Haas, 1916). As ammonium penetrates much more readily than Cl ions, cells laid in NH_4Cl solution become alkaline, although the solution itself is acid (Jacobs, 1922).

The sour taste thresholds of hydrochloric and sulfuric acid solutions are not entirely parallel to their *p*H, so that some other factor enters (R. B. Malmo and Ellis, 1941).

Restoration of the Potential $H^{(+)}$ and $OH^{(-)}$ Ions.—The regulating mechanism of the blood is important for protecting the body against sudden changes, for meeting temporary emergencies. However, this impairs the stock of potential $OH^{(-)}$ and $H^{(+)}$ ions, and therefore would not furnish permanent protection. Other mechanisms are called into play to restore the normal ratio of these potential ions, mainly by regulating the excretion of CO_2 through the lungs, by varying the reaction of the urine, and by the more or less complete conversion of NH_4 into urea.

Regulation by Excretion of CO_2.—Addition of acid to the blood liberates CO_2 from the bicarbonate. This increases the CO_2 tension, and thus its excretion by the lungs. The increased CO_2 tension stimulates the respiratory center, and thereby hastens the elimination. This restores the normal ratio of $H_2CO_3 \div NaHCO_3$. Conversely, the addition of alkali diminishes the tension of CO_2 and thus its excretion.

Regulation by Combustion of Organic Acids.—The organic acids arising in metabolism are normally oxidized to CO_2 and H_2O, and excreted by the lungs and urine. This mechanism is disturbed in disease, starvation, and so forth, and then gives rise to acidosis. Conversely, the injection of alkali materially increases the excretion of unoxidized lactic acid by the urine (Macleod and Knapp, 1918).

Regulation by the Urine.—The urine, like the blood, contains a mixture of acid and neutral phosphates (Orth found a mean of 60 per cent as MH_2PO_4 and 40 per cent as M_2HPO_4). When acid is introduced, the ratio of acid phosphate is increased; alkalis increase the proportion of alkaline phosphate. This elimination of the excessive acid or alkali ions rapidly restores the potential acidity or alkalinity of the tissues. The flow of urine is also increased, so that acids and alkalis act as *diuretics.* The administration of acids first increases the PO_4 excretion; later, this decreases with the available supply of these ions (Fitz *et al.*, 1907). Under normal conditions, the human kidneys free the body of 60 to 70 cc. of normal acid per day. In diabetic coma, this quantity may be increased ten times (Henderson and Palmer).

Bicarbonate Regulation.—R. F. Pitts and Lotspeich, 1946, report a fixed renal threshold of about 25 millimols per liter of plasma, below which practically all the bicarbonate of the glomerular filtrate is reabsorbed. That above this concentration is excreted as a linear function of the plasma concentration, and is therefore relatively independent of the glomerular filtration rate.

Mineral Metabolism in Experimental Acidosis of Rabbits.—Goto, 1918, administered 25 to 75 cc. of N/4 HCl daily for one to four weeks. Most of the animals that received more than 25 or 30 cc. per day died within one to two weeks. The major alkali reserves were utilized in the following order: first the plasma bicarbonate; then the alkaline carbonate and phosphate of the muscles; and the calcium carbonate of the bones.

Regulation by Ammonium Metabolism.—In man and in the carnivorous animals the more or less complete conversion of the ammonium ion into the neutral urea also serves to regulate the alkali balance. If the acidity tends to rise, a larger part of the ammonium is left unconverted, and is used to neutralize the excessive acid. If the alkali tends to rise, more of the ammonium is converted, leaving its anion to neutralize the alkali. The ratio of unconverted ammonia (reflected in the ratio of NH_4 to total N of the urine) rises if acids are introduced (Walter, 1877), or formed in the organism (acidosis); and is lowered when alkalis are administered (Janney, 1911). After large doses of alkali, ammonium disappears completely from the urine. The administration of ammonium chloride increases the acidity of the urine, since the formation of urea releases unbalanced Cl^- ions, which convert Na_2HPO_4 into NaH_2PO_4 (Haldane, 1921).

Acidosis or acid intoxication arises clinically when the elimination of acid fails to keep step with its production. The inadequacy of elimination may be respiratory, circulatory, renal or metabolic, the latter by failure to burn organic acids to the more easily eliminated CO_2. Acidosis therefore occurs in asphyxia, in cardiac decompensation, in shock and with capillary poisons, nephritis and diabetes mellitus. It occurs also in healthy individuals by excessive exercise or by alterations of pulmonary ventilation. It may be induced by the administration of acids or acid-forming drugs. So long as there is an adequate store of potential alkali, the actual reaction of the blood is not materially changed, although its carbonate content is lowered. This decrease of reserve alkali without decrease of *p*H constitutes *compensated acidosis* (Rowntree, 1916). The diminished reserve probably alters the *p*H of the tissues, as it gives them less concentration gradient for buffering. The symptoms of acidosis develop and the acidity and the ammonium content of the urine increase. *True acidosis*, an actual fall in the *p*H of the blood below 7.4, occurs only when death approaches and the impaired respiration fails to remove the carbon dioxide. Actual acidity of the blood, with *p*H below 7, is not seen clinically.

The alkali reserve of the blood may be judged indirectly by the alveolar CO_2 tension, and by the "*alkali tolerance test*": When the bicarbonate of the blood is lowered, a larger dosage of alkali is required to change the reaction of the urine to alkaline than is the case normally. This increased tolerance for alkali is a delicate index of decreased potential alkalinity of the body and therefore of even slight degree of acidosis, including renal acidosis; and an equally reliable criterion of the progress of the acidosis and of the need of alkali therapy (Palmer and Henderson, 1913). It is misleading if there is marked renal insufficiency.

Ketogenic acidosis is a special type due to failure of complete combustion of the fatty acids with an even number of carbon atoms, the ketone acids, betahydroxybutyric, acetoacetic and propionic, and acetone. These are produced chiefly by the liver (Chaikoff and Soskin, 1928), as part of its fat metabolism, and burned normally by extra-hepatic tissues, especially muscle, as a source of energy (I. A. Mirsky, 1942). Their production is increased when additional fat is burned to take the place of deficient carbohydrate contribution (A. H. Neufeld and Ross, 1943). Part of the additional acid escapes combustion and passes into the urine (Stadelmann, 1883) and causes acidosis (Minkowski, 1888), including increased ammonium excretion. This occurs in starvation (Benedict and Osterberg, 1914) or on fat-rich diet, in diabetes mellitus when this is not adequately treated, and in hepatic disorders (Mottram, 1915; Woodyatt, 1916). Diabetic coma usually involves acidosis (Stadelman, 1883), and before the introduction of insulin it was treated with alkali (F. Walter, 1877; Magnus-Levy, 1899).

Ketone substances may also be formed from leucine and tyrosine, and therefore from protein, but not from carbohydrates. The agents that can give rise to the ketone substances are called *ketogenic;* those that tend to prevent this are *antiketogenic* (review, S. Soskin and Levine, 1944).

Toxicity of Ketone Substances.—Salts of the ketone acids stimulate the respiratory center materially more than salts of other organic acids (Tiemann, 1930). Ehrmann, Esser and Loewy, 1911, claimed that the injection of neutral oxybutyric salts produces coma, so that the diabetic coma would not be a pure acidosis.

Symptoms of Acidosis.—The first clinical sign of moderate acidosis is the hyperpnea, required to eliminate the liberated CO_2 (Douglas and Haldane, 1901; Winterstein, 1915). When the actual reaction of the blood becomes noticeably changed, the vasomotor and other medullary centers are also stimulated, especially if the change is acute, as with intravenous injection of acid. With further rise of the H ion concentration, the nervous centers become depressed, as does also the cardiac muscle. The effects agree with those of excessive CO_2 tension, asphyxia, oxygen deprivation, and diabetic coma, which are really forms of acidosis. The final symptoms are coma, convulsions, depressed respiration and fall of blood pressure. Death takes place by respiratory paralysis, generally before the blood becomes actually acid. The respiratory stimulation is mediated partly through the carotid sinus (Heymans *et al.*), but is chiefly a direct action on the respiratory center (C. F. Schmidt, 1932). Even if the *p*H of the blood is not altered, the diminution of reserve alkali may result in a local acidosis of the cells of the respiratory center, since the gas metabolism of nerve cells is nearly a hundred times as great as that of muscles (Alexander, 1912).

Role of H Ion Concentration and Carbon Dioxide.—In general, the respiratory stimulation is proportional to the H ion concentration (Winterberg; T. B. Robertson, 1912). However, carbonic acid stimulates more than would correspond to its acidity (Kopaczewski, 1914). R. W. Scott, 1918, found that excess of CO_2 stimulates respiration even if the blood is made distinctly more alkaline ($pH = 7.65$), as by sodium carbonate injection. The greater efficiency of carbonic acid is probably due to more ready penetration into the cells as CO_2, with subsequent hydration and ionization; so that it is toxic even from solutions in which it is buffered to neutrality (tadpoles, M. H. Jacobs, 1919; asterias and arbacia ova, H. W. Smith and Clowes, 1923). The factor of penetration probably also modifies quantitatively the action of *other acids*. The organic acids generally penetrate, as unionized molecules, better than do H ions.

Circulation.—Acidosis, especially when it is induced acutely, raises the blood pressure by stimulation of the vasomotor center, partly directly, partly by the carotid sinus reflex (Pilcher and Sollmann, 1915; Heymans *et al.*, 1932). The heart is affected through the blood pressure changes, the sinus reflex and venous return (review, Wiggers, 1929).

Intravenous injection of dilute acid produces flocculation of the plasma proteins, and therefore colloidoclastic reactions predominate over the acidosis. This has been employed against infections; but as the amount of flocculation cannot be controlled, it seems an undesirable form of nonspecific therapy.

In clinical practice, hydrochloric acid, 1:500 to 1:1000, is injected slowly, beginning with 2 to 3 cc. and increasing to 10 cc., every second to seventh day. It has been reported that it hastens recovery from aliphatic narcosis (McGilora, 1934), but the claim has not been confirmed by later workers (Shambaugh and Boggs, 1934; Kinard and Erve, 1935). The intravenous injection of 0.5 cc. of normal lactic or other acid per kilogram of dog produces, however, a marked increase of the rate and amplitude of respiration (S. J. Cohen, 1918). The *toxicity of acids* varies greatly according to conditions. In cattle, for instance, Berg, 1915, sometimes found considerable tolerance (0.87 Gm. of HCl as 0.9 per cent intravenously per kilogram).

The effects of pH on excised organs are important for experimentation, but not in the body, since they require greater changes of *p*H than occur during life.

Hydrogen Ion Concentration of Perfusion Solutions.—Distilled water, if carelessly prepared or if stored, becomes distinctly acid (*p*H about 6.3), and imparts this acidity to sodium chloride or glucose solutions prepared from it (J. R. Williams and Swett, 1922). The balanced solutions contain sufficient alkali to overcome this. The *p*H of Locke's solution is about 7.5, but it has a low buffer value. That of Tyrode's solution is 8 to 8.1 (G. G. Roth, 1917). Only bicarbonate can be used for buffering, as other buffer ions precipitate or disionize calcium.

Frog's Heart.—The automatic contractions continue only within certain ranges of H concentrations, which differ for the various portions of the heart (Dale and Thacker, 1913). The sinus requires the highest H ion concentration, the ventricles the lowest. O. W. Barlow, 1929, found *p*H 7.2 optimal for perfused frog heart.

Perfused Terrapin Heart.—Hydrogen ion changes within the physiologic range produce definite effects. *Increased alkalinity* (*p*H 7.6 to 7.8) increases tonus, especially of the auricles, and diminishes the excursions. *Diminished alkalinity* (7.3) increases the output, by increasing the amplitude of the beats and diminishing the tonus (Andrus, 1919).

Isolated Mammalian Heart.—The effects of oxidizing substances, acids and alkalis are described by Loevenhart and Eyster, 1913. Yanagawa, 1916, reported the coronary vessels constricted by increase of alkalinity, dilated by acidity. The *coronary vessels* of the perfused heart are dilated by acids, CO_2 being especially potent (Berthier and Gley, 1939).

Lymph Flow.—Yanagawa, 1916, found the thoracic lymph flow unaffected by the intravenous injection of acids, to the point of toxicity. Alkalis acted only like neutral salts.

Smooth Muscle.—Increase of acidity depresses, relaxing the tonus and weakening and slowing the rhythmic contractions. Higher concentrations produce death in the relaxed state. Increased *alkalinity* quickens the rhythm, but may diminish the excursions. The effects are independent of the innervation and are therefore directly muscular (Evans and Underhill, 1923).

Peripheral Action on Vessels.—Weak acids tend to relax and alkalis to constrict (Gaskell, 1880 to 1882; Schwarz and Lemberger). However, the *p*H changes necessary for these effects lie far outside the variations that can occur in the living body. Excised arterial rings do not respond satisfactorily to acid (I. Adler, 1916). Atzler and Lehrmann, 1921, claimed that the greatest dilatation of frog vessels occurs about *p*H 6. *Capillaries* are also dilated, but this also requires concentrations not reached in life (Krogh).

Excised intestines, of rabbits or cats, suspended in Ringer's solution are depressed progressively by increase of acidity. They are arrested about *p*H 6.2 to 6.0. If the acidity is produced by CO_2, recovery occurs more promptly when the neutral reaction is restored. Increase of alkalinity stimulates the intestine progressively up to *p*H 8. When added as $NaHO_3$, the stimulation is perceptible at 0.008 per cent, increases to 0.04 per cent, and becomes spastic about 0.08 per cent. Higher concentrations depress (Oettingen *et al.*, 1928). Gaseous CO_2 depresses frog's intestine in a moist chamber (Hooker, 1912). In intact dogs, intravenous injection of sodium bicarbonate (50 cc. of 2.5 to 6 per cent solution) produces stimulation (King and Church, 1922). *Excised uterus of guinea pig* has its response to pituitary stimulation decreased by increase of bicarbonate, and enhanced by CO_2 (Hastings and Van Dyke, 1927). *Excised ureter* movements are depressed by acid, stimulated by alkalinity (G. B. Roth, 1917). Alkalinity increases the motility of *spermatozoa* (Virchow, 1854); diminishes the rhythmic movements of *medusae* (Bethe, 1909); increases the resistance of *fundulus* to lack of oxygen (Packard, 1906). *Striped muscle* is relatively insensitive to small changes of *p*H. When immersed in somewhat higher concentrations of *acid*, there is an initial increase of tension, which is reversible; and then a slower, irreversible shortening, which constitutes rigor. These effects occur in narcotized muscle and are not conducted to parts of the muscle that are not immersed. They are due to precipitation of the muscle protein (Ranke, 1865; Burridge, 1910; Verzar *et al.*, 1922). Alkalinity beyond the physiological limit (*p*H = 9) increases the excitability of the *myoneural junction*, in frogs (M. H. Grant, 1920).

Metabolism.—The administration of nontoxic doses of acids and bases (to dogs) does not materially alter the balance of N, Ca, Mg or P (Givens and Mendel, 1917). It alters the ammonium metabolism. Acidosis tends to *mobilize calcium*, lead and similar elements from *trabecular bone.*

Doses as large as 13 Gm. of sodium carbonate, 20 Gm. of sodium bicarbonate, or 40 Gm. of sodium citrate do not influence the total nitrogen excretion. Macleod and Haskins, 1906, found increased elimination of endogenous *uric acid* and purines. Abl, 1913, attributed this to the intestinal derangement. The alkalis, especially potassium bicarbonate, acetate and citrate, had some reputation *in acute and chronic rheumatism*, and gout, but their efficiency is questionable. There is no good foundation for the assumption that they increase the oxidation of uric acid or its solubility in the tissues.

The **use of alkalis against acidosis** requires rather large doses, administered as sodium bicarbonate or acetate or citrate. For long-continued administration, it may be supplemented by calcium carbonate and magnesium oxide. The carbonate can take up more carbonic acid than bicarbonate, but this advantage is illusory, for the ratio of carbon dioxide and carbonate is immediately adjusted in the lungs to the normal equilibrium (Sellards).

Administration and Dosage in Acidosis.—The use of alkali should begin as soon as the acidosis is recognized and not delayed until coma has set in, for it may then be too late. The initial daily dose of sodium bicarbonate by mouth may be 30 to 45 Gm., in divided doses and freely diluted, best between meals. This may be raised to 100 Gm. or more. (The equivalent of 30 Gm. of sodium bicarbonate by oral administration is furnished by each of the following: sodium acetate or citrate, 40 Gm.; calcium carbonate, 15 Gm.; magnesium oxide, 7 Gm.)

After coma has set in, 4 per cent sodium bicarbonate solution may be administered by the drop enema; but this may not secure sufficient absorption, and then requires to be supplemented by intravenous injection, generally of 5 per cent bicarbonate. Generally, 500 cc. (containing 25 Gm.) injected slowly during half an hour is a safe maximum (Sellards). Larger amounts cause tetany. If the solution is sterilized by boiling, it loses CO_2 and forms carbonate, which produces hemolysis, perhaps also calcium flocculation. It would cause serious sloughing if it escaped into the subcutaneous tissue. A boiled solution may be restored to the proper reaction by passing CO_2, or adding HCl, until it is colorless to phenolphthalein.

Intravenous bicarbonate in shock and dehydration were thought to give better results than plain saline infusion, the rise of blood pressure being more sustained and the respiration deeper (Seelig *et al.*, 1913); but excessive doses of alkali result in alkalosis, and the advantages of intravenous injection are now considered doubtful.

Asiatic cholera results in considerable loss of reserve alkali, with the production of acidosis. It is benefited by the early administration of sodium bicarbonate, increasing the dose with the severity of the symptoms (Sellards, 1914). According to Brouardel ("Les Asphyxies," p. 11) alkaline saline intravenous infusions were successfully used in algid cholera by Lorain, 1866.

Alkalosis consists in excessive *p*H or bicarbonate, or both, in the plasma. It may arise clinically from excessive administration of alkali, especially of sodium bicarbonate as in the treatment of peptic ulcer; or from salts of organic acids which are burned to carbonate in the body. Fruits and green vegetables increase the alkali reserve. Alkalosis occurs also from the loss of HCl through persistent vomiting, progressing to fatal tetany (McCann, 1918; Hastings, Murray and Murray, 1921), and in nephrosis with hypertension even on a normal alkali income (Way and Muntwyler, 1930).

The *clinical symptoms of alkalosis* generally appear some ten days after beginning alkali treatment, with nausea and distaste for food, then headache of increasing severity, and weakness. More severe degrees develop *tetany*, uremia, edema and delirium. The plasma *p*H is high unless the alkalosis has been compensated. Plasma bicarbonate is high if the cause is excessive alkali income; it is normal or low in hyperemesis. The plasma chloride is decreased, the nonprotein and urea nitrogen are increased. The urine is alkaline and often contains albumin. The hemoglobin holds its oxygen more firmly than normal (Barcroft), tending to anoxia of the tissues. The kidney injury contraindicates the employment of large doses of sodium bicarbonate (not of calcium carbonate and magnesium oxide) in renal disease, especially since this impairs the elimination of the alkali and therefore tends to exaggerate the alkalosis.

Compensation of alkalosis is fairly efficient, so that serious degrees are not common even with rather reckless alkali administration, if the kidneys are sound. It is accomplished chiefly by the excretion of alkaline urine, increasing the ratio of its Na_2HPO_4 to NaH_2PO_4. This is aided by more complete oxidation of ammonium, by neutralization of proteins and by increase of unoxidized organic acid, especially lactic acid.

The injection of *lethal doses* of alkali produces tremors, rigidity; finally vomiting, convulsions, relaxation of sphincters; sometimes edema and ascites (Rowntree, 1916). An excessive intravenous injection of bicarbonate, in a human subject, was followed by tetany, with recovery (Harrop, 1919).

Therapeutic modification of urine reaction is used incidentally as *indicator* for the treatment of acidosis and alkalosis. The administration of either acid or alkali salts increases the *urine flow*, often considerably. Acid salts are markedly adjuvant to the diuretic effect of the mercurials, caffeine group and posterior pituitary solution (Tiffeneau *et al.*, 1931). Acidification of the urine renders it less favorable to *bacterial growth*, and greatly enhances the antiseptic potency of a number of other urinary antiseptics, especially methenamine and mandelic acid. Some mixed urinary infections resistant to acidification yield to *alternation*, every five to ten days, of acid and alkali reaction; but the efficiency is restricted, perhaps questionable. Acid urine irritates the bladder when this is inflamed, and alkalis give relief. Urate, oxalate and cystine *calculi* form only in acid, and phosphate calculi in alkaline urine. When they are present, or when the urine contains them habitually, the reaction that favors their formation must be avoided. The opposite reaction prevents their growth, although it does not dissolve those already formed (G. D. Oppenheimer and Pollack, 1937); alkalinization may, however, disintegrate the mucus and fibrin that cement them, and thus sometimes secure their evacuation.

Acid Irrigation of Phosphatic Renal Calculi.—These dissolve, although slowly, in 0.06 per cent HCl. Since this strength would be harmless, Geisinger *et al.*, 1918, suggested its use by continued irrigation, for stone in the renal pelvis or ureter. *Malic acid*, 1 to 3 per cent, has given some success, but continuous irrigation produces vesical and ureteral spasm (L. D. Keyser, 1935). *Sodium hexametaphosphate* is reported as the best solvent *in vitro* for phosphatic renal calculi (D. R. McCullagh *et al.*, 1941). *Magnesium citrate* solution may be used (H. J. Suby and Albright, 1943).

Ureter Flow.—In excised kidneys of rabbits, perfused with sodium chloride solutions, the ureter flow varies niversely to the H ion concentrations (Isaacs, 1917). In life, however, the conditions are much more complex.

Therapeutic Acidification of the Urine.—The reaction of the urine may be altered toward the acid side by the administration of mineral acids, but their scope is limited by their local actions. Larger changes are practical by the use of acid salts, such as sodium biphosphate, which combine considerable potential with a relatively low actual acidity; or by the administration of ammonium chloride, which leaves an excess of unbalanced chloride ions when the ammonium is dehydrated into the urea; or by ammonium biphosphate in the same dosage, which secures both actions (Alstead, 1936); or by calcium chloride, which also gives an excess of Cl ions, because part of the calcium is precipitated as carbonate in the intestines. All these are given in doses of 1 to 2 Gm., 15 to 30 grains, three to four times per day, in water or milk. The acidification of the urine does not surpass the normal upper limit.

For instance, the administration of the maximal dose of acid sodium phosphate raised the acidity from *p*H 6.7 to 5.8 (L. J. Henderson and Palmer, 1913); and from 7.2 to 4.85 (Hanzlik and Collins, 1913). Benzoates have a tendency to render the urine acid (Jordan, 1913); also boric acid, 2 Gm. daily (G. G. Smith, 1913); but these are not advised for therapeutic use.

Mandelic acid, $C_6H_5CH(OH)COOH$, was introduced by M. L. Rosenheim, 1935, as a practically nontoxic keto acid which is excreted unchanged in the urine and renders this bacteriostatic, especially if the reaction of the urine is kept fairly acid and the water intake limited. It is successful against some obstinate nonspecific urinary infections which resist sulfanilamide. Its occasional untoward actions are not serious, if it is used carefully, but it should not generally be employed when there is renal insufficiency (review, Braasch, 1937).

Historical.—A. L. Clark, 1931, 1935, reported the efficacy of ketogenic diet (poor in carbohydrate and rich in fat) in urinary infections, but as such diets tend to derange digestion and are difficult to apply this was considered a last resort, when all other measures had failed. A. T. Fuller, 1933, showed that the bacteriostatic effect of ketogenic diet is due to a special bactericidal action of *free betahydroxybutyric acid.* To be effective, this requires at least 0.5 per cent of the acid and *p*H of 5.5, and becomes more potent with increase of the acid and acidity (Helmholz and Osterberg, 1936). This suggested experimentation with other keto acids to Rosenheim.

Administration.—Mandelic acid is bactericidal to most organisms when its concentration in the urine is $\frac{1}{4}$ to 1 per cent, and the *p*H 5.0 to 5.7 (Helmholz and Osterberg, 1936). These conditions are secured clinically by the oral administration of 3 Gm. of mandelic acid four times daily, before meals and at bedtime; or preferably calcium mandelate, 2 Gm. every four hours for six doses daily; together with 4 to 8 Gm. of ammonium chloride per day, to acidify the urine; or ammonium mandelate may be administered directly, 3 Gm. three times daily in water. The taste of mandelates is unpleasant and difficult to disguise. Sodium mandelate may be given intravenously if there is much digestive disturbance (G. Caroll and Coleman, 1943).

Concentration of the mandelic acid must be secured by limiting the fluid intake to five glasses or less per twenty-four hours; failure is likely if this is neglected. The *p*H of the urine must be checked daily and kept at 5.5 or less, by administering additional ammonium chloride. With these conditions the urine usually becomes bactericidal within two or three days, and free from bacteria in six or seven days. It is rarely necessary to continue beyond twelve or fourteen days. If further administration appears advisable, a rest period of one or two weeks should be interposed as precaution against irritation. The treatment is successful in some 80 per cent of uncomplicated urinary infections, and some of the others are considerably improved. It is apparently most effective against coli and proteus ammoniae, and less so against staphylococci and pyocyaneus (Caroll *et al.,* 1936). It is more effective than sulfonamides against streptococcus fecalis. Even partial success is valuable in preparing the urinary tract for instrumentation and surgery. It acts only on the excreted urine, and not on the deeper tissues. *Untoward effects* are not common, nor serious. *Nausea* occurs in less than 1 per cent and is less severe than with ketogenic diet, but may force discontinuance with a few patients. *Diarrhea* occurs in some 10 per cent, but is unimportant. *Hematuria* (L. P. Dolan, 1936) is common but rarely gross, and ceases on suspending the drug. *Renal irritation* is doubtful; but a few hyaline casts are common, and dogs show a temporary rise of nonprotein nitrogen in the blood, after intravenous injection. Liver damage (fatty degeneration, especially of the Kupffer cells) has been reported; it may be due to an oxidation product, benzoylformic acid. Hepatic insufficiency is a contraindication, and administration should be stopped if icterus occurs (K. Meier, 1940).

Urinary Antiseptics.—The urine and the bladder may be disinfected to a considerable degree by drugs administered through the mouth. The efficiency of urinary antiseptics is naturally limited by the brief contacts. Comparative studies of their clinical efficiency were made by E. Davis and Sharpe, 1932, and N. F. Miller and Chu, 1934, the latter especially on the influence of water intake. Methenamine is highly effective in acid urine. Acriflavine is effective if the urine is alkaline. Hexylresorcinol is independent of the reaction, but of uncertain efficiency. Pyridium is generally ineffective. Sodium salicylate or benzoate, or salol, copaiba, cubeba, sandal wood and methylene blue were used against gonorrhea, and santal oil against staphylococci, but none of these are very effective (Hinman, 1915). Increased acidity of the urine also destroys bacteria. Dilute mineral acids, or acid sodium phosphate, may be used (Jordan, 1911), or a ketogenic diet. Periodic alteration of acid and alkali administration may be more effective. Penicillin and sulfonamides are especially effective in gonorrhea.

PREPARATIONS.—***Mandelic Acid,** U.S.P., racemic phenyl-glycolic acid. White crystalline powder. Gradually darkens and decomposes on exposure to light. Soluble in 6.5 parts of water, freely soluble in alcohol. Dose, 3 Gm. *Calcium Mandelate,* U.S.P., is only slightly soluble in cold water. Dose, 4 Gm. *Syrup Ammonium Mandelate,* N.N.R., corresponds to about 4 Gm. of mandelic acid in 10 cc. of the syrup.

Ketogenic diet in epilepsy has given variable results. Helmholz, 1930, reported 30 per cent freed from attacks, 20 per cent improved, 50 per cent unaffected. Notkin, 1934, observed increase in the number of convulsions in eighteen of twenty patients. Apperly and Norris, 1933, found that it produced alkalemia in three normal women. H. M. Keith, 1933, reported that injection of sodium acetoacetate prevents thujone convulsions in rabbits; also organic or hydrochloric acids, but less potently. To obtain the ketone effects, carbohydrates must be reduced to less than 20 or 30 Gm. per day, proteins to less than 60 Gm., and the ratio of molecules of fat to dextrose must be higher than 2:1. *Petit mal* and psychomotor seizures associated with slow-wave electrograms respond better to ketogenic diets. This may be connected with the acidosis, for promising results are reported for *dl-glutamic acid hydrochloride,* which has no effect on grand mal seizures (J. C. Price, Waelsch and Putnam, 1943).

Therapeutic Alkalinization of the Urine.—The administration of alkalis can increase the alkalinity somewhat beyond the normal range; *i. e.*, 20 to 40 Gm. of $NaHCO_3$ per day produced a maximal alkalinity of *p*H 8.7 (Henderson and Palmer, 1913); 4 Gm. changed the reaction from *p*H 6.5 to 7.4 (Hanzlik and Collins, 1913). About 5 to 10 Gm. of $NaHCO_3$, or 10 to 15 Gm. of sodium acetate or citrate, per day would be required to keep the urine of a normal individual alkaline. The acetate and citrate have an advantage in not upsetting the reaction of the digestive tract. For the urinary effect, alkalis should be taken especially at bedtime, since the night urine is most acid; not at mealtime, because the urinary acidity is lowest during digestion.

Alkali Injection in Nephritis.—Energetic alkaline therapy was advocated by M. H. Fischer, who conceives nephritis and edema as acidosis. The clinical results in the hands of others have often been unfavorable and sometimes dangerous (Newburgh, 1913). Renal injury spontaneous glomerular nephritis of dogs) renders the acid-base equilibrium unstable, so that it is easily upset by anesthesia, especially by chloroform. This results in more severe nephritis, anuria or failure to respond to diuretics (MacNider, 1918).

Bicarbonate Edema.—Large doses of sodium bicarbonate (about 20 Gm. per day) may lead to the retention of water and eventually to edema, in proportion to the dose (Hayem, 1890). This may occur in diabetic as well as in normal individuals (Beard and Rowntree, 1917). It is probably analogous to salt edema.

Alkalis and Salicylates.—The administration of sodium bicarbonate with inorganic salicylates tends to prevent the precipitation of the irritant salicylic acid in the stomach. It has been affirmed that it would also prevent the albuminuria and acetone that sometimes follow salicyl administration (Glungen, 1911); but it is ineffective for this purpose (Hanzlik).

Alkalis and Cinchophen.—These are often prescribed together, with the view of preventing the precipitation of the increased uric acid in the urine.

Local Actions.—Concentrated acids and alkalis are corrosive by destroying protein. *Dilute acids* precipitate protein and are therefore *astringent* and *styptic* (Hanzlik, 1918). Saturated or half-saturated solution of boric acid is used on congested mucous membranes, especially in *conjunctivitis.* Slightly more concentrated acids are irritant. Vinegar is applied locally to harden the skin in *hyperidrosis.* Salicylic acid and benzoic acid are used in dermatology to stimulate the skin and slowly to dissolve calluses. *Sodium carbonate* is strongly irritant, and corrosive if the contact is prolonged. *Dilute alkalis* swell and dissolve protein, particularly *mucus*, and at the same time increase mucus secretion through a mild irritation. Sodium bicarbonate or borate is useful as washes or gargles (1 to 4 per cent) in *catarrhal conditions;* as expectorants; in cystitis, dysentery, and so forth. The false membranes of diphtheria, croup, and the like, are composed largely of mucus, and may be broken down by alkalis. These may be applied by inhaling the vapors produced by slaking lime in the sickroom. Alkalis are applied to the *skin* to soften the crusts in eczema; as a soothing lotion in dermatitis and burns; and to relieve itching.

The **digestive tract** is largely governed by the hydrogen ion concentration of its contents, as to its motor activities, secretions, ferment actions and bacterial flora. This is especially important in the stomach and the adjacent duodenum. The administration of moderate quantities of dilute acid or alkali has little or no effect, however, on normal digestion, because they are buffered by the mucus and readily compensated by the secretions. They become important when the digestive tract, especially the stomach and duodenum, is not normal. **In the mouth,** acids have a characteristic "*sour*" taste, and are slightly astringent. This taste determines their use as flavors. They soften the enamel of the *teeth*, and should therefore be taken through a glass tube. They reflexly increase the flow of saliva, but this is of little practical importance. The addition of acid makes it easier to take larger quantities of cold water than could conveniently be taken without. They are therefore of therapeutic value in *fevers*, to obtain at the same time the refrigerant action of cold and the diuretic effect of large quantities of fluid.

In the stomach, acid is important for the digestion of proteins and connective tissue; for its antiseptic properties; and for the elaboration of the anti-anemia fraction.

Gastric Acidity.—Pure human gastric juice is normally secreted with about 0.4 to 0.5 per cent of free HCl (Roeder, 1905; Rehfuss and Hawk, 1914; Carlson, 1915), the same as in dogs or cats. This corresponds to *p*H = 0.95 to 1 (Menten, 1915). This acidity, however, is not normally maintained in the stomach, the acid being rapidly neutralized by the saliva, the mucus and the reflux of duodenal contents, to 0.15 or 0.2 per cent HCl (Boldyreff). The breaking down of this mechanism appears to be the basis of "hyperacidity," in which the acid remains at the same concentration (0.5 per cent HCl) at which it was secreted (Carlson, 1915). The curve of the acidity during normal digestion was studied in man by McClendon, 1915.

The secretion of the gastric hydrochloric acid is confined to the parietal cells, where it first appears either in the cytoplasm immediately adjacent to the intracellular cananiculus, or in the cananicular wall (F. Hollander, 1943). The parietal cells have a high content of carbonic anhydrase (H. W. Davenport and Fisher, 1938), which converts their metabolic CO_2 into H_2CO_3. This exchanges with the NaCl of the plasma to form HCl and $NaHCO_3$ (J. S. Gray, 1942).

The *secretion of gastric* juice is normally provoked by the psychical and chemical processes connected with eating. Acid secretion may be stimulated especially by *histamine*, and by an analogous substance, *gastrin*, formed in digestion. The ingestion of dilute *acid* also increases the secretion of gastric juice. This effect is partly reflex, for it is observed in Pavlov's separated stomach (Bickel, 1905), but only when the acid is given with food (Heinsheimer, 1906). It was formerly believed that gastric secretion is also stimulated by the administration of alkali, but later experiments indicate that it is rather diminished both in quantity and acidity (Pavlov, 1897; Chiari, 1915).

In the duodenum, acid causes the secretion of mucus (Florey and Harding, 1934). It provokes the secretion of pancreatic juice, through the formation of secretin (Bayliss and Starling, 1902). It also causes increased secretion of bile and contraction of the gallbladder (Okada, 1915).

The threshold of duodenal acidity for stimulating pancreatic secretion in dogs lies about *p*H 5, and is greater at *p*H 4, which is commonly present in meat digestion (J. E. Thomas and Crider, 1940). Introduction of acid into the duodenum inhibits gastric secretion if the acidity exceeds *p*H 2.5 (I. J. Pincus *et al.*, 1942).

Digestive Action.—Pepsin acts only in the presence of *free acid.* Any acid may answer for this purpose; hydrochloric is most efficient in the concentration existing in the gastric secretion; it also aids in the *solution of the connective tissue of meats* and determines the *antiseptic* qualities of gastric juice. Most other digestive ferments are favored by slightly acid reaction, but trypsin can act in a weakly *alkaline* medium. Pepsin is inhibited or destroyed by alkalinity (Hamburger, 1915). Diastases are hindered by free alkali, and are indeed sensitive to it.

Salivary Digestion in the Stomach.—Slight acidity accelerates the action of all diastases, but somewhat stronger concentrations depress. However, the bulk of the food remains for an hour or more in the cardiac pouch, with only the surface layer impregnated by acid (Heyde and Gruetzner). Salivary digestion proceeds practically undisturbed during this time (Cannon, 1911).

Digestive leukocytosis may be produced by the introduction of dilute HCl into the empty stomach and therefore need not involve the digestion of proteins (Cathcart, 1923).

The discharge of gastric contents was believed to be controlled chiefly by the acidity of the gastric acid duodenal contents, acting on the pyloric sphincter (W. B. Cannon, 1911). Improved investigative methods show that this is erroneous. The emptying is accomplished by the peristaltic pressure gradient from the stomach to the duodenum. The pyloric sphincter is generally open and acts in the same direction as the bulb and antrum. They are important chiefly for preventing reflux of the duodenal contents. Acid food in the duodenum and emotional states delay emptying by depressing gastric motility, not by pyloric spasm (J. P. Quigley, 1943). *Administration of therapeutic doses of hydrochloric acid* (2 cc. of dilute acid in 100 cc. of water) has no significant effect on the gastric emptying time of healthy young men. *Sodium bicarbonate* (5 Gm. in 100 cc. of water) shortens the time by an average of 16 per cent. An equal effect results from disodium phosphate, 4 Gm. in 100 cc. (E. J. Van Liere and Sleeth, 1940). Dilute solutions of alkalis leave the stomach promptly; *hypertonic solutions*, whether acid or alkaline, do not pass readily from the stomach into the intestines (T. Grier Miller, 1939).

Perversions of Gastric Acidity.—The *p*H of gastric juice is not so constant as is commonly supposed. The free acid may range normally between 0.05 to 0.5 per cent HCl; in achlorhydria it is reduced to practically nothing, and with gastric ulcer it may rise to 1 per cent (K. P. Becker *et al.*, 1934, 1935). *Achlorhydria* is an important feature of pernicious anemia. *Hyperchlorhydria* occurs in nervous dyspepsia and gastric ulcer. It is due to retention of the acid in the stomach by pylorospasm, more than to increased acidity of the secretion itself. The prolonged acidity is probably an element in the development of peptic ulcers (Mann and Williamson, 1923; L. R. Dragstedt, 1935; Wilhelmj *et al.*, 1936).

The *pain of gastric ulcer and of hyperchlorhydria* is not due directly to increased acidity, but to hyperesthesia toward the ordinary acidity, and to muscular spasm, which is felt as painful only when free acid is present, not when this is neutralized (W. L. Palmer, 1943). "*Heart burn*" probably arises from regurgitation into the esophagus, which is sensitive to ordinary acidity (W. C. Alvarez, 1944).

In human subjects with normal stomachs, J. E. Schmidt, 1909, found no symptoms with 0.5 to 2 per cent HCl. With 5 per cent, Boring reports a sensation similar to hunger pains. The results on patients with gastric ulcer are more variable. Pain was sometimes, but not always, present after 0.1 to 0.4 per cent HCl. Ginsberg *et al.*, 1916, found that the pain is always accompanied by strong contractions, indicating that it is due to tension. This was relaxed by alkalis or amyl nitrite, strengthened by pituitary. L. L. Hardt, 1918, found that ulcer pains occurred in the absence of free acid and may sometimes even be relieved by 0.3 per cent HCl.

Through a gastric stoma in a normal man, S. G. Wolf and Wolff confirmed that no pain is felt from the healthy stomach on pinching with forceps, faradic stimulation, moderate distention, or on applying 50 and 95 per cent alcohol, $\frac{N}{1}$ HCl, $\frac{N}{10}$ NaOH, or mustard suspension; but severe pain results from these agencies when the mucosa is inflamed.

Use of Acids in Indigestion.—Acids are administered in dyspepsias in which the secretion of acid is deficient; in the achylia of pernicious anemia; in putrefactive fermentation; and in infantile diarrheas due to this cause. All mineral acids act alike. Dilute hydrochloric acid (1 cc., diluted, just before or after meals) is generally preferred. It is often combined with bitter stomachics. Doses much greater than the ordinary would be required to restore the normal acidity, but when taken after meals the acid would be confined to the surface of the food mass and would therefore suffer little dilution. The increased flow of pancreatic juice and of bile is probably too small to be of any value. Acids are *contraindicated* in catarrhal conditions. Even in normal individuals the prolonged administration of large quantities of acids is likely to prove too irritant, and interferes with digestion. This led to the popular use of vinegar to reduce *obesity*.

Administration of Alkalis on Normal Digestion.—E. J. Van Liere and Sleeth, 1940, found that 5 Gm. of sodium bicarbonate shortens the gastric sojourn of normal men. W. L. Adams *et al.*, 1943, report increased gastric pouch secretion in dogs; but the effects of moderate doses are not important in normal individuals. The utilization of food remains practically perfect. *Very large doses* inhibit gastric movements more or less completely (W. H. Dickson and Wilson, 1924) and cause diarrhea.

This may explain the use (or rather misuse) of alkalis in *obesity*. Full doses of alkalis temporarily lower the arterial pressure, probably as a result of the nausea. Scheffer, 1908, advocated sodium silicate for this purpose in *arterial hypertension;* bicarbonate accomplishes the same result, but the benefit is questionable. *Strong alkalis*, including sodium carbonate, cause gastritis.

Alkalis in digestive disorders are useful to dissolve excessive mucus, but particularly to neutralize hyperacidity. Sodium bicarbonate acts most promptly, magnesium oxide and carbonate produce a more lasting action and are laxative. Calcium carbonate is constipating.

Gastric Hyperacidity; Functional Dyspepsias, Heart Burn; Gastric Flatulence, and Similar Conditions.—In these conditions, the soluble alkalis (sodium bicarbonate or aromatic ammonia) are commonly used and effective. They neutralize the excessive acid, relax the spasmodic pylorus (Enriquez, Binet and Gaston Durand, 1914) and thus empty the stomach and lessen the pain and irritation. The liberated CO_2 stimulates the gastric movements (Schierbeck, 1891), and promotes the expulsion of the gas. It acts perhaps also as a mild local anesthetic. The bicarbonate is usefully combined with an aromatic carminative (peppermint) and cathartic (rhubarb). The *time of administration* has given rise to much theoretical and unproductive discussion. The alkalis should evidently be given when the digestive conditions call for them. This is better recognized by the symptoms than by rules. The soluble alkalis (bicarbonate, 1 Gm.; aromatic ammonia, 2 cc.; for infants, lime water) should be administered whenever they are indicated by gastric distress, and repeated as often as needed; also at bedtime and on arising. For intestinal effect, they should be given on an empty stomach.

Gastric ulcer is treated with closely spaced doses of alkali so as to prevent the gastric contents from becoming acid.

In the *Sippy routine* (1915), milk or soft food is given every hour. Midway between the feedings the patient receives an alkali, alternating between (1) magnesia and sodium bicarbonate, each 0.65 Gm., 10 grains, and (2) bismuth subcarbonate, 0.65 Gm., 10 grains, with sodium bicarbonate, 2 Gm., 30 grains. The progress is controlled by the reaction of the stomach contents. The alkali treatment of peptic ulcer might be expected to favor the formation of *urinary calculi*, and Eisele, 1940, found that 11 per cent of a series of patients with renal or ureteral calculi had received courses of alkali for peptic ulcer or other chronic digestive derangements; but H. L. Kretschmer and Brown, 1939, found this to be so in only 1.2 per cent of their calculi.

Intestinal catarrhs are also treated with alkalis, but the results are less striking. Neutralization of gastric acidity would protect the duodenum. Only the slowly soluble alkalis, magnesium oxide or carbonate or calcium carbonate, could have any effect on the reaction of the lower levels of the intestines, and there the laxative or constipating action of their cations is more important than their alkalinity.

Enemas, of 1 per cent sodium bicarbonate (a teaspoonful to a pint), are used for cleansing and in mucous colitis.

The *intestinal bacterial flora* may be utilized to acidify the intestinal contents. This is sometimes effective against persistent intestinal putrefaction. Implantation of lactic acid organisms by oral administration has not proved successful. Better results are obtained by feeding lactose. The beta variety is more effective than the alpha (C. R. Robinson and Gilliand, 1937).

Preparations.—Official dilute mineral acids have a uniform strength of 10 per cent. They are colorless, odorless liquids, of strongly acid taste; miscible with water, alcohol or glycerin. They are *incompatible* with alkalis and the salts of weak acids (carbonates, salicylates, sulfides, sulfites, and so forth). *Dose,* 1 to 2 cc., 15 to 30 minims, diluted.

***Dilute Hydrochloric Acid,** U.S.P., is the most commonly employed. Dose, 2 to 4 cc. (30 to 60 minims) in half a glass of water, taken through a glass tube to avoid corrosion of the teeth; it may be repeated in half an hour. In *pernicious anemia*, to 4 cc. four times daily, with meals. *Aromatic Sulfuric Acid* is an alcoholic dilution of sulfuric acid, flavored with ginger and cinnamon. Contains free sulfuric acid and ethylsulfuric acid equivalent to about 20 per cent of H_2SO_4. A clear, reddish-brown liquid; pleasant aromatic odor; intensely acid. Dose, 0.5 cc., 8 minims, diluted. It is doubtful whether it has any advantage over other acids. Ethylsulfuric acid acts simply as a mineral acid (Uyedo, 1910).

***Sodium Bicarbonate,** U.S.P. (Baking Soda), is a white, odorless powder; of cooling, mildly alkaline taste; permanent in dry air, but slowly decomposes in moist air. Sol in water, 1:10, practically without decomposition. When heated, it loses CO_2, and is converted into normal carbonate. Practically insol. in alc. Incompatible with acids and acid salts, and with the salts of most alkaloids, metals and earths; not with magnesium salts in moderately dilute solutions. Dose, 1 to 4 Gm., 15 to 60 grains. "*Soda Mint*" tablets generally contain 5 grains, with $\frac{1}{8}$ minim of oil of peppermint. *Potassium Bicarbonate,* U.S.P., has similar properties, but is more soluble in water (1:2.8). *Potassium Carbonate,* U.S.P., is even more soluble (1:1).

ORGANIC ACIDS AND THEIR SALTS

Acetates and formates are easily absorbable salts, with simple ion actions. Tartrates, citrates, lactates and malates are not easily absorbed and therefore act as saline cathartics. The free acids are relatively feebly dissociated and therefore produce relatively mild acid effects on the skin and mucous membranes and in the digestive tract. They are burned more or less completely to carbon dioxide and water (Buchheim, 1888). Their salts therefore are administered to combat acidosis or to render the urine alkaline, with avoidance of acid effects in the digestive canal. They also cause saline diuresis. Sodium citrate forms a double, nonionized salt with calcium, and so prevents coagulation when added directly to the blood. Free citric and tartaric acid are used mainly for flavoring and for producing effervescence with carbonates. Lactic acid is employed as mild caustic for the solution of false membranes, and in laryngeal tuberculosis. Formic acid is used as counter-irritant.

Nutrition and growth are markedly impaired if rats are given 0.25 per cent acetic or formic acid as their sole drink; 0.5 per cent causes loss of weight as rapid as with complete starvation (Sollmann *et al.*, 1921).

Acetylation of sulfanilamide is increased by administration of acetate, pyruvate, lactate, glucose and alcohol (J. Fraenkel-Conrad and Greenberg, 1946).

When injected intravenously as sodium salts into nephrectomized dogs, acetate disappears most rapidly from the circulation, then butyrate, caproate, and caprylate, indicating that they are metabolized in this order (J. A. Dye and Babcock, 1943). Tracer experiments with heavy hydrogen show that acetate is used in synthesizing *cholesterol;* propionate, butyrate, succinate, pyruvate, and acetoacetate are not (K. Bloch and Rittenberg, 1942). Rats fed with sodium *acetate* containing deuterium in the methyl group utilize this in the synthesis of fatty acids (D. Rittenberg and Bloch, 1944). Liver and kidney slices readily oxidize acetate chiefly through the intermediate formation of acetoacetic acid, by coupling two acetyl groups. Slices of heart tissue oxidize without forming acetoacetic acid, and this may occur to a minor degree with liver and kidney slices (S. Weinhouse *et al.*, 1945).

The *antacid action* is exerted only by the oxidation of the absorbed salts. The CO_2 formed from the free acids would be exhaled. The ordinary antacid dose of sodium acetate or citrate is about 15 Gm. per day, freely diluted.

Sodium acetate is probably the least disagreeable, but some prefer mixtures, such as potassium citrate, 1 Gm.; sodium bicarbonate, 2 Gm.; sodium acetate, 3 Gm.; this dose three times daily. Potassium salts are deliquescent and should therefore not be dispensed as powders. Such mixtures were formerly prescribed against *rheumatism* and *gout.*

ACETATES

Potassium and sodium acetates are used mainly as alkaline diuretics and to counteract acidosis. The toxicity of sodium acetate is low, even on intravenous injection. Free acetic acid acts locally simply as a feeble acid.

***Sodium Acetate,** $NaC_2H_3O_2 \cdot 3H_2O$, occurs as colorless crystals or granular powder; odorless; saline taste, efflorescent. Sol. in water (1:0.8). Dose, 1.5 Gm.; to alkalinize urine, 5 to 10 Gm. per day. *Potassium Acetate,* U.S.P., deliquesces and should not be dispensed in powders. Dose, 1 Gm., 15 grains, diluted. *Acetic Acid* contains about 36.5 per cent of absolute acetic acid; *Glacial Acetic Acid* contains 99 per cent. *Dilute Acetic Acid* contains 6 per cent, about the same concentration as vinegar (Acetum). Its dose is 2 to 4 cc., 30 to 60 minims.

FORMATES

Local Action.—Free formic acid occurs in several animals (ants and so forth, Faust, 1910) and plants (nettles), and is partly responsible for their irritant effects. (Berchart, 1915, concluded that the effects of nettles are not due to formic acid.) Formic acid resembles acetic acid, but is more volatile, more irritant, more antiseptic and more resistant to oxidation. It has a popular reputation as a counterirritant, but is probably not superior to other irritants. It is usually employed in the form of *Spiritus Formicarum,* corresponding to 1 per cent of the absolute acid in two-thirds alcohol (this was formerly obtained by macerating ants).

On oral administration, formic acid behaves almost quantitatively like acetic acid. Water containing 0.25 per cent of either formic or acetic acid, administered to rats for many weeks, in daily dosage up to 0.2 cc. of acid per Kg. of body weight (equivalent, in man, to 6 liters of 0.2 per cent acid per day), produced no effects whatever; not even diuresis. Twice this dosage interfered materially and progressively with growth and appetite, both acids again behaving alike (Sollmann, 1921).

Formates by Mouth.—The toxicity is low, so that 6 to 10 Gm. of sodium formate may be taken daily for some time (Fleig). Eppinger, 1913, administered sodium formate, 3 to 4 Gm. daily, to three patients. Two felt no discomfort; the other developed albuminuria and hematuria, persisting for five days; but this must have been a coincidence.

Action after Absorption.—The formates act practically as indifferent salts. The general circulation is not affected by large doses. Enormous doses depress the heart (Livierato, 1906). They are said to produce methemoglobinuria (Croner and Seligmann, 1907). Diuresis may result (Fleig), doubtless owing to simple salt action. Stimulant effects of various kinds have been claimed, but shown to be absent (Fleig, 1907, literature).

Therapeutic Uses.—Formates were exploited rather fantastically as an elixir of youth, destined to confer on man the vigor and indefatigability of insects; and to cure various ailments, mainly of the neurasthenic type (H. Stern, 1906). Fleig exposed the uncritical nature of the evidence and showed that the results were due solely to suggestion.

Fate.—Formates are oxidized less readily than acetates, so that a greater proportion (up to two-thirds) appears unchanged in the urine. With smaller doses, the destruction may be more complete (Pohl). The oxidation occurs mainly in the liver (Fleig, 1907).

Normal Occurrence.—A small quantity of formate occurs normally in mammalian tissues. In man, the normal daily urinary excretion is 13 to 120 mg. This indicates that considerable quantities are formed in intermediate metabolism, probably of all classes of foods. It is also formed from formaldehyde and methyl alcohol, but not from ethyl alcohol (Dakin, Janney and Wakeman, 1913).

Acid formicum, as official in foreign countries, contains 25 per cent of HCO_2H. The dose is stated as 1 to 20 drops.

Allyl formate and other allyl compounds act similarly to monoiodoacetate by interfering with the breakdown of carbohydrate, in yeast, frog skin, and liver tissue (A Fleckenstein, 1944). In rats, intraperitoneal injection injures the sinusoidal capillaries of the liver and produces hydropic degeneration and necrobiosis of the hepatic cells, and hemorrhages into periportal areas (A. Rosin and Doljanski, 1946).

◆

SUCCINATES

Sodium succinate can be used for clinical alkalinization of urine. It is reported as effective as acetate or citrate, and better tolerated (Becker-Freyseng and Liebich, 1938).

Analeptic.—Intravenous injection of sodium succinate is reported to awaken patients from narcotic sleep; see under Barbiturates.

Leukocytes.—Hypodermic injection of 0.1 cc. of 1 per cent sodium succinate in man is said to increase the leukocyte count of the blood by 20 to 70 per cent (Hammett *et al.*, 1917).

Heart.—Direct application of concentrated solutions depresses the heart, similarly to tartrates (Salant and Livingston, 1917).

LACTATES

These are but slowly absorbed and therefore act as saline cathartics. They are completely burned in the organism and have no other action (Faust, 1910). It has been claimed that lactates somewhat limit nitrogen metabolism, after the manner of fats. Lactic acid is an important link in the energy metabolism and rigor mortis of muscle and other tissues. It is formed in the brain after decapitation, more rapidly than in any other tissue (McGinty, 1925). Various preparations of lactic acid administered by mouth or hypodermically have a slight inhibiting effect on transplanted *mouse sarcoma,* probably by disturbing the metabolism of the animals (Parfentjev *et al.*, 1934).

It should be remembered that lactic acid is a strong, corrosive acid. Several infants have died from milk acidified with supposedly 0.8 per cent lactic acid (E. G. Young and Smith, 1944).

Sodium r-lactate, N.N.R., is used for the treatment of acidosis by intravenous or hypodermic injection of one-sixth molar solution (1.87 per cent W/V, approximately isotonic with blood). The rate of injection should usually not exceed 300 cc. per hour. *Sodium Lactate Injection*, U.S.P., is to be made with water for injection, the concentration to be specified. *Lactate Ringer solutions* are also used.

MALATES

These are largely destroyed, even on hypodermic administration, but from 3 to 40 per cent escapes into the urine. They produce much less damage than tartrates or citrates (Wise, 1916).

◆

CITRATES

These are used chiefly as alkaline diuretics, and in blood transfusion. Citric acid (about 1 per cent) is employed as a refrigerant drink in fevers, often as lemonade.

Fruit Acids.—The acidity of fruits is due mainly to citric acid; other acids occur only in small quantities. Tartrates are important only in grapes (Bigelow and Dunbar, 1917). *Lemon juice* contains about 8 per cent of citric acid, a large lemon about 4 Gm., ordinary lemonade about 0.5 per cent. Oranges contain sufficient base so that the drinking of *orange juice* turns the urine alkaline; the oxidation is complete even when large quantities are taken, *i. e.*, 2400 cc., containing about 48 Gm. of acid, in a day (Blatherwick and Long, 1922).

Routine use of lemon juice in water dissolves dental enamel (E. C. Staine and Lovestedt, 1947).

Fate and Use as Antacid.—Citrate is rapidly absorbed and completely and quickly oxidized in the body or transformed into liver glycogen (C. A. Kuether and Smith, 1941). After oral administration, less than 1 per cent is excreted unchanged by the urine. Large doses of sodium citrate (30 to 50 Gm. per day) can be administered clinically for alkaline diuresis without digestive disturbance (Lichtwitz, 1911).

In normal individuals, the *change of acid:base balance* after ingestion of 6 to 12 Gm. of sodium citrate or its equivalent of sodium bicarbonate (4.5 to 9 Gm.) is neither prolonged nor marked. After 20 Gm., the change is maximal one and one-half to two hours after administration (Cape, 1935). With *oral administration* of sodium citrate, 0.2 to 2 Gm. per Kg., the rise of citrate concentration in the blood lasts three and one-half to seven and one-half hours. An average of 0.7 per cent escapes oxidation and is excreted in the urine; no extra citrate appears in the feces. The addition of free citric acid to a constant diet does not affect the *p*H of the urine (C. C. Sherman, Mendel and Smith, 1936). When *injected into a vein*, the citrate disappears rapidly from the circulation. None escapes into the urine with intravenous injection, up to 0.5 Gm. per Kg. After *hypodermic injection* in rabbits, about 12 per cent is excreted in the urine; with cats, 30 per cent; with dogs, 40 per cent (Salant and Wise, 1916).

Normal Occurrence.—Human and dog's urine, blood and other body fluids constantly contain small amounts of citrates, which are probably synthesized as well as oxidized in normal metabolism (C. C. Sherman, Mendel and Smith, 1936). The normal human *urinary excretion* is about 0.5 Gm. daily (Amberg and McClure, 1917); the level in *blood serum* is normally about 2.5 mg. per 100 cc., with a range of 1.5 to 5 mg. in pathological conditions, the highest values in hepatitis (Thunberg, 1933). Its concentration in *body fluids* is between 20 and 200 mg. per cent; in *soft tissues*, 0.1 to 0.2 mg. per cent (A. H. Smith and Orten, 1937). Human *prostatic fluid* contains 0.5 to 2.5 per cent (C. Huggins and Neal, 1942). The *skeleton* contains 70 per cent of the total citrate of the body, more than one per cent of the mineral matter, presumably in combination with calcium (F. Dickens, 1941). Human and dogs' *teeth* contain somewhat over 0.5 per cent of their dry weight, the dentine having five to eight times the concentration of the enamel (A. H. Free, 1943). The urinary output is increased by alkalis (Kuyper and Mattill, 1933); in dogs up to a hundred times the normal (Sherman *et al.*, 1936). Changes of calcium excretion induced by diet or parathyroid deficiency produce parallel changes in the urinary citrate (E. Shorr, Almy *et al.*, 1942). Conversely, hypodermic injection of sodium citrate into dogs causes prompt and considerable increase of urinary calcium excretion, the blood calcium level being practically unaffected. Repeated injections into puppies or young rats result in bone changes similar to those caused by large doses of parathormone (G. Gomori and Gulyas, 1944).

Disionization of Calcium.—Citrates form double salts with calcium which do not liberate calcium ions, as judged by their chemical behavior (Sabbatani, 1901), conductivity measurements (Shear and Kramer, 1928) and pharmacologic tests such as the frog heart (Hastings, McLean *et al.*, 1934). With *p*H 7.7, a part exists as $CaCi^-$ anion (Mg and Sr behave similarly). Citrate makes the entire serum calcium ultrafiltrable, presumably by taking it away from protein. Lactate and acetate do not affect the normal nonfiltrable calcium ratio of 45 to 47 per cent, in rabbits (Shelling and Maslow, 1928).

Serum Calcium and Phosphate Level.—Intravenous injection of sodium citrate into normal dogs causes an immediate fall of Ca, although less than with oxalate. It recovers rapidly and completely in a few hours. The phosphate is slightly lowered during the Ca fall, and rises markedly during the Ca recovery. The recovery is attributed to mobilization of bone Ca and PO_4, apparently by mediation of the parathyroids, for after excision of these, the recovery is much slower (Tsai and Hsu, 1930).

Coagulability of the Blood.—Citrates, like other Ca inactivators, render the blood noncoagulable *in vitro*. The addition of 0.2 per cent of citrate to shed blood prevents coagulation completely, even for forty-eight hours; 0.1 per cent does not hinder it at all. One per cent of citrate (1 cc. of 10 per cent citrate per 10 cc. of blood) keeps the blood noncoagulable for two weeks, but shrinks and injures the corpuscles.

Intravenous injection of sodium citrate has the opposite effect: it shortens the coagulation time. This occurs in human subjects with 10 to 50 cc. of 10 per cent citrate (Weil, 1915), returning to normal within twenty-four hours (Lewisohn, 1917). It has been attributed to injury of the platelets, leading to liberation of the thromboplastin (N. Rosenthal and Baehr, 1922).

With intramuscular injection, the effect depends on the dose, the coagulability being increased by relatively small doses (0.125 Gm. per Kg.) and diminished by large doses (De Souza and Hocking, 1935). In *hemophilia*, intravenous injection produces an immediate and marked shortening of the coagulation time. This is followed in one to two days by return to the original or even to slower coagulation. Intramuscular injection has no effect (Ottenberg, 1916).

Use in Transfusion.—Weil, 1915, introduced the use of "citrated blood," the blood of the donor being kept uncoagulated by the addition of sodium citrate. This may be injected at once, or preserved for a time. Wassermann, agglutination, hemolysis and other tests must be made as usual. *Citrated normal human plasma*, U. S. P., contains 0.4 per cent.

Dosage.—Lewisohn, 1915, 1917, advised 0.25 per cent of sodium citrate. The total injection should not exceed 1200 cc., corresponding to 4.8 Gm., or toxic citrate effects may ensue (A. C. Ivy, Greenzard *et al.*, 1943; J. Bruneau and Graham, 1943).

"Reactions" Following the Transfusions of Citrated Blood.—Citrated-blood transfusions are sometimes followed by a fairly severe chill and fever of about 2.5° F., in half an hour, returning to normal in four to eight hours. This reaction has little practical importance, and is apparently due to alterations produced in the corpuscles (Drinker and Brittingham, 1918).

Other Anticoagulants.—In laboratory experiments, the coagulability of blood can easily be diminished or abolished. Leech extract, heparin and certain azo dyes have this effect, whether they are injected or added to shed blood; albumoses, only when injected; citrates, hexametaphosphate, oxalates, fluorides, concentrated solution of other salts and urea, formaldehyde, hydrocyanic acid, and so on, only on shed blood (by removing the calcium or inhibiting the fibrin ferments).

Other actions of citrate on intravenous injection or excised organs (not with oral administration) correspond to calcium deprivation (Sabbatani, 1901; Vietinghoff-Scheel, 1902; Martin, 1904; Gordonoff *et al.*, 1930).

The *intravenous toxicity* varies with the rate of injection. The oral toxicity is low (Salant and Wise, 1916). The injection of minute quantities into the *brain* produces convulsant effects. Repeated hypodermic injections of increasing doses create considerable *tolerance* (Robertson and Burnett, 1912).

Effects on Circulation.—As used clinically, this is practically unaffected. Larger doses, 30 mg. of sodium citrate per Kg., depress the heart muscle and stimulate the vasomotor center in dogs. The renal vessels may be dilated (G. R. Love, 1923). Citrate lowers the threshold of ventricular fibrillation by galvanic stimulation (A. G. Rojas *et al.*, 1942). The *cardiac vagus* is completely paralyzed by intravenous injection of sodium citrate, in cats and in turtles, probably between the pre- and postganglionic fibers. Oxalate produces the same effect. It is apparently due to lowering of the calcium ion concentration, and may be prevented by injection of calcium chloride. Spontaneous recovery is complete in twenty to thirty minutes in cats (G. D. Shafer and Crismon, 1936).

Excised Intestines.—Strong solutions depress all portions of the intestines of rabbits; weaker concentrations stimulate the small and depress the large. With cats, the small and large intestines are both depressed (Salant and Schwartze, 1917). When injected intravenously into dogs, small doses of sodium citrate stimulate the gastric and intestinal movements feebly. Larger doses, 100 mg. per Kg., rapidly injected cause a temporary depression of the stomach and intestines, and a sympathetic stimulation similar to epinephrine (G. R. Love, 1923). *Excised uterus* of guinea pigs, virgin or pregnant, respond with marked increase of tonus to the addition of 0.00015 to 0.0009 per cent, with decreased tonus above 0.001 per cent (Messini, 1929).

Coagulation of Milk.—The inactivation of calcium by citrates prevents the clotting of milk. Their addition to cows' milk produces a looser curd in the stomach. This is utilized in infants (1 to 3 grains of citrate per ounce of milk), when ordinary milk is not well borne (curds in vomitus and stools). It should be reduced or omitted as soon as the need is passed (Cotton, 1906; R. Curtis, 1916).

PREPARATIONS.—***Sodium Citrate, U.S.P.**; $Na_3C_6H_5O_7\cdot 2H_2O$; a white granular powder; odorless; cooling saline taste. Efflorescent. Freely sol. in water (1:1.5); insol. in alc. Dose, 1 to 4 Gm., 15 to 60 grains. *Anticoagulant Sodium Citrate Solution*, U.S.P., contains 2.5 per cent of the official citrate in 0.9 per cent solution of sodium chloride. It is available as (1) nonsterile; (2) sterile not for parenteral use; and (3) for parenteral use. The last (in water for injection) is dispensed unless the others are specified. *Anticoagulant Acid Sodium Citrate and Dextrose Solution*, U.S.P. ("ACD Solution"), contains sodium citrate, U.S.P., 2.2; citric acid, 0.8; dextrose, 2.45, in 100 cc. of water for injection. *Potassium Citrate*, U.S.P., has similar properties. *Effervescent Potassium Citrate*, U.S.P., contains 20 per cent of potassium citrate, with sodium bicarbonate and tartaric and citric acid; average dose, 4 Gm., 1 drachm. *Citric Acid*, U.S.P., $C_3H_4(OH)(COOH)_3\ H_2O$, is a tribasic organic acid obtained from the juice of limes or lemons. Colorless, translucent prisms or a white powder; odorless; having an acid taste:

efflorescent in warm air. Very sol. in water (1:0.5); freely sol. in alc. (1:1.8). Dose, 0.3 to 2 Gm. *Citric Acid Syrup,* U.S.P., containing 1 per cent of citric acid and 1 per cent of Lemon Tincture, is used as flavored vehicle.

Propionate of sodium, $CH_3.CH_2.COONa$, or of calcium, which is used under the trade name "Mycoban", to inhibit the growth of molds in dough and dairy products, has been found effective clinically against superficial fungus infections, ringworm and thrush; it is also effective against bacteria. It may be used as a dusting powder (10 per cent, with talcum) or as 10 per cent ointment (E. L. Keeney *et al.*, 1944).

Undecylenic acid, $CH_3.C_2H_2.C_7H_{14}.COOH$, appears to be even more effective. A. L. Shapiro and Rothman, 1945, recommend 5 per cent of the acid and 20 per cent of zinc undecylanate in a vanishing cream base. This does not irritate inflamed lesions.

M. B. Sulzberger and Kanof, 1947, who compared the prophylactic and treatment value of nine formulas against dermatophytosis in the Navy, found undecenylate somewhat superior; propionate ranked fifth, a boric-salicylic powder seventh; but the differences were not great.

◆

URATE SOLVENTS

Acid urates occur in solution in the blood and tissues; and as the peculiar sodium biurate deposits in gouty tophi. In the urine, acid urates also occur in solution. When the urine is scanty or acid, they may be deposited as free uric acid or "quadriurate"; *i. e.*, a mixture or compound of free uric acid and acid urate. These deposits may concrete into urinary calculi. Once formed, they are difficult to redissolve by restoring the reaction, unless this is strongly alkaline. It is impossible to do this in the tissues; it is doubtful even for the urine, but in this, further urate precipitation can be prevented by dilution and moderate alkalinization (Buchheim, 1853), taking care that the latter does not lead to the precipitation of phosphates which might be deposited on the calculus. It has been attempted to dissolve the urate by the administration of lithium and particularly diethylene diamine (piperazine) and related organic bases, which form relatively soluble urates in pure solution, but these bases have no material advantage; in the presence of excess sodium, the less soluble salt is formed. Deposition of urates in the tissues is not affected by alkalis (Ritter) since these do not change the *p*H of the tissue fluids. The urate level of the blood may be diminished somewhat by liberal diuresis, and more effectively by salicylates and cinchophen, which lower the renal threshold for urates, and this may perhaps diminish somewhat the tendency to the formation of tophi, but it does not redissolve those already deposited.

Salts of Uric Acid.—*Uric Acid,* $C_5H_4N_4O_3$, is a weak dibasic acid, which under proper conditions can form three series of salts, namely: *Neutral urates,* $C_5H_2N_4O_3Na_2$; also called dibasic, normal or secondary urates. These are formed only by strong alkalis, and cannot occur under natural conditions, being decomposed by CO_2 and even water. They need not be considered further. *Acid urates,* $C_5H_3N_4O_3Na$; also named monobasic or primary urate or biurates. They are neutral to litmus. *Quadriurate,* $C_5H_3N_4O_3Na + C_2H_4N_4O_3$; also named hemibasic urates or tetraurate. It is a mixture or solution of uric acid and acid urate. The quadriurate forms the sedimentum lateritium in cooling acid urines. On standing, it separates uric acid crystals. Water dissolves out the acid urate and leaves the uric acid. *Other urate deposits in urine* may consist of uric acid in acid urines; of acid urates in acid or neutral urines; and ammonium urate in neutral or ammoniacal urine. The acid urate is generally amorphous, but may be crystalline in neutral urine. The consolidation of urinary precipitates into *urinary calculi* involves the cooperation of a "colloidal mortar," presumably fibrin (H. Schade). *Urate tophi* consist always of acid urates (Ritter, 1897); so do the uratic deposits in animals, even when free uric acid is injected (Loghem, 1907).

Solubility and Precipitation.—Free uric acid is very little soluble. The acid urates also have a limited solubility. They behave as colloids, and their solution may be favored or hindered by a variety of conditions, some little understood.

The study of the solubilities is complicated by the small quantities going into solution, the polyvalence, formation of colloidal solutions, supersaturation, the influence of small quantities of impurities, decompositions, and so forth (His and Paul, 1900). Pure water dissolves at 18° C. only 25 mg. of uric acid per liter = 1:40,000 (His and Paul). At 40° the solubility is probably doubled. *Alkalis,* even the bicarbonate or phosphate, transform part of the uric acid into acid urate, and therefore increase its solubility. *Free acids* diminish the solubility, since they decrease the ionization; undissociated uric acid is less soluble (His and Paul). Haskins, 1916, found that the solvent power of *urine* for uric acid varies with its reaction and concentration. Urines of *p*H = 6.1 or less cannot dissolve any added uric acid; those that are less acid take up more according to their alkalinity. Concentrated urines dissolve more (though not in strict proportion) than do dilute urines of the same reaction. The acid NaH_2PO_4 liberates and precipitates uric acid; this is counteracted by the presence of the alkaline Na_2HPO_4; but excess of the latter precipitates the acid urate by "salting out" (Ritter). Addition of free uric acid to urine may precipitate a part of the uric acid originally in solution (Voit), presumably by acting as a crystallizing nucleus. The solubility in *serum* is much greater (500 mg. per liter) than in water (Bechold and Ziegler, 1909). This is probably due to the *colloids,* and it is likely that the colloid constituents of the urine also contribute to the solubility of the uric acid and urates (Lichtwitz, 1910). Ruedel, 1892, claimed that *urea* has an important solvent action, but Ritter, 1897, found this limited. O. S. Gibbs, 1929, adduced evidence that fowls' blood contains a specially soluble form of uric acid.

Uric acid excretion occurs almost exclusively by the urine. The *normal threshold* is lowered by cinchophen and salicylates, and by water or saline diuresis (J. H. Robertson, 1914; J. L. Morris and Rees, 1923). Strenuous exercise and ingestion of lactic acid decrease the output (Quick, 1935). Injection of uricase into hens lowers the uric acid concentration of their blood sharply (E. H. Oppenheimer, 1941). *Methenamine* and the related compounds (Citarin, and so forth) have a solvent and destructive action on uric acid, even in acid urines (Stevens and May, 1911; Haskins, 1915). This is due to their formaldehyde. They were therefore advocated as urate solvents. The action, however, is imperceptible with the ordinary doses (review, Hanzlik, 1916).

Intravenously injected uric acid remains in the blood of gouty patients longer than with the nongouty (McClure and Pratt, 1917). It disappears promptly from the blood of dogs and rabbits and is at first fixed almost exclusively in the kidneys, but these return to normal in a few hours. The amount eliminated by the urine is but little increased. The ultimate fate is not known (Bergami, 1930). In fowls, the injected urate is promptly excreted completely, and even lowers the urate level of the blood (Gibbs, 1929).

Actions of Urates.—The importance of these lies in the fact that they may be formed or retained in excessive amounts in pathologic conditions, when they first produce inflammatory necrosis of cells, and are then deposited in insoluble granular form. This, becoming crystalline, acts as a mechanical irritant, producing the phenomena of gout. These can be stimulated in animals by the injection of suspensions of acid sodium urate, and in birds by the subcutaneous injection of chromates, or even by ligation of the ureters. The cause of the abnormal appearance of the uratic deposits in gout and similar conditions is not understood.

Relation of Uric Acid to Gout.—The occurrence of urate tophi is a striking proof of disturbed uric acid conditions in this disease. The uric acid of the blood is generally increased. It was formerly believed that definite changes in the uric acid content of the blood occurred during the acute gouty attacks, but modern results indicate that the urate concentration is the same during as between attacks. Attacks occur also when the urate concentration has been lowered by cinchophen (Daniels and McCrudden, 1915). The urate deposits are not due to simple oversaturation, for the solvent power of serum for uric acid is much higher than the concentration in gout. Presumably it is caused by alterations, local or general, of the colloidal equilibrium (Lumiere).

Piperazine, diethylene-diamine, $NH(CH_2)_4NH$, produces no symptoms and is practically nontoxic. The solvent power for uric acid, in pure solution, is higher than that of Li_2CO_3 (Stevens and May, 1911), but still insufficient to make much impression on a urate stone (Penzoldt). In the presence of Na salts, and therefore in the blood and urine, it is not superior to other alkalis (Meisels, 1893); and since a part is oxidized, and therefore only a fraction appears in the urine, its solvent power is less than that of $NaHCO_3$ (Haskins, 1916). These limitations apply also to the derivatives of piperidine (dimethylpiperazine = *Lycetol,* Wittzack, 1894; ethylene-ethenyldiamine = *Lysidine.* Ladenburg, 1894). Eczema has been reported from lysidine (Ortner). *Piperidine,* $CH_2(CH_2)_4NH$, was introduced as urate solvent by Tunnicliffe and Rosenheim. The dose of the bitartrate is 0.6 to 1 Gm. three times daily. Its pharmacologic effects resemble those of coniine (C. R. Linegar *et al.,* 1943).

METALS AND THEIR COMPOUNDS

The various metals and their compounds have many pharmacological features in common. Their salts combine with proteins, and therefore act locally as astringents, irritants, corrosives and antiseptics. Their absorption, storage and excretion are similar. After absorption, their effects are chiefly on the capillaries, analogous to inflammation, resulting in collapse, enteritis, colitis, nephritis and sometimes hepatitis. With continued exposure, the effects are cumulative and result in chronic poisoning, chiefly nutritional and nervous, peripheral and central. Many metals stimulate the bone marrow and mobilize the reticulocytes; large doses become toxic and produce anemia. Iron is an indispensable component of hemoglobin, and traces of some other metals (copper, manganese, zinc) promote growth and are probably also indispensable; aluminum and nickel are apparently not needed (Sharpless, 1933). The activity of metal compounds depends on their *solubility,* and their systemic action on their absorbability, which varies greatly. Compounds insoluble in water may undergo chemical changes in the intestinal tract or in the subcutaneous tissue which render them soluble and absorbable. The free metals rarely if ever act directly, but only after being transformed into compounds. Most of the soluble metal compounds may be arranged into the following *groups:* (1) *Ionizable salts,* such as ferric chloride, generally precipitate proteins and therefore have marked local actions. They circulate in the blood, probably as protein salts, and produce the typical actions of each metal. (2) *Double salts,* such as iron and ammonium citrate, contain the metal as part of a complex anion (ferrocitrate), which do not precipitate proteins directly, and therefore have but little local action. They generally split off some metal cations, however, and therefore eventually produce the systemic actions of the ionizable compounds. (3) *Molecular compounds,* where the metal forms an integral part of a nonionizable molecule. These may have direct actions that differ materially from those of the ionizable compounds, as the iron in hemoglobin; or they may break up fairly readily and form ionizable compounds, as with cacodylic acid. *Metal alkyls,* which belong in this group, act first as aliphatic narcotics, then as molecular compounds, and finally, after decomposition, they produce the ionized metal effects. They penetrate into living cells much more easily than ready-ionized compounds (Sollmann and Seifter, 1939). (4) *Colloidal metals and metallic oxides and salts* have but little action directly, but because of their large surface they are fairly readily converted into ionizable salts. Their direct injection into the blood stream provokes colloidoclastic reactions, and they are taken up by the reticular endothelium.

The action of metals on cells occurs in two stages (Euler and Waller, 1924): (1) rapid adsorption on the surface, reversible by hydrogen sulfide; (2) slow penetration, producing irreversible effects. The *local actions of metallic salts,* as also their direct antiseptic action, were discussed under *Local Irritants and Astringents.*

Habituation to the Local Action.—If the administration of a metallic salt is begun with small doses and gradually increased, it may become possible to administer without local effect doses which would at first have produced corrosion (Hausmann, 1906). Habituation diminishes the absorption of arsenic, but not of antimony (Cloetta, 1906, 1911). *Lower organisms,* yeasts, bacteria and protozoa, acquire considerable tolerance to the various metals. This may be transmitted for generations, and may or may not extend to other metals (infusoria, Neuhaus, 1910; trypanosomes, Ehrlich, 1910).

Absorbability of the Metals.—Arsenic, mercury and uranium are the only metals whose ordinary salts are absorbed sufficiently to cause acute systemic poisoning with noncorrosive doses. Phosphorus, which behaves pharmacologically in many respects like metals, is absorbed still more readily. Other metals are absorbed much more slowly. To this class belong lead, silver, tin and iron. Metallic poisons are generally more toxic to herbivora than to carnivora, probably because they remain longer in the alimentary canal of herbivorous animals, allowing greater absorption. Any metallic salt, if given in strong solution, will cause *corrosion* of the mucous membrane of the alimentary canal and will then be absorbed, and would exert its systemic action were it not that the local effects often kill before the systemic can come into play. Lead, copper and zinc oleates are said to be *absorbable through the skin* (C. Voegt and Burchardt, 1916). This holds also for mercury oleate.

The **excretion** of metals occurs mainly by the urine and feces. The urinary excretion is generally the greater, perhaps by five to ten times, and the concentration in the urine averages about ten times that of the blood. The urinary output reflects at least the direction and very roughly the quantity of the blood concentration. The fecal excretion is more complex and less proportionate. It occurs chiefly by the bile, but in part directly into the intestines, probably by the histiocytes. With oral administration the feces may contain large amounts of the unabsorbed compounds. Traces may continue in the excretions by mobilization from the tissues, long after the administration has been discontinued.

Distribution and Retention of Metals.—The ingested or injected metal compounds leave the blood rapidly for the tissues, which soon have the higher concentration. A part is excreted, promptly or more often slowly, according to the compound used; the greater part of the metal is generally retained in the tissues for a long time, at first particularly in the reticulo-endothelial system, later in the interstitial tissue, partly as visible granules (as in hemochromatosis, argyria, chrysiasis, and so forth), often persisting through life; part also is in diffuse form, probably in the tissue cells. Lead and some other metals are stored in the bony trabeculae, analogous to calcium. With oral and intramuscular administration, the chief deposits are in the liver and kidneys; with intravenous injection the lung and spleen may be relatively richer for a few hours, by straining off the flocculates. Other organs contain considerably less, but generally more than the blood. The relative concentration in the kidneys and liver varies reciprocally for different metals, as shown in the following series,

higher in kidney: *higher in liver:*

$$\Lsh \text{U} \leftarrow \text{Au} \leftarrow \text{Bi} \leftarrow \text{Hg} \leftarrow \text{Pb} \rightarrow \text{As}^{\text{V}} \rightarrow \text{Th} \rightarrow \text{As}^{\text{III}} \rightarrow \text{Ag} \rightarrow \text{Cu} \Rsh$$

(Hevesy and Wagner, 1930). The explanation of this selectivity is not known; the local acidity is concerned in colloidal silver (Koller-Aeby and Koller, 1930). *Phosphatase* may be another factor, since metal phosphates precipitate rather easily, especially in the kidneys, as well as in the bones. When the metals are first absorbed into the blood stream, they must be ionizable, at least in part, since sulfides are precipitated in the mucous membrane of the mouth and colon. When they enter the tissues, however, they become insoluble, physiologically inactive, and difficult to mobilize. The therapeutic and injurious effects are probably determined in the short time when effective concentrations of the metal ions are circulating in the blood. The delayed effects may be conceived as later consequences of the primary injury, and the cumulative actions are probably the gradual summation of successive toxic injuries.

The **acute effects of metal compounds** are dominated by the local actions of the ionizable salts, based on protein precipitation, resulting in irritation on oral or hypodermic injection, and intravascular precipitation or flocculation on intravenous injection. The slow absorption of most metallic compounds adds to the difficulty of observing acute systemic effects. Molecular compounds devoid of these objections act primarily as molecules rather than as the metal.

Intravenous injection of dissociable metal compounds generally causes colloidoclastic shock, with sharp or slow fall of blood pressure, in proportion to the mutual precipitation of the compound and of blood protein. The more manageable colloidal metals, and some molecular compounds such as mercurochrome and flumerin, have been used to produce "nonspecific" reactions to combat septicemia, sometimes with good and often with bad results. A milder degree of this action constitutes the "nitritoid crises" such as occur with arsphenamine injections.

Acute systemic effects from easily absorbable metallic salts are seen with arsenic, mercury and uranium. They involve chiefly injury to the capillary endothelium, especially of the abdominal viscera, resulting in acute enteritis, with shock and dehydration, even on parenteral administration; colitis, nephritis and sometimes hepatitis. It appears probable that all the damage is done soon after absorption, and that the later phenomena are the consequences of this early injury.

The actions of arsenic, mercury and probably of most metals appear to be concerned with the *-SH groups* that are essential to cellular metabolism. Metal actions also combine with the *carboxyl groups* of amino acids and therefore render proteins more basic.

The capillary injury varies at least in degree for different metals, and it has been suggested, probably too schematically, that these may be divided into *two groups;* the first group acting mainly peripherally on the *blood vessels,* and the second group acting peripherally on the *heart.* To the first group belong arsenic, antimony, uranium, bismuth, iron, magnanese, selenium, tellurium, aluminum, tin, nickel, cobalt, gold and platinum (Wohlwill, 1907); to the second group, lead, phosphorus, copper, zinc, cadmium, mercury, vanadium, cerium and thallium. In the *perfused heart,* all metals (in the form of lactates) produce block and diastolic standstill (Voegtlin, 1915).

Metal nephritis begins usually in the epithelium of the convoluted tubules and spreads to the glomeruli. If the poisoning is chronic, the nephritis may become interstitial and lead to renal cirrhosis.

Nephritis has been described in poisoning by the following metals: Ag, Al, As, Au, Be, Bi, Cd, Ce, Co, Cr, Cu, Hg, Mn, Ni, P, Pb, Sb, U, W, Zn. There may also be renal *glycosuria, i. e.,* the appearance of sugar in the urine without hyperglycemia (Luzzato, 1914). *Tissue cultures of renal epithelium* are especially sensitive to Pb and Cu; of *liver cells* to Zn, Co and Ni (Samnié and Verne, 1934).

Subacute metal poisoning develops from the acute, if this is not quickly fatal, since the consequences of the capillary and tissue injury progress for a time. Indeed, with nonprecipitant compounds symptoms may be delayed for several days, when the metal may have disappeared from the blood (White, 1880). Tartar emetic, when injected in appropriate doses into a vein, disappears from the blood in ten minutes, but the first symptoms may be seen only after some twelve hours.

Chronic metal poisoning may develop from subacute, but commonly involves repeated or continued exposure with cumulation of injury. The phenomena take chiefly two directions: nutritional—digestive disturbances, anemia, cachexia, nephritis; and *nervous,* functional and anatomical, peripheral and central lesions, neuritis with tremors and paralyses, encephalopathia, vasomotor disturbances, colic, arthritis and gout. The two groups interlock, in that the nutritional disturbances tend toward neuritis, and conversely.

The *digestive disturbances* are among the earliest indications of chronic metal poisoning. Small doses of practically all metals produce more or less hyperplasia of the bone marrow and increased *hematopoiesis;* large doses cause injurious irritation, anemia and toxic mobilization of immature erythrocytes. Iron is an indispensable constituent of hemoglobin. Its utilization is aided by small doses of other metals: Cu, Co, Mn, Ge, As and even Hg. Traces of Cu, Mn and Zn promote *nutrition* and growth, and are probably essential.

Stomatitis occurs in chronic poisoning by mercury, bismuth and lead. It is due to the formation of the irritant and toxic sulfides of these metals with the products of bacterial putrefaction, in a vicious circle. The local effects of these sulfides depend partly on their different solubilities (Santesson, 1934).

The *reaction of living bone to various metals and alloys* was investigated by H. A. Davenport and Bothe, 1941. Copper produces local necrosis; Ti, Pb, Cr, Al, vitallium and stainless steel are well tolerated.

Colloid metals may be obtained by establishing an electric arc between metallic wires under water, or by the action of reducing agents on solutions of metallic salts. These can be made into more concentrated solutions (Voigt, 1914). Colloid solutions of Pt, Ag, Hg, Au, Bi, Cd and Ir, and also of their insoluble oxides and salts, have been prepared by these methods. Colloid solutions do not produce the ion actions of the metals directly. The colloid condition, however, gives them *catalytic properties; i. e.,* minute quantities may induce reactions in large quantities of other substances (*e. g.,* conversion of alcohol into acetic acid), the metal taking no part in this transformation. This catalysis is hindered by many poisons. The metals *pass readily from the colloid into the ionic condition, e. g.,* by the action of bacteria, and may then exert the ordinary action of the metals. Since this conversion occurs but slowly, these actions are mainly local and produce a minimum of irritation. After intramuscular or peritoneal injection, the *absorption* is slow, and not exclusively by the leukocytes (Voigt, 1916). If injected intravenously, they sojourn only a few minutes in the blood (Niculescu, 1912), and are then deposited, especially in the liver and the hemopoietic and excretory organs (Voigt, 1914, 1916).

Protein Stabilizers.—Colloidal metals for clinical use (for instance Collargol) are often "stabilized" by the addition of proteins. These may produce active or passive anaphylaxis (Hanzlik and Karsner, 1920), and are at least partly responsible for the therapeutic and toxic "reactions."

Pharmacologic Actions of Colloid Metals.—Their gradual transformation into the ionized form eventually produces the ordinary systemic effects of metals. They have been used, hypodermically and intravenously, for this purpose, without serious advantage. (Solutions should not be made isotonic with salt, since electrolytes cause precipitation.) They also produce other rather indefinite and inconstant effects, probably attributable to the colloid condition: hyperpyrexia, first hypo-, then hyperleukocytosis, renal and intestinal irritation, and fatal coma (Gros and O'Connor, 1911). They may be followed by increased excretion of nitrogen and uric acid (Ascoli and Izar, 1907). Repeated intravenous injections of colloid metals or of other foreign colloids produce marked irritation of the lymphoblastic tissue of the spleen, lymph glands and bone marrow (Nissen, 1922). An interesting effect has been described by Gaudrelet: in a normal animal, the intravenous injection of the dye thionin has little effect, but it exaggerates the hypotensive effect of nigrosin injection. This response fails to occur in animals injected with electrocolloid metals, peptone or other colloids.

Therapeutic Use Against Infections.—Colloid silver was extravagantly lauded as an internal antiseptic in puerperal and other septicemias and infections; but the claims do not stand critical examination (Report, Council on Pharmacology and Chemistry, 1909). Gros and O'Connor found that colloid metals, like charcoal, adsorb poisons, alkaloidal as well as toxins, and therefore decrease their toxicity, but the decrease is insignificant and does not occur at all unless the poison was treated before being injected. Phagocytosis is perhaps somewhat increased for some bacteria, but not for all (Le Fèvre de Arric, 1913). Colloid silver or mercury is fairly antiseptic, but not germicidal (Marshall and Killoh, 1915).

Dangers.—Colloid silver preparations are likely to deteriorate into the insoluble form and may thus produce embolism (H. J. Hamburger, 1909). A number of deaths have occurred probably by vascular embolism from the injection of collargol into the renal pelvis for x-ray diagnosis (Eisendrath, 1914). Buerger, 1914, found that these injections may penetrate the renal parenchyma to the surface of the kidney, and lead to necrotic and suppurative foci.

Metal chemotherapy of cancer started with the announcement of Wassermann, Keysser and Wassermann, 1911, that they had succeeded in causing the disappearance of rat tumors by the intravenous injection of selenium eosin compounds. Since then, similar favorable results were reported for colloidal copper, platinum, sulfur and some other colloids and organic metal compounds (L. Loeb and co-workers, 1912 to 1913). Even human tumors seemed to show some retrogression. Uhlenhuth, 1912, and Walker, 1912, failed to confirm the animal experiments with eosin selenium. Keysser's further experience (1914) was also discouraging. C. Lewin, 1928, interpreted the effects of colloidal metals and of arsenic as nonspecific actions on the capillaries of the tumor. Carcinomatous tissue of mice shows some selective concentration of bismuth, after hypodermic injection, but not of lead or thorium (Hevesy and Wagner, 1930). The injection of lead will be discussed under that heading. *In tissue cultures* of a rat sarcoma, the addition of zinc or copper hindered growth. Minimal quantities of iron increased the growth rate and emigration of the cells; moderate concentrations increased the oxydase granules; higher concentrations retarded growth and finally caused degeneration (Uei, 1926). The biochemistry of malignant tissues was *reviewed* by Voegtlin, 1937. In human cancer, the reported improvement has been symptomatic only, and this has little significance. Weil, 1913 and 1915, pointed out that the only admissible sign of improvement is reduction of the size of the tumor; from this standpoint the clinical reports are negative.

INORGANIC ARSENIC COMPOUNDS

Arsenical compounds act locally as mild and slow corrosives and have been employed in superficial cancer. Systemically, they relax the capillaries and increase their permeability, thus simulating inflammation. This change is most conspicuous in the splanchnic area. In acute arsenic poisoning, it results in violent gastro-enteritis, closely resembling cholera. The dilatation of capillaries introduces changes in the circulation which cause secondary disturbances in the function of more remote organs, particularly in the *nervous system;* but the latter are probably direct, for they occur acutely in frogs whose nervous functions are not immediately influenced by the blood supply. *Fatty degeneration* of the cells is seen, especially in glands and muscles, with other disturbances of nutrition and metabolism, particularly in chronic poisoning. There may also be a direct paralysis of the *heart.* Milder degrees of the same action may stimulate metabolism beneficially. This might explain the therapeutic uses of arsenic in malnutrition, anemias and skin diseases; but the mechanism of their action, and indeed the results, are in doubt. There are also characteristic effects on the bones and bone marrow. Arsenic, especially in the organic forms, is highly effective against protozoan infections.

Arsenous and Arsenic Compounds.—Trivalent As (arsenites) is generally much more toxic for protozoa, bacteria and yeast cells than is pentavalent As (arsenates) (Kionka, 1911). This holds also for the different valence in organic compounds, and for the corresponding antimony valences (Friedberger and Joachimoglu, 1917). It has been assumed that the 5-valent As is nontoxic until it has been reduced to the 3-valent (Loew, 1887).

The following shows the relation of the inorganic trivalent and pentavalent compounds:

As^{III}: AsH_3 = arseniureted hydrogen
As_2O_3 = arsenous trioxide
$+H_2O = H_2As_2O_4 = 2HAsO_2$ = arsenous acid
$KAsO_2$ = potassium arsenite
$KH(AsO_2)_2$ = potassium acid arsenite

As^{V}: As_2O_5 = arsenic pentoxide
$+H_2O = H_2As_2O_6 = 2HAsO_3$ = arsenic acid, meta
$+3H_2O = H_6As_2O_8 = 2H_3AsO_4$ = arsenic acid, ortho
Na_3AsO_4 = sodium arsenate
Na_2HAsO_4 = sodium arsenate, dibasic

Relative Toxicity of Arsenic Compounds.—With intraperitoneal injection into guinea pigs, the toxicity decreases in the order of: arsenites, arsenates, colloidal arsenic, atoxyl and cacodyl (Launoy, 1918). *Elementary arsenic* (precipitated) has one-fortieth the toxicity of the trioxide, hypodermically, for rabbits and guinea pigs (Cannava, 1938). The *ratio of toxicity of arsenous acid: arsenic acid* varies for different tissues. With intravenous injection in rabbits, it is as 6:10; for the excised frog's heart, as 300:1. The arsenous is also more toxic for the excised intestine of rabbits. These different ratios indicate that the toxicity of arsenic acid is due to reduction to arsenous acid, which varies in degree for different tissues (Joachimoglu, 1915). Schulz, 1884, and Binz, 1897, attempted to explain the arsenic effects as *alternating oxidation and reduction* of the cells, due to the easy passage of arsenous and arsenic compounds into each other (which Schulz, 1892, demonstrated on organ emulsions). Husemann, 1892, pointed out that if this were true, both forms should have the same toxicity. The difference is not great for mammals, but considerable for lower animals and plants (O. Loew). The explanation is therefore not tenable. It is now generally believed that the arsenicals hinder protoplasmic oxidation. Relatively low concentrations of arsenic arrest assimilation of oxygen by rabbits' liver, yeast, bird erythrocytes, and insects. Arsenous oxide inhibits various oxidation systems (P. P. Cohen, 1939). Peters *et al.* found that sodium arsenite and lewisite check the pyruvate oxidase system of brain mash, which depends on the —SH group for its activity. It appears that trivalent arsenicals are toxic by combining with the —SH group of the activating proteins of enzyme systems, which are concerned in carbohydrate transformation and fat metabolism. Voegtlin, Dyer and Leonard, 1923, showed that the arsenous oxide binds and thus inactivates organic *sulfhydryl groups,* especially glutathione, and conversely, glutathione antagonizes the toxic and therapeutic actions of arsenicals (S. M. Rosenthal and Voegtlin, 1930).

Absorption of inorganic arsenicals occurs readily, to some extent even from the intact skin. Poisoning may therefore result from the external use of arsenical cosmetic preparations. With hypodermic injections, the diarrhea often sets in within an hour.

Excretion occurs by all the usual channels—urine, feces, sweat (Tachau, 1911), milk and epithelium of the skin (Heffter, 1905). With oral administration, the main part leaves by the feces; with hypodermic, almost completely by the urine. The excretion is always slow and incomplete, especially with prolonged administration (Croner and Seligmann, 1907).

Time of Excretion.—The excretion begins in two to eight hours after the administration, but lasts for a long time—three to ten days, after a single dose; to seventy days when it had been given continuously. In rabbits' urine it was found for 120 days, in dogs' for 160 days, after the administration was stopped. The elimination and retention in dogs were studied by Dutcher and Steel, 1914.

Retention.—A considerable proportion of arsenic is retained even at low income levels, increasing greatly with higher income. It is stored in all the tissues.

The storage of arsenic with long-continued feeding of subtoxic doses to rats and dogs has been studied extensively by Calvery and his associates, 1938. The storage was much greater when arsenic was fed as calcium arsenate than as the trioxide (H. J. Morris, 1938). Dogs store much less than rats at the same intake level; and both store much less than they do of lead.

Distribution in the Tissues.—The *kidneys and liver* have by far the highest arsenic content of the viscera, and the concentration in the kidneys is much the higher. That in the *cerebrospinal fluid* is low. The hair has a high concentration in chronic poisoning. The arsenic passes across the placental circulation of the *fetus* (Laug *et al.*, 1938).

Radioactive potassium arsenite injected hypodermically into man, apes, rabbits, and guinea pigs shows the highest concentration in the kidney and liver, lower concentration in the blood. In leukemic blood there is ten times as much arsenic per leukocyte than per erythrocyte. Rats have the highest concentration in the blood; 95 per cent of the blood arsenic is in the erythrocytes, and follows the globin and heme fractions (F. T. Hunter *et al.*, 1942). Extensive and accurate data for continued feeding of rats and dogs are given by H. J. Morris, 1938, and E. W. Wallace, 1938. Morris noted that the *weight of the liver* averages 41 per cent heavier than in the control animals, while that of the brain was 8 per cent less. Slowtzoff, 1922, claims that the arsenic exists in the liver as a nucleoprotein compound. Older data for animals are reported by Blarez and Deniges, 1907; for *human* by Eckeley, 1913, and Schellbach, 1922; *cerebrospinal fluid* by Eckeley and by Finel and Leroid, 1913. After the administration of arsenic, the *hair* contains detectable quantities, in firm combination. The deposition is slow but persistent. Therefore none is found in acutely fatal poisoning, the earliest demonstration being after two weeks. It may then persist for months or years, long after the metal has disappeared from the liver and bones or from the skin (Heffter, 1915; M. Oppenheim and Fantl, 1934).

Normal Occurrence of Arsenic.—A Gautier, 1899, found minute traces of arsenic in normal tissues. Its universal presence was confirmed by Bertrand and all those who worked with sufficiently delicate methods (C. N. Myers and Cornwall, 1925). In man, it occurs especially in the thyroid (0.16 mg.); also in the thymus, brain and skin. It appears to be in organic combination with the nuclein. None is found in the liver. Normal human blood contains 0.064 mg. per 100 cc. (H. Guthmann and Grass, 1933). This arsenic is introduced with the food and especially the drinking water. The quantity of arsenic normally present in the intestinal canal *never* exceeds $\frac{1}{10}$ mg. Larger quantities point to poisoning (Gautier, 1904). The *urine* generally contains traces, up to 0.5 mg. per day, depending mainly on the arsenic content of the food (I. Bang, 1916).

Local Actions.—The arsenicals are not precipitant and therefore irritate only weakly, even on wounds or mucous membranes; but the cells die slowly after prolonged contact. This is due to injury of the capillaries, which results in congestion, stasis, thrombosis, leading to local ischemia and necrosis. There is no direct action on the cells, for the cornea, which does not have capillaries, is not injured, nor are dead tissues corroded (J. Witzel, 1898; Ellinger, 1931). The destructive action is sometimes used for killing exposed *dental nerves* and superficial *epitheliomas*. Arsenic is much more destructive to pathologic cells, so that the cancerous tissue may be killed without injury to the surrounding normal tissue. As with all cancer salves, some of the deeper tumor cells generally escape, leading to inoperable recurrences. Their use is therefore inadvisable. Relatively benign epitheliomas may be caused by prolonged arsenic contact (H. Montgomery and Waisman, 1941).

Circulation.—Fall of blood pressure to shock level is characteristic of acute and subacute arsenic poisoning. It is due to paralysis and increased permeability of the capillaries, analogous to traumatic shock, enteritis, and peptone or histamine injection. The vasodilatation is most conspicuous in the splanchnic area; but the blood pressure falls even when the intestines are tied off, so that the muscular vessels are also dilated. The dilatation can be demonstrated by perfusion of excised organs. It is therefore peripheral. The vessels, however, continue to react to splanchnic stimulation till very late, and to epinephrine even after the splanchnic response is lost (A. Loeb, 1911). The arterioles must therefore still be capable of contracting.

Intravenous injections of large quantities of salt solution cause edema in animals poisoned with As, but not in the normal (Magnus, 1899). The thoracic *lymph flow* is increased by arsenic, the phenomena being similar to those of peptone (Yanagawa, 1916). The application of arsenite to the exposed *mesenteric vessels* of the frog or rat causes dilatation, first with faster flow. Soon the capillary walls become altered and the flow is slowed, with diapedesis of corpuscles (Ellinger and Schmidt, 1933). However, arsenic inhibits the migration of leukocytes in the inflamed mesentery of frogs (Ikeda, 1916). Since *increased permeability* of the capillaries is one of the essential features of inflammation, the phenomena of arsenic poisonings are similar to those produced by irritating inflammation, although the primal cause is different.

Heart.—In the excised (Langendorff) heart the amplitude is first increased, then diminished; the rate may be slowed, quickened or arrhythmic. Arsenites are more toxic than arsenates, and these more than the organic.

Of the latter, cacodylate is the most potent; arsphenamine and its oxidation products are inactive (Archangelski, 1912). In intact animals the cardiac action of the arsenicals is relatively unimportant, for the heart is able to maintain a fairly high pressure if the aorta is clamped (Boehm and Unterberger, 1874).

Gastro-Enteritis.—The first and principal symptoms of acute arsenic poisoning are those of violent inflammation of the digestive tract. This suggested that arsenic acts as a corrosive. However, the autopsy rarely shows extensive corrosion, and the gastro-enteritis may be obtained with at least equal readiness if the arsenic is injected into the circulation or subcutaneously. This would not definitely exclude all local action, since some arsenic is excreted into the alimentary canal, but the quantity is not nearly enough to account for the symptoms.

The inflammation is due to the systemic action on the capillaries, which is strongest in the intestines, no matter how the arsenic has been introduced. The capillary paralysis results in the production of exudation into the connective tissue. This raises the epithelium and causes it to be thrown off in shreds or false membranes. The exudation is then poured into the lumen of the intestine and largely coagulates. This distention, as well as the circulatory changes, causes increased peristalsis and *watery diarrhea;* the shreds of mucus and coagulated exudation give to the evacuation the character of "*rice water*" stools (Boehm and Pistorius, 1882). The pathology is the same as that of Asiatic cholera, and without a history it is impossible to distinguish between the two conditions except by chemical examination of the dejections. The extreme distention of the capillaries may lead to their rupture, to the formation of ecchymoses, or possibly bleeding into the intestine or stomach, and consequently bloody vomiting or diarrhea.

Kidneys.—Arsenic produces nephritis, at first mainly vascular (Schlayer and Hedinger, 1907), but always with more or less involvement of the epithelium (MacNider, 1912).

The vessels of the kidneys participate in the capillary dilatation. The glomerular capillaries are swollen so as to fill the capsule; the urine is albuminous and scanty, and cannot be increased by caffeine (Hellin and Spiro, 1897). The retention of nitrogen in the blood is relatively slight (Karsner and Denis, 1914). The types of nephritis from different arsenic compounds, and the actions of arsenicals on the *adrenals* are described by L. Pearce and Brown, 1915.

Muscle Metabolism.—Acute arsenic poisoning of rabbits decreases the concentration of hexose monophosphate and adenyl pyrophosphate in the muscle (Nonnenbruch *et al.*, 1936).

Etiology of Arsenic Poisoning.—Arsenic trioxide, "white arsenic," was formerly used extensively for *criminal poisoning.* It is readily obtainable, and is easily administered without suspicion, since it is odorless and nearly tasteless. The symptoms also are not likely to arouse suspicion, the acute and subacute course resembling that of a severe gastro-intestinal upset, which by repeated graduated administration may take the color of indefinite ailing, with nephritis, neuritis, and so forth. An Italian woman, Tofana, at the end of the 17th century was credited with special skill in such poisoning by an "*Aqua Tofana*" prepared from the putrefied juices of animals poisoned with arsenic. However, much of the traditional poison lore of former centuries smacks of the witches' cauldron. The development of chemical methods of detection has changed this situation. Among the ignorant, however, it may still be unsuspected. The use of arsenical embalming fluids constitutes a difficulty in its medico-legal detection, which is also complicated if arsenical medicines have been administered. *Accidental or suicidal* acute arsenic poisoning is still common, since arsenic is easily accessible as arsenic trioxide in rat and fly poisons, and as insecticides, lead or calcium arsenate, and Paris green. Arsenic trioxide when sold at retail should be colored with lamp black or indigo so that it may not have the innocent appearance of powdered sugar. *Therapeutic arsenic poisoning* may occur subacutely by special susceptibility to the organic arsenicals; inorganic arsenic therapy may easily lead to chronic poisoning. *Chronic arsenic poisoning* arises chiefly from arsenical cosmetics, dyes and fabrics, and from foods contaminated with insecticide sprays. Many of the cosmetic preparations on the market contain arsenic and have given rise to accidents. The use of arsenic compounds, such as Schweinfurt green, as pigments has been absolutely prohibited; but many of the coal-tar dyes require arsenic in their preparation, and frequently this is not entirely removed.

Arsenical Dyes.—Wall paper dyed with arsenic compounds was formerly a frequent source of arsenic poisoning, but this has now largely disappeared. The arsenic is given off from these papers as dust. Undoubted cases of poisoning have also occurred, however, when the arsenical paper was completely covered by a harmless paper; in these, some volatile arsenic compound must have been formed. Modern wall papers contain practically insignificant traces (Schulz, 1915). The permissible limit of arsenic in papers is placed at 0.1 grain per square yard; but this is probably not quite harmless. The Bureau of Chemistry of the United States Department of Agriculture has analyzed a number of papers on the American market (Haywood and Warner, 1904). Over 90 per cent of these contained less than 0.046 grain per square yard, and are therefore safe. *Furs, rugs and fabrics* were less satisfactory. *Black stockings* particularly often contained quantities of arsenic (above 0.01 grain per square yard), which must be deemed dangerous, considering their intimate contact with the skin.

Arsenic in Foods.—The use of arsenical insecticides has become practically indispensable in agriculture, but they entail some danger to health unless they are carefully controlled. Arsenic is used chiefly as Paris green, and as calcium arsenate and lead arsenate, the last involving also the more serious risk of lead poisoning (H. A. Kuhn, 1930). Fruits and vegetables subjected to these sprays contain the metals for long periods (Sonntag, 1915), particularly in the exposed outer layer. They can, however, be removed by suitable washes to insignificant and harmless proportions.

The United States food control regulations limit the quantity of spray residue permitted in food. The current limit for arsenic is 0.01 grain per pound, 1.4 mg. per Kg. If three pounds of food consumed in a day contained this concentration, it would amount to 0.03 grain = 1.95 mg. of arsenic. The allowance for lead is nearly twice as high. The use of arsenates in sprays between 1917 and 1936 in the United States increased from 14.5 to 125 million pounds per year, a pound per person (Calvery, 1938).

When fed to rats over long periods, calcium arsenate is more toxic than lead arsenate, and this is more toxic than lead carbonate (L. T. Fairhall and Miller, 1941). Orchardists exposed to the lead arsenate spray routine have a urinary arsenic concentration of 0.06 to 0.22 mg. per liter; nonexposed individuals have 0.03 to 0.15 mg. The difference is not considered practically significant (P. A. Neal *et al.*, 1941).

Arsenical insecticides are the most extensively used "*stomach poisons*" that kill insects after they are eaten. They produce desquamation of their intestinal epithelium (M. Pilat, 1935). Arsenates (lead or calcium) are more useful, since arsenites are relatively more injurious to *plants*. Somewhat high concentrations kill the leaves outright, blackening them in a day or two. Smaller amounts have no perceptible effect for some weeks; then the leaves turn yellow and drop. Still smaller amounts increase the respiration of the foliage. Arsenic-sprayed citrus trees mature their fruit faster. *Lead arsenate*, the most used arsenical insecticide, is relatively insoluble, but is partly hydrolyzed by water to basic lead acetate and arsenous acid (McDonnell and Graham, 1917) and may therefore scorch the foliage. *Paris green*, aceto-arsenite of copper, has also been used for *malaria control* by dusting it on the pools, where the particles are eaten by the larvae. *Arsenic trioxide* and *sodium arsenite* are used on insect baits, never on the foilage. Sodium arsenite is also employed to kill *weeds* (H. H. Shepard, 1939).

Course of Acute Arsenic Poisoning.—The symptoms appear only after several hours, and sometimes on the next day; illness occurring promptly after eating the suspicious food is probably not arsenical. Once started, the course may be rapid: in *fulminant cases*, the withdrawal of the blood from the general circulation into the splanchnic area may produce prompt collapse, convulsions, paralysis, unconsciousness and death before enteritis has time to develop (corresponding to "dry cholera"). The typical course, however, extends through eighteen hours to three days and sometimes four to fourteen days. The suspicion of the patient may have been aroused by the sweetish astringent taste of the substance. The *symptoms* start with vomiting and profuse and painful diarrhea. The withdrawal of water from the body leads to great thirst, dryness of the mouth and throat, and difficulty in swallowing and articulation. The urine is diminished and often bloody and albuminous. The nervous symptoms consist in vertigo, headache and pain in the limbs. The patient is cyanotic, with cold extremities. Toward the end occur syncope, coma, clonic and tonic spasms and general paralysis. A deceptive remission may occur on the third or fourth day, with cessation of the vomiting and diarrhea and with apparent improvement in the general condition, but with recurrence of the collapse within a day. Death usually occurs by exhaustion as a result of the prolonged gastro-enteritis, as in cholera. In case of recovery, the symptoms gradually regress, but severe diarrhea may persist for weeks and sometimes finally weaken the patient to a fatal termination. In the *subacute poisoning* the inflammation of the mucous membrane of the alimentary canal is prominent. Inflammation of other mucous membranes also becomes conspicuous, and shows as conjunctivitis, coryza, stomatitis, salivation and pharyngitis. Skin eruptions make their appearance if the arsenic poisoning is at all prolonged. In this case there are also symptoms arising from the central nervous system, as well as neuritis. The *diagnosis of acute arsenic poisoning* is made by the violent gastro-enteritis. This can usually be easily distinguished from that produced by acids and alkalis, by the history of the case, absence of corrosion in the mouth, and by the lesser prominence of the local symptoms.

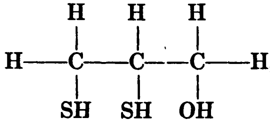
Autopsy Findings.—The patient appears emaciated from the withdrawal of liquid from the body by the profuse diarrhea, and this even if he retains a fair amount of adipose tissue. The appearance of the alimentary canal with its large amount of fluid and the presence of shreds of mucus and false membrane, with usually no pronounced corrosion, are characteristic. Microscopically, gastro-adenitis and cell infiltration are often seen. The body after arsenic poisoning usually putrefies slowly and may become mummified, which causes a suspicion, although it is not at all a proof of such poisoning. The positive proof is furnished only by the chemic examination. It must not be forgotten that arsenic may be introduced into the body in the embalming fluid.

Treatment of Acute Poisoning.—Acute arsenic poisoning is best treated by emetics and gastric lavage with warm water followed by a saline cathartic. The kidneys would be protected by a milk diet. The chemic antidotes are of doubtful value. *Magma Ferri Hydroxidi* (see Index) was introduced by Bunsen and Berthold, 1834, and was long considered the best antidote, the ferric hydrate and arsenic forming a compound which was deemed almost insoluble; but experienced pharmacologists (De Busscher, 1902; McGuigan *et al.*, 1923) found that the antidote at best postpones death for a few hours, and apparently gives a slightly smaller percentage of fatalities; the differences may lie within the experimental error. It is conceivable that this antidote and other colloids may somewhat delay absorption by absorbing the arsenic (Lockemann and Paucke, 1911), and its administration can do no harm, provided that it is *promptly followed by effective evacuation.*

Para-aminobenzoic acid administered to rats diminishes the renal lesions and the mortality ratio of pentavalent arsenic and antimony compounds (P. N. Harris, 1944).

The hypodermic injection of *magnesium sulfate* has saved animals from fatal doses of arsenic, even when the latter was also injected hypodermically. Presumably, difficultly soluble arsenic magnesium compounds are formed (Sieber, 1912). The antidote must be used promptly, and the effective dose of magnesium is itself dangerous.

Dimercaptopropanol, "*BAL*" ("*British Anti Lewisite*"), Dimercaprol, 2,3-dithio-propanol, "dithiol,"



$$\begin{array}{ccccccc} & & H & & H & & H & \\ & & | & & | & & | & \\ H & — & C & — & C & — & C & — H, \\ & & | & & | & & | & \\ & & SH & & SH & & OH & \end{array}$$

was developed during the war especially as an antidote to the arsenical lewisite "gas," and is effective against other arsenicals, mercury, gold, antimony, bismuth, cobalt and nickel. It is ineffective against lead and selenium, and additive with tellurium (H. A. Braun *et al.*, 1946). Excessive doses are directly toxic. It is recommended against untoward effects of intensive arsenic therapy. Mercury poisoning appears to require larger doses (reviews, L. L. Waters, 1945; A. Gilman, 1946; Council on Chemistry and Pharmacy, report, 1946, J.A.M.A., *131*:824. A symposium of papers appeared in the J.P.E.T., 1946, *87*, No. 4, Suppl.).

Mechanism.—Dimercaptopropanol and closely related dithiols have a greater arsenic affinity than do the tissue thiols, and so prevent and remove the inhibition of enzymes by lewisite and other arsenicals. However, dimercaprol is directly toxic to some enzyme systems. It is a potent reducing agent and is rapidly oxidized by catalytic amounts of copper and hemin. It instantly reduces methemoglobin to hemoglobin and destroys this and hemin by opening the porphyrin ring. The *cytochrome oxidase activity* is arrested by preventing the oxidation of cytochrome. Brain glycolysis is inhibited by combination with the metal protein components that take part in the enzymatic process. Oxidized dimercaptopropanol inhibits enzyme systems containing essential -SH groups It destroys the activity of *insulin*, possibly by reducing its -S-S- groups. The inhibitory effects of *other heavy metals* on succinoxidase are removed by certain dimercaprol derivatives, indicating that the toxicity of these metals also is due to inhibition of -SH enzymes.

Dimercaptopropanol mobilizes the tissue arsenic in cats treated with oxophenarsine, producing a sharp rise in the arsenic concentration of the plasma (W. F. Riker and Rosenfeld, 1946).

Systemic symptoms after administering dimercaprol to man, 3 to 5 mg. per Kg. intramuscularly, consist in paresthesias (tingling of the nose, eyes, mouth and skin); perspiration and feeling of warmth, pain in various regions, lacrimation, blepharospasm, salivation, vomiting; restlessness, apprehension, weakness, fatigue, quickened heart rate, usually rise of blood pressure. These symptoms generally subside in one-half to four hours. With 8 mg. the effects are more marked, but return to normal in an hour or two. Repeated administrations, 5 mg. every three hours, do not produce significant cumulation, but rather some tolerance in some cases (H. Gold and Cattell, 1946). The same symptoms are shown by dogs. *Larger doses* produce increased depth and rate of respiration; muscle tremors of gradually increasing intensity; rapid thready pulse, nystagmus; *finally,* repeated tonic and clonic convulsions, acidosis, coma and death. The convulsions are alleviated by anesthetics and barbiturates (J. H. Durlacher *et al.,* 1946). Intramuscular or percutaneous administration causes intense vasoconstriction in skin and muscles, resulting in transient rise of blood pressure. Rapid intravenous injection produces circulatory collapse and direct cardiac injury (M. B. Chenoweth, 1946). *Pathologic* changes are slight: some congestion of the viscera, and sometimes fluid in the serous cavities and lungs. The LD_{50} for rats is 105 mg. per Kg. The actions on isolated skeletal muscle of frogs are reported by S. Krop, 1946.

Local application to the skin produces erythema and edema, but not vesication or necrosis. It is intensely irritating to the respiratory and gastric *mucous membranes,* causing edema and ulceration. In the eye, 10 per cent solution in oil produces temporary lacrimation, blepharospasm and pain, but no lasting ill effects.

Percutaneous application produces the typical systemic effects on the circulation (Chenoweth, 1946).

The pharmacology of several substances related to dimercaprol is described by Chenoweth *et al.,* 1946, and by O. G. Fitzhugh, Woodard *et al.,* 1946.

Effectiveness against Arsenical Poisoning.—Dimercaptopropanol seems effective in arsenic poisoning in man. It protects completely against *local effects of lewisite* on the skin, even when erythema has started. In the eyes it furnishes marked protection up to five minutes, and improvement up to thirty minutes. It protects contaminated animals against the *systemic effects of lewisite* or phenyldichlorarsine also when it is applied at a distance, and increases the excretion of arsenic. It should be applied to the burned area and administered systemically (H. E. Harrison *et al.,* 1946). It is effective against acute and subacute *oxophenarsine poisoning* in rabbits and cats, the arsenic being removed from its combination in the cells and excreted as the relatively nontoxic thioarsenite (H. Eagle, Magnuson and Fleischman, 1946; W. F. Riker, 1946). It resuscitates *micro-organisms* poisoned by various trivalent arsenicals, including oxophenarsine.

It is effective against clinical arsenic poisoning, as well as in animals, decreasing the mortality and hastening recovery (H. Eagle, 1946). Its value in arsenical dermatitis is reviewed by M. B. Sulzberger and Baer, 1947

Dimercaptopropanol decreases the toxicity of some *antimonial drugs,* notably tartar emetic and stibanose, but increases the mortality with fuadin, neostam and neostiban (J. F. Gammel *et al.,* 1947). It gives some protection in acute *mercuric chloride poisoning* (recovery of twenty-two patients: W. T. Longcope and Leutcher, 1946), and appears successful in serious poisoning by *gold* (A. Cohen *et al.,* 1947), even with the granulocytopenia (L. M. Lockie *et al.,* 1947). It also prevents the pulmonary reaction to inhalation of *zinc and cadmium fumes.* With cadmium, however, it forms toxic complexes in the body which cause serious renal damage. It is probably effective against *arsenical dermatitis and encephalitis,* but probably not against the hepatitis.

Dosage.—Dimercaptopropanol (BAL) is unstable in watery solution. It is marketed as a 10 per cent solution in oil, with 20 per cent of benzyl benzoate, which is administered intramuscularly. The dose schedule against *arsenic* is 3 mg. per Kg. of body weight, every four hours for the first two days, then four injections on the third day and two injections daily for a further ten days or until recovery. Against *mercury,* the first dose should be 5 mg. per Kg., as early as possible, followed by 2.5 mg. per Kg. in one or two hours, and again in two and in four hours; two such injections are given on the second day, and one on the third.

The mortality in acute clinical arsenic poisoning is high, 50 to 75 per cent (Lewin). The *fatal dose* varies, especially with the solubility of the preparation. Of the trioxide, 5 to 50 mg. are toxic; 0.1 to 0.3 Gm. is usually fatal; but recovery may occur after much larger quantities.

The dry trioxide or ordinary white arsenic is so slowly soluble that its toxicity is greatly influenced by the *fineness of the powder* in which it is taken; for instance, it requires 500 times more of the coarse powder than of the solution to produce emesis (Schwartze, 1922). The U.S.P. therefore specifies the maximal size of the particles in powders that are to be administered in solid form. *Pure metallic arsenic* is not very poisonous, nor are the pure *sulfides,* but they are generally contaminated with toxic oxides.

Parenterally, arsenic in solution is as toxic when injected into the mesenteric, as by the jugular vein, showing that the liver neither neutralizes nor retains it. It is less toxic on hypodermic injection, since it enters into more slowly dissociated compounds with the tissue elements.

Resistance of Species.—Arsenic is toxic to all animals which have a central nervous system; also to most of the higher plants, but not to all lower organisms. Its antiseptic action is comparatively small. Newborn salamanders show marked tolerance. Among *mammals,* the resistance is greatest in mice; then come the hedgehog, rabbit, dog and cat (Willberg, 1913). The susceptibility of *rats* to arsenic trioxide is decreased by sexual maturity (E. Agduhr, 1941).

The toxicity is the same for splenectomized as for normal mice (Towels, 1916). The *penetration* of various arsenic compounds into living and dead cells was studied by M. M. Brooks, 1923, 1925.

Habituation and Tolerance.—The mountaineers of Styria and certain other regions consume arsenic once or twice weekly, as a general stimulant and tonic. There is evidence that they gradually accustom themselves to use with impunity quantities of arsenic trioxide (to 0.4 Gm. per day) which would produce serious toxic, irritant and cumulative effects in ordinary individuals (Tschudin, 1851; Knappe, 1875). This tolerance can also be induced in dogs and rabbits. Cloetta, 1906, attributed it to diminished absorption from the alimentary canal. However, tolerance may be induced by intraperitoneal injections in rats (E. R. Norris and Elliott, 1945). Hausmann, 1906, attributed it to increased excretion. The latter also showed that the corrosive action on the intestines is decreased by habituation. Withdrawal does not cause any abstinence symptoms, even if the arsenic has been consumed for years. Joachimoglu, 1916, finds that the absorption of small doses, in dogs, is not diminished by habituation.

Fibroblast cells in *tissue cultures* do not develop any tolerance to arsenic trioxide with thirty-eight passages through increasing concentrations (O. Bucher, 1942).

Tolerance to some organic arsenicals can be induced by repeated administration in rats and rabbits. With carbarsone and arsacetin it may attain to three times the fatal dose. It is more moderate for mapharsen, tryparsamide and most of the others; slight or absent for the arseno compounds, none for sodium arsenite or cacodylate. Tolerance induced by one organic arsenical confers more or less tolerance to other organic arsenicals, but not to inorganic; nor does treatment with the inorganic induce tolerance to the organic. Induced tolerance to tryparsamide does not decrease its efficiency against trypanosomes (Kuhs *et al.*, 1939).

Subacute and chronic arsenic poisoning may produce chronic gastro-intestinal catarrh, sometimes ulcerative; some kidney injury and degeneration, and considerable tendency to edema: swelling of the eyelids is an early indication of therapeutic overdosage. Other phenomena are likely to be more important, especially with organic arsenicals and in slow chronic poisoning. They affect particularly the skin, liver, peripheral nerves and bone marrow. Fatigue and loss of energy may be the only symptoms in light chronic poisoning. The *skin changes* are particularly characteristic. They may extend to the mucous membranes, especially the conjunctiva. They include disorders of the vasomotor innervation, with flushing, edema and hyperidrosis; eczema, acne, thickening and scaling of the epidermis, keratoses beginning on the flexor surface of the hands and feet and sometimes progressing to epithelioma (Franseen and Taylor, 1934); falling out of hair, detachment of the nails, herpes zoster and sometimes fatal exfoliative dermatitis. Some patients develop a peculiar and characteristic melanosis (melanodermia) beginning in parts normally more deeply pigmented. In contrast to Addison's disease, it does not involve the mucosae. It is not due to a deposition of arsenic, but to organic pigment granules in the epidermis and exterior layers of the cutis (Gans, 1914). *Polyneuritis* occurs, with various symptoms, atrophy of the muscles, disturbance and paralysis of sensation and of the special senses (blindness). The voice may be altered by paralysis of the vocal cords. Severe mental disorders are relatively rare. *Liver injury* involves especially fatty swelling which may compress the bile ducts, resulting in increase of the bilirubin content of the blood, and in visible icterus. Occasionally, acute hepatitis may be rapidly fatal, especially with the organic arsenicals. *Injury to the bone marrow* leads to exhaustion of the blood-forming mechanism, resulting in the picture of pernicious aplastic anemia with hyperchromia and leukopenia. The *diagnosis of chronic arsenic poisoning* may be difficult because the symptoms are sometimes obscure or resemble closely those of chronic lead poisoning. They differ in the electric reaction of muscle and the absence of the blue line on the gums, which are characteristic of lead. Chemical examination may be necessary for the definite diagnosis.

Actions on Bone Marrow and Blood Formation.—In normal animals, the effects of arsenic on the marrow are mainly destructive: atrophy of the fat cells, dilatation and multiplication of the capillaries; increase of the leukoblastic, but not of erythroblastic, cells (in contrast to hemorrhage). Larger doses cause hyaline degeneration and anemia. Similar changes are produced by other metals, organ extracts and peptones (Stockman and Charteris, 1903), by phenylhydrazine and by excessive irradiation of the bone marrow (Isaacs, 1928). Saneyoshi, 1913, found that ordinary doses of arsenic do not normally stimulate the production of corpuscles. It is conceivable, but not demonstrated, that it acts more positively in anemia; von Hoesslin, 1913, claimed restoration of hemoglobin and erythrocytes, decrease of lymphocytes and increase of neutrophils. The viscosity of the blood is sometimes slightly increased (Farmachidis, 1912). The *resistance of erythrocytes*, as judged by hypotonic hemolysis, is increased by therapeutic doses of arsenic in anemias. Hill, 1915, suggested this as an explanation of the clinical improvement. Arsenate increases the rate of glycolysis by human red corpuscles (H. K. Barrenscheen and Hübner, 1930).

The *effects on metabolism* resemble those of phosphorus: *therapeutic doses* check oxidation, and favor nutrition and growth, even in adults. The bones become larger and more compact. The condition of the skin is especially improved. The blood formation seems stimulated under suitable conditions. Gain of weight under arsenic is not always due to improved nutrition, for it may be simulated by edema.

Arsenic is probably not an important "trace element", for rats grow normally when practically deprived of it (E. Hove *et al.*, 1938). The *growth* of rats is markedly impaired by the continued administration of "therapeutic" doses of trioxide, *i. e.*, 0.015 to 0.05 mg. per Kg. per day, corresponding to $\frac{1}{60}$ to $\frac{1}{20}$ grain for man (Sollmann, 1921). *Excessive doses*, as with phosphorus, lead to increased excretion of nitrogen, loss of weight, lessened gas metabolism, fatty degeneration of tissues, acidosis, decreased functionation of organs, destruction of blood, icterus, inability of the liver to form glycogen. A further analogy with phosphorus poisoning is the *fatty degeneration of the liver cells*, more marked with inorganic than with organic arsenic compounds. With intravenous injection, this is localized around the central veins; with hypodermic, it is more general (Ullmann, 1914). Toxic doses produce degenerative changes also in the kidneys, capillaries and blood. Pathologic tissues—malignant lymphomata, syphilitic gummata, and so forth—are more susceptible and may be attacked even by therapeutic doses. Experimental tumors may also be liquefied and destroyed (Neuberg, Caspari and Loebe, 1912). Arsenic leads to *thickening of the bones* and filling up of the Haversian canals (Gies, 1877), which may possibly justify its use in *osteomalacia*, but practically it is unreliable. It diminishes the *storage of lead* in bones of rats by about half (L. T. Fairhall and Miller, 1941).

Inorganic Arsenic in Therapy.—This was formerly used extensively and indiscriminately, as an "alterative and tonic," in nutritional disturbances, neuralgia, rheumatism, arthritis, asthma, chorea, malaria, syphilis, tuberculosis, diabetes, skin diseases and every kind of blood disturbance. These uses have become more and more restricted, and replaced by better, more certain and less dangerous agents. Inorganic arsenic is capricious, unpredictable and uncontrollable both as to good and harm, but the harm is more certain and generally more frequent than the good; but it is still used in leukemias and anemias, in the latter as a supplement to iron; and in skin diseases.

Arsenic in Leukemia.—The results are not brilliant, but it usually improves the general conditions somewhat. The early, milder stages are most promising (Hahn, 1914).

Skin.—Arsenic is administered externally and internally to improve the nutrition of the skin and hair, and in nonparastic chronic skin diseases. It should never be used in acute inflammatory conditions. The results are often disappointing. Hartzell, 1908, considered it most successful in recent, slowly spreading psoriasis; in chronic stationary lichen; and of limited value in pemphigus. Its injudicious use is often harmful to the skin. Brown discoloration, especially of naturally pigmented areas of the skin, may appear long after the arsenic administration has been discontinued. Arsenic is used extensively in *veterinary practice*, to improve the appearance of horses by brightening the coat and increasing the subcutaneous (also the peritoneal) fat.

Glycosuria.—Arsenic treatment (not salvarsan) lessens alimentary glycosuria in dogs. It has no effect on epinephrine glycosuria (Begemann, 1912). It has been tried in *human diabetes*, but without much success. Arsenic poisoning causes rapid loss of glycogen from the liver, and leads to the formation of lactic acid. Small doses increase, larger doses retard, *autolysis* (of the liver; Lacqueur and Ettinger, 1912). Small doses increase the *catalytic action* of the blood; larger doses have little effect (Duncker and Jodlbauer, 1911).

Dosage.—The ordinary "tonic" dose of arsenic trioxide is 1 to 2 mg., $\frac{1}{40}$ to $\frac{1}{30}$ grain; of the liquid preparations, 2 to 3 drops, three times daily. For more energetic effects, it is aimed to establish a tolerance by beginning with small doses, and gradually increasing these until some local manifestation of the arsenic appears—usually diarrhea, colicky pains, conjunctivitis or swelling of the eyelids. As soon as these are seen, the amount must be diminished. The starting dose may be 3 drops of Solution of Arsenious Acid, or 5 mg. of the Arsenic Trioxide, three times daily, increased by 1 drop or 1 mg., every day. All the official liquid arsenic preparations contain the equivalent of 1 per cent of arsenic trioxide. They may be given in water; the trioxide in pills, often with iron. "Fowler's solution" is the traditional favorite, but as it is alkaline, it is subject to incompatibilities, *f. i.*, with alkaloids, which may be avoided by the Solution of Arsenious Acid, which has the same arsenic content.

Preparations.—**Arsenic Trioxide,** U.S.P. (Arsenous Anhydride, Arsenous Oxide, Arsenous Acid, White Arsenic); As_2O_3; occurs as a white powder, or irregular masses of two varieties; one, amorphous, transparent and colorless, like glass; the other, crystalline, opaque and white, resembling porcelain. Both are odorless. Slowly sol. in 30 (glassy) or 100 (powdered or porcelain) parts of water; in 15 of boiling water; sparingly in alc. Freely sol. in hydrochloric acid and alkalis. Dose, 1 to 3 mg., $\frac{1}{60}$ to $\frac{1}{20}$ grain. It may be prescribed as ***Solution of Arsenous Acid,** U.S.P. (Solution of Arsenic Chloride), arsenic trioxide dissolved in Dilute Hydrochloric Acid and therefore of acid reaction; or as *Solution of Potassium Arsenite*, U.S.P. (Fowler's Solution; Liquor Kali Arsenicosi), which is slightly alkaline, and therefore *incompatible* with alkaloidal salts (in addition to salts of iron and magnesium, lime water and tannins, with which all arsenic solutions are incompatible). The dose of either solution is 0.1 to 0.3 cc., 1½ to 5 minims. Both contain the equivalent of 1 per cent of As_2O_3.

ARSENIURETED HYDROGEN

This gas, AsH_3, also called *arsine*, has a characteristic garlic odor. It is toxic in dilution of 1:20,000; a few bubbles (0.3 to 0.6 Gm.) may be fatal to man. The susceptibility varies considerably in different species. The gas is produced in lead burning; by the action of impure sulfuric acid on metals; from ferrosilicon, and so forth. Its toxic action is due to its *affinity for hemoglobin*, with which it forms a compound in the corpuscles, where it is gradually oxidized to arsenic oxide. This destroys the corpuscles, resulting in extensive hemolysis and anemia (Stadelmann, 1882). The blood count falls in a few hours. The hemoglobin is excreted by the urine, beginning in the sixth to tenth hour. Within a week, 70 to 80 per cent of the corpuscles may become hemolyzed, the blood count falling to a million. Death occurs from loss of hemoglobin, producing anoxemia and often pulmonary edema.

The *clinical symptoms* of anoxemia develop usually several hours after exposure, and resemble those of mountain sickness. The milder cases exhibit weakness, malaise, vertigo, intense headache, followed by nausea, vomiting and epigastric pain. In severe cases, the vomiting becomes continuous and bloody and the liver and kidneys become painful. Jaundice, hemato- and hepatogenous, appears, with a peculiar bronze tint of the skin, from the blending of the yellow with the cyanotic pallor. The urine contains hemoglobin, methemoglobin, hematin and bile pigments. The kidneys may be blocked by the debris of the blood corpuscles, or anuria may result from asphyxia. Oliguria indicates an unfavorable prognosis. Nervous symptoms, neuralgias and neuritis, may occur as in other arsenical poisoning. The blood picture is that of severe secondary anemia. Death may result in two to six days, preceded by convulsions, delirium and coma. The mortality is about 30 per cent. Recovery may occur even with severe cases. It may be complicated by the phenomena of subacute arsenic poisoning, with delayed death from nephritis. The *treatment* includes repeated transfusion, inhalation of oxygen and abundant fluid intake.

In vitro, arsine hemolysis is prevented by several fat-soluble mono- and di-thiol compounds. Some of the dithiols, but none of the mono-thiols, protect the respiration of tissue slices. 2, 3-Dimercaptopropyl ethyl ether protects intact animals against the arsine (C. J. Kensler *et al.*, 1946).

Hydrides of *antimony, selenium, tellurium and germanium* produce similar hemolytic effects (S. H. Webster, 1946).

Fate of the Arsenic.—A large part of the arsenic absorbed as AsH_3 is found in the blood corpuscles, much more than in the plasma or in other organs, except the spleen, where it accumulates from the destroyed corpuscles. The next highest concentration is in the liver and kidneys. The excretion occurs chiefly by the kidneys (Thauer, 1934).

Chronic poisoning with AsH_3 has been studied on animals by Kiese, 1937. The effects are blood destruction, at first compensated by active regeneration of erythrocytes, which fails in time, so that a stationary level of anemia becomes established. The hemoglobin may fall by 60 per cent. Other organs show but little injury. The *arsenic content* of the organs was unequal, but highest in the spleen, liver, bone marrow, erythrocytes and hair. The corpuscles always contain more than the serum.

"Ferrosilicon" is a mixture of Fe and Si compounds, used in the manufacture of steel. In the presence of water or moist air (as in shipment) it liberates phosphoreted and arseniureted hydrogen, which have produced fatal poisoning (J.A.M.A., *55:* 781, 1910). The grades containing 30 to 70 per cent of silicon are much more subject to the decomposition, and are therefore more dangerous than those containing a greater or smaller percentage.

Garlic odor with arsenic is a characteristic feature under certain conditions. It is noted when the metal is burned in air to As_2O_3. Moulds growing on damp wall paper and other arsenicals produce it by forming *ethyl arsine*, $As(C_2H_5)_2H$. The odor is sometimes observed in arsenic vomitus (Gumprecht), and is probably due to reduction products. Garlic breath does not occur, or but rarely, in the therapeutic administration of inorganic arsenic compounds, but is strong after the use of cacodylates.

ORGANIC ARSENIC COMPOUNDS

Trivalent and pentavalent arsenic can be introduced into a large variety of organic molecules. In this nonionic condition it does not immediately produce the ordinary arsenic effects; but in the course of the oxidation and reduction and other cleavage which these organic molecules undergo in the body, more or less ionic arsenic is gradually split off, and this produces the ionic arsenic actions in a delayed and generally milder form. The decomposition is usually slow, and progresses through intermediate stages of simpler organic molecules, so that a considerable part of the arsenic is generally excreted in organic form, before the cleavage is completed. In the meantime, the original compounds and their organic derivatives have the opportunity to exert their distinctive effects. These are much less toxic to the higher animals than is ionic arsenic; they lack particularly the paralyzing action on capillaries. On the other hand, they are much more toxic to protozoan parasites, trypanosomes, spirochetes, amebae, plasmodia, and so on, so that their administration arrests these protozoan infections, especially syphilis, sleeping sickness and spirillosis. The compounds that are practically useful have relatively little parasiticidal action *in vitro*. Their full effect develops in the host as with most antiprotozoal agents, probably by checking the multiplication of the parasites. In the arsenicals it is partly due to transformation into more active cleavage products. The toxicity and efficiency of the organic compounds are determined by a number of complex factors, especially the relation of absorption, distribution, sojourn and storage, and the rate and course of the decomposition. In the digestive tract the organic molecules are likely to undergo toxic cleavage, so that they must generally be administered parenterally. The compounds of the arsphenamine type tend to form colloidal solutions, and their intravenous injection may produce colloidal reactions with the blood. These differ for the individual compounds and can be minimized by careful technic in the preparation and injection of the solutions.

Chemic Structure.—The therapeutic organic arsenic compounds may be arranged under those containing *pentavalent* arsenic (cacodylic acid, arsanilic acid, tryparsamide, carbarsone and the like) and those with *trivalent* arsenic, the arsphenamines and the phenarsines (mapharsen, and so on). The *arsenic content* of the compounds is of less importance than the manner in which it is combined.

Historical on Arsenic in Protozoan Infections.—Arsenic had some reputation in syphilis since Fallopius (Herzfeld, 1911), and the cacodylate was employed in this disease by Gautier in 1896. Arsenic was also used in malaria with fair success. Laveran and Mesnil, 1902, found that arsenous acid causes the temporary disappearance of trypanosomes from the blood of infected mice. It has been tried in human cases (Merck's Report, *21:* 223), but the really effective dose is too dangerous.

Chemotherapy.—This term was restricted by Ehrlich to the parasiticidal treatment of infections by chemical agents. Such "specific remedies" had been discovered empirically for several protozoan diseases: quinine against malaria; mercury against syphilis; and ipecac against amebic dysentery. Ehrlich, 1909, sought systematically to extend this field by the search for substances which would combine a relatively high toxicity for the parasites with a relatively low toxicity for the host; *i. e.*, which would have a favorable "chemotherapeutic index," a low ratio of

$$\frac{\text{(Minimal effective dose)}}{\text{(Minimal lethal dose)}}.$$

He assumed that the relative toxicity for parasite and host would depend chiefly on the selective affinity of these for the toxic agent, and believed therefore that the therapeutic index would depend on the ratio of "parasitotropism" to "organotropism" (Bechhold and Ehrlich, 1906). It is now recognized that destruction of the parasite *in vivo* often does not depend on the direct "parasitotropism" of the agent, but more generally on interferences with enzyme systems that are essential to the metabolism of the parasite. In analogy with sulfonamides, para-aminobenzoic acid is a highly effective antidote to otherwise fatal doses of organic pentavalent arsenic compounds for rats. So also are many other benzene derivatives, the isomeric para-aminobenzoic acids, benzoic acid, phenylacetic acid and others (J. H. Sandground, 1944). The tropism theory was only a working hypothesis, however, and was not directly involved in Ehrlich's work. This took the direction of determining experimentally the therapeutic index of a variety of substances, and culminated in the discovery of the trypanosomicidal dyes and arsenicals, and of the more widely applicable arsphenamine; and this in turn led to the introduction of the other parasiticidal metals.

The trypanosomes which cause the tropical "sleeping sickness" and similar diseases in animals are easily transmitted to white mice, and therefore presented a convenient test of therapeutic efficiency. Ehrlich and Shiga, 1904, studied in this way a great variety of substances. The search was at first haphazard; but when partly successful results were obtained, it was sought systematically to improve these by altering the side chains so as to increase their specific affinity for the chemoreceptors of the parasites. The effective trypanocidal agents found by Ehrlich and by independent workers belong to four groups: (1) Benzidine Dyes (Trypan Red, and so forth); (2) Basic Triphenylamine Dyes (Malachite Green, Parafuchsin, and so on); (3) Arsenic Compounds; and (4) Antimony and Bismuth Compounds.

Experimental investigations were important mainly by elucidating the general principles of chemotherapy, for it was soon found that the detailed results could not be transferred directly to man: Agents effective in one species of host were often much less effective in another. Nor can the results for one kind of parasite be transferred to another kind (Longley, Clausen and Tatum, 1939). The dyes in particular were not practical, since they cause intense coloration of the body, irritation and necrosis of the skin and severe cachexia. However, the trypanosome studies, with somewhat refined technic (Voegtlin and Smith, 1920; Dale and White, 1922), are useful for preliminary orientation. For antisyphilitic agents, the results should be checked on rabbits and mice inoculated with syphilitic virus (W. H. Brown and Pearce, 1916; L. Pearce and Brown 1922). The final clinical decision must rest with clinical tests on man. Ehrlich thought it essential that the parasites should be killed by one single massive dose of the antiseptic ("Therapia Magna Sterilisans"). Clinical experience has shown this to be generally impossible and fortunately also unnecessary. There may be advantage, however, in employing simultaneously or successively agents belonging to different groups; for strains resistant to atoxyl, for instance, need not be especially resistant to mercury (Nierenstein and Todd, 1907).

Acquired Resistance ("Fastness") of the Parasites.—Injection of ineffective doses of the chemotherapeutic agents may render the trypanosomes more resistant to the agents of the same group, although they preserve their susceptibility to the other groups (Ehrlich, 1907). The resistance is preserved for many generations, even if the resistant parasites are passed through a succession of hosts (Voegtlin, Dyer and Miller, 1924). The acquisition of drug resistance by spirochetes has not been demonstrated *in vivo;* it has been induced *in vitro, i. e.,* in cultures, but is lost in a few generations, so that it would not be important therapeutically (Akatsu and Noguchi, 1917). It is not known whether the fastness is a genuine habituation, or merely a selective survival of the more resistant strains; the latter appears more likely.

Splenectomy greatly decreases the effectiveness of arsphenamine against relapsing fever in mice (Kritschewski and Meersohn, 1926) and of tryparsamide and arsenoxide against trypanosome infections of rats, but in these splenectomy also increases the multiplication of the parasites in the untreated animals (H. M. Kelly, 1930); with scrotal implantation of syphilitic material in rabbits, splenectomy rather intensifies the spirochetocidal action of arsphenamine (W. Frei and Fröhlich, 1931). *Blocking of the reticulo-endothelial cells* with India ink decreases the curative effect of arsenicals on trypanosomiasis, although the serum of the blocked animals has a higher arsenic content and is more trypanocidal *in vitro.* The blockade has little effect on the storage of arsenic in the liver and spleen (L. Reiner *et al.,* 1932).

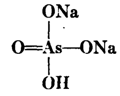
◆

SODIUM CACODYLATE

The effects of cacodylic acid (dimethylarsenic acid) are essentially those of the inorganic arsenic, to which it is partly reduced in the body. Since this reduction occurs but slowly, the action is more prolonged and less toxic, and the local irritant effects are avoided. However, the degree of reduction, and therefore of the effect, is variable. Cacodylate, especially when given by mouth, imparts a *garlic odor* [from cacodyl oxide, $As_2(CH_3)_4O$] to the breath, sweat, urine, and so forth. To avoid the more rapid reduction in the stomach, intestines and liver (Heffter, 1901), it is usually administered hypodermically or intramuscularly. Excessive doses produce *toxic symptoms,* due mainly to the ionic arsenic (Schulz, 1879; Heffter, 1901; Dawes and Jackson, 1907), although the cacodyl molecule may conceivably play a part. It is used *therapeutically* in the same condition as inorganic arsenic. The *dosage* is from 0.025 to 0.15 Gm.

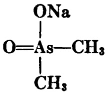
ORGANIC PENTAVALENT ARSENIC COMPOUNDS

These are illustrated by the following formulas:



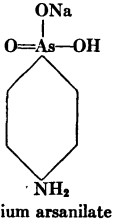
$$\begin{array}{c}\text{ONa}\\ |\\ \text{O=As—ONa}\\ |\\ \text{OH}\end{array}$$

Sodium arsenate

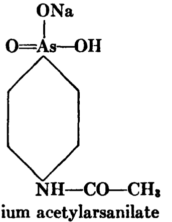


$$\begin{array}{c}\text{ONa}\\ |\\ \text{O=As—CH}_3\\ |\\ \text{CH}_3\end{array}$$

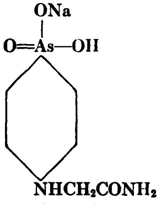
Sodium cacodylate



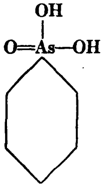
Sodium arsanilate (atoxyl)



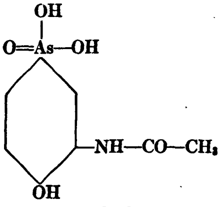
Sodium acetylarsanilate (arsacetin)



Sodium phenylglycinamide arsonate (tryparsamide)*



Paracarbamidophenylarsonic acid (carbarsone)



Acetylaminohydroxyphenylarsonic acid (acetarsone, stovarsol) per day, as pills; or hypodermically, as a freshly prepared warm sterile solution; also by enema.

---

*The commerical product contains a half-molecule of water of crystallization.

Cacodylate is not effective in chemotherapy. The arsanilate derivatives are effective against trypanosomes, amebas, trichomonas and similar parasites, but are not very potent against spirochetes. They are quite toxic, and are likely to cause optic neuritis and blindness. Tryparsamide, which is less toxic, has a special field in neurosyphilis.

In *syphilis* it is ineffective even with doses that produced albuminuria and hematuria (intravenous injection of 0.5 Gm. every three days for 4 to 6 doses; Cole, 1916). Brayton, 1917, confirmed its lack of value, and pointed out that it produces fibrosis of the vein in nearly every patient and is sometimes followed by severe nephritis.

Fate of Cacodylate.—A part is excreted unchanged in the urine (on hypodermic injection, 6 to 10 per cent, Dawes and Jackson); but the greater part undergoes reduction, first to the volatile cacodylic acid, and a small part finally to inorganic arsenic.

A *bibliography* of cacodylate is given by de Biehler, 1907. It was introduced into therapeutics mainly by Gautier, 1899.

SODIUM ARSANILATE (ATOXYL)

This salt, sodium aminophenylarsenate, may be derived from sodium arsenate by replacing one hydroxyl by aniline. (It was at first believed to have a different constitution.) The name of "Atoxyl" is misleading, for the substance is quite dangerous. It had at one time considerable prominence as an organic form of arsenic, effective in all conditions in which arsenic is indicated; especially in sleeping sickness, in which it has been superseded by its less toxic derivatives; and in syphilis and other protozoan infections, in which it is greatly inferior to arsphenamine (Tomasczewski, 1908; Greven, 1910). The chief objection to "atoxyl" is the fairly frequent occurrence of *toxic effects*, especially permanent blindness, from therapeutic doses. These, as well as the therapeutic actions, are mainly due to the reduction products, probably trivalent, which are formed in the organism. Sodium arsanilate should not be given by mouth, since it is decomposed and rendered more toxic. The hypodermic dosage is from 0.02 to 0.2 Gm. every other day. The injections are said to be nonirritant.

This compound was first prepared by Bechamp in 1863, and its general actions were investigated by F. Blumenthal, 1902. It was then used as an arsenic substitute in skin diseases, anemias, and the like. Its toxicity to mammals is much less than that of arsenic trioxide, its acutely fatal dose being some forty times as great. H. W. Thomas, 1905, found it highly efficacious against experimental *trypanosome infections* of mice, and it was tried extensively in human sleeping sickness, especially by Robert Koch, 1907. It causes prompt disappearance of the trypanosomes from the blood, but they may recur, so that the injection must be repeated every seven days (R. Koch, 1907). Kopke's (1906) clinical results were less favorable. The parasites become gradually resistant. B. Moore *et al.*, 1907, recommended alternation with mercury, which acts on another stage of development (Hodges, 1908).

Toxic Effects of Atoxyl in Man.—Acute symptoms occur especially with doses exceeding 0.5 Gm. They resemble partly those of ordinary arsenic poisoning and consist in nausea and vomiting; colic, vertigo, general weakness and somnolence; neuritis, pain in limbs; deafness, retention of urine, sometimes nephritis; iritis and not uncommonly permanent optical atrophy (Hallopeau, 1907; Fordyce, 1911). Chronic poisoning presents the ordinary phenomena of chronic arsenic intoxication. The *eye symptoms* usually appear within a few weeks (in Koch's series only when the dosage exceeded 0.5 Gm.). They begin with scintillation, cloudiness, diminished vision and contraction of the visual field (Fordyce, 1911). The anatomic changes in animals as well as in man (Birch-Hirschfeld and Koster, 1910) show degeneration of the optic nerve and retinal ganglia, the retina being the more susceptible. The cerebral cells are also injured. *Inorganic arsenic and cacodyl* may also cause optic neuritis (of the nicotine type), but only rarely (Sulzer, 1911). Arsphenamine does not seem to cause the optic injury. Boyd, 1911, found in two human cases that arsanilate causes *nitrogen retention.*

Toxic Effects of Atoxyl on Animals.—The acute toxicity of atoxyl is perhaps one-fortieth of that of inorganic arsenic; injections have no acute effects on blood pressure. They produce, however, chronic effects and anatomic lesions, the distribution of which varies quantitatively in different animals (Igersheimer and Itami, 1909); dogs show mainly characteristic renal hemorrhages with secondary nephritis; cats exhibit mainly nervous symptoms with histologic lesions in the brain and cord. Rats and rabbits are intermediate. The *distribution of the arsenic* corresponds with the differences in effects. In cats, *f. i.*, the arsenic is found mainly in the nervous system; in dogs, in the parenchymatous organs (Igersheimer and Rothmann, 1911). Mammals also show the optic degeneration, both on local and systemic administration. (The toxicity of atoxyl was investigated experimentally by Cianni, 1908.) In *frogs*, Sanno, 1911, found that the toxicity is greatly increased by raising their temperature, presumably by favoring its transformation into more toxic products.

Reduction.—Since arsanilic acid is itself practically nontoxic to trypanosomes, it must undergo some changes in the tissues. The degree of decomposition and therefore the efficiency and toxicity vary in different animals. The decomposition products have not been isolated, but it is probable that they contain the arsenic in trivalent form. (Rothermundt and Dale, 1912, however, believed that it is directly trypanocidal.) The artificial reduction products, which vary according to conditions, are much more active than the arsanilate, and paraminophenol-arsenous acid kills the parasites in the test tube. B. T. Terry, 1912 found that emulsions of liver and blood reduce arsanilate into directly effective products.

Excretion.—After a single dose of arsanilate, the arsenic is excreted promptly and exclusively by the urine (Croner and Seligmann, 1907). With continued administration, the excretion is somewhat more prolonged; the greater part leaves within three days (Simonot, 1910), but traces continue to be excreted for three weeks (Welander, 1909). The effects are therefore somewhat cumulative. A small part leaves by the feces. Only a small proportion is excreted in inorganic form. A relatively large part of the arsanilate remains for a long time unchanged in the blood and tissues (Simonot, 1910), but a part is fixed and changed in the cells. The characteristic distribution in different animals is described by Igersheimer and Rothmann, 1909.

Sodium Arsanilate (Atoxyl) occurs as white, odorless crystals, of faintly salty taste. Readily sol. in water (1:5 or 6). Dose, 0.02 to 0.2 Gm. hypodermically every other day; gradually increasing if necessary until the single dose reaches 0.65 Gm. and until a total of 6.5 Gm. has been given. It must not be administered by mouth.

Arsacetin, sodium acetyl arsanilate, $C_6H_4(NH.CH_3.CO)AsO.OH.ONa.\ 4H_2O$, is less toxic acutely than arsanilate, and is highly parasiticidal in mice. In man, however, it is no more effective than the original substance, and is equally liable to cause blindness (J.A.M.A., 1910, *54:* 1559). It is even more likely to produce renal irritation (Borchers, 1910). Its only advantage is the greater stability, so that it can be sterilized without decomposition. The dosage, hypodermically, is 0.1 to 0.5 Gm. Ehrlich, 1907, noticed that some mice treated with arsacetin acquire a curious waltzing habit.

TRYPARSAMIDE

This pentavalent arsenic derivative, sodium phenylglycinamide arsonate, is highly effective in certain forms of trypanosomiasis (Tr. gambiense, African sleeping sickness and mal de caderas) and fairly successful in selected cases of cerebral syphilis. It also cures the "blackhead disease" of turkeys. Its parasiticidal action is more marked for trypanosomes than for spirochetes. It penetrates the tissues, including the central nervous sytem, more readily than most arsenicals. Its excretion is rapid, so that there is no cumulation. Its acute toxicity is low; doses corresponding to 4 Gm. of arsenic have sometimes been injected without bad effect; but even the smaller therapeutic doses usually produce more or less visual disturbance and sometimes permanent blindness. A few patients develop jaundice. Other untoward effects are unimportant and exceptional.

The compound was developed especially through the Rockefeller Institute; it was synthetized by Jacobs and Heidelberger, 1919; investigated on animals by W. H. Brown and Pearce, 1919; and in human trypanosomiasis by Pearce, 1921. Its application to neurosyphilis is due to Loevenhart and Lorenz of Wisconsin, 1922 and 1923.

Excretion.—About 70 per cent is eliminated in the urine within twenty-four hours; in part at least unchanged (A. G. Young, 1923).

Use in Trypanosomiasis.—In Trypanosoma gambiense infections, a single intravenous injection causes the complete disappearance of the parasites from the human blood; but they are likely to recur after three days to six months. If the injections are repeated in courses, the cure is complete and permanent (L. Pearce, 1921, 1939; Pearce and Brown, 1922). Other trypanosome infections (surra, dourine, nagana) are not so amenable. Tryparsamide is mildly toxic to trypanosomes *in vitro.*

Other Trypanocidal Drugs.—Tryparsamide and suramin are now used most extensively, but several aromatic diamidines appear promising, such as pentamidine, stilbamidine and propamidine (E. C. Faust, 1946). Especially good results are reported for *p-arseno phenyl butyric acid* in Tr. Gambiense before central nervous system involvement (H. Eagle, 1946).

Therapeutic Results in Neurosyphilis.—Tryparsamide probably does not act clinically as a treponemocide, for it is practically not effective against the primary and secondary stages of syphilis, nor against the gummata, and has apparently little effect in the early cerebrospinal manifestations. Its value is confined mainly to the disseminated sclerosis, before this has resulted in irreparable degeneration of the nerve cells. Loevenhart was inclined to attribute the effect to the provocation of local inflammatory reactions that would resolve the sclerotic lesions.

Of patients with early paresis, 40 to 50 per cent show improvement or complete remission. In tabes, the results are less striking, but there is generally some relief of pain and sometimes improvement of coordination. Most patients improve in physical condition and gain in weight. The Wassermann reaction decreases, but not parallel to the symptoms. Advanced cases of sclerosis are not benefited; they may, indeed, react with temporary exacerbation. The improvement in the early paresis is sufficiently frequent and marked to class tryparsamide as a valuable therapeutic agent, were it not for the risk of blindness. This must be carefully weighed. Tryparsamide generally would be restricted to cases of the type in which it has been most successful, and which have failed to respond to other treatment. It is used especially after malarial therapy, beginning with 1 Gm. and increasing gradually to 3 Gm. intravenously, with weekly intervals. It must be continued for months or years; less than a hundred injections give only transient improvement. Should the vision become blurred, the injections are intermitted for a time and resumed later.

Tryparsamide Amblyopia.—Minor temporary impairment of vision occurs in 10 to 50 per cent of the patients; both those with trypanosomes and with treponemas; in 5 to 10 per cent, the minor impairment remains permanent; in 1 to 5 per cent, the impairment is serious. The occurrence and outcome are at present largely unpredictable and unavoidable. However, they follow most frequently on the first injection, and do not seem to occur after the fourth injection; nor do they seem to occur in noninfected individuals. It would therefore appear that they are not due to the arsenical, but rather to an immunologic reaction. It is doubtful whether preexistent syphilitic optic lesion contraindicates or indicates tryparsamide.

The optic phenomena are discussed by A. C. Woods and Moore, 1924. The *pathological changes* in a case studied by Leinfelder, 1938, seven days after the onset of the blindness, consisted in acute degeneration of the retinal ganglion cells and of the innermost portion of the nuclear layer, with no evidence of primary degeneration of the optic nerves and tracts. There were no general pathological arsenic changes elsewhere. Treatment with increasing doses produced practically complete blindness in four out of five rhesus monkeys (Longley *et al.*, 1941). *Organic arsenic compounds produce blindness in monkeys* by decrease of retinal ganglion cells, proliferation of glial cells and demyelination of the optic nerve (B. J. Longley *et al.*, 1942).

Other Untoward Results.—The arsenical and direct toxicity of tryparsamide is remarkably low. Even minor disturbances are rare; the more common are dizziness and tinnitus; more exceptional are nausea, vomiting, nitritoid reactions, urticaria, mild dermatitis. A few patients are jaundiced. Skin eruptions may occur in patients with intolerance to trivalent arsenic (E. Epstein, 1939).

*Tryparsamide, U.S.P., sodium N-phenylglycinamide-p-arsonate, containing about 25.3 per cent of arsenic, is a white, odorless, crystalline powder; sol. in water (1:2). The solution is neutral to litmus. It should be freshly prepared each day and should not be heated or exposed to strong light or chemical fumes. Dose, *Caution!* intravenous, 2 Gm., dissolved in 10 cc. of sterile water. In trypanosomiasis this is administered twice weekly for twelve weeks. It should not be taken by mouth, but may be injected intramuscularly.

AMIDOPHENYLARSONIC ACIDS

Two derivatives, carbarsone and acetarsone, have been introduced chiefly as amebicidal agents. They are also potent against trichomonas and Vincent's angina. They are effective against syphilis, but much less so than the arsphenamines. They are administered by mouth. Their toxicity is relatively low. *Arsphenamines* have not been found satisfactory against amebiasis.

Carbarsone, paracarbamidophenylarsonic acid, was introduced as an amebicide by A. C. Reed, Anderson, David and Leake, 1932, as having the most favorable therapeutic index of the drugs which they tried. It is less toxic and more effective than acetarsone, but may produce similar untoward effects. It may be administered by mouth or rectum without interfering with the patient's ordinary routine. Its cost is relatively low. Its efficiency is high: in California, about nine-tenths of the patients respond satisfactorily to the oral administration, especially those with encysted amebae (the most frequent form in the United States), with or without acute or chronic symptoms, *i. e.*, including carriers. Those with motile amebae, usually with acute dysentery or diarrhea, are more resistant to oral treatment, and may require rectal injections (Anderson and Reed, 1934). There is no evidence of any prophylactic value. In rats with intestinal trichomonas, a single dose of 1 Gm. per Kg., by mouth or vein, proved permanently curative (Gabaldon, 1936).

Serious *untoward effects* are uncommon even with prolonged administration, up to fifteen months, but it is advisable to watch for cutaneous and other arsenical manifestations. Carbarsone should not be used in renal and hepatic disease, including amebic hepatitis.

Various dosages and velocities are being tried; indeed, the whole method is still on trial.

With 330 patients, only one, with acute hepatitis, showed serious intolerance. A few had slight gastric distress, in which impurities may have played a part. There was no evidence of damage of the kidneys, optic nerve, skin or other tissues (Anderson and Reed, 1934). Exfoliative dermatitis and other manifestations, usually mild, have been recorded by others (Report, Council on Pharmacy and Chemistry, J.A.M.A., *103:* 258), and one fatality with acute hepatitis, from a therapeutic dosage (Epstein, 1936). In animals, lethal doses produce lethargy, loss of weight, diarrhea and some degeneration of renal tubules (Reed, 1934).

Pemphigus is reported markedly improved by carbarsone, after three or four weeks, administering two capsules of 0.25 Gm. before breakfast for three days, then intermitting three days (R. P. Little, 1945).

Carbarsone, U.S.P. contains about 28.5 per cent of arsenic. It is a stable, white, almost odorless and tasteless powder, slightly soluble in water, freely soluble in dilute alkalis. It is usually administered *by mouth,* in gelatine capsules of 0.2 Gm., two or three times daily, to a total of 25 doses (*i. e.*, 5 Gm.). This course may be repeated several times if necessary, with rest intervals of ten days to prevent cumulative effects, since the excretion is slow. *Rectal administration* is substituted in resistant cases, or with acute symptoms: 2 Gm. dissolved in 200 cc. of 2 per cent sodium bicarbonate, on alternate nights, for a maximum of 5 doses (omitting oral administration during the course). The enema must be retained and is therefore preceded by a cleansing enema and by a sedative dose of barbiturate.

Acetarsone, N.N.R. ("Stovarsol"), acetylaminohydroxyphenylarsonic acid, containing about 27.3 per cent of arsenic, was recommended against *amebic dysentery* by Marchoux, 1923, but effective doses are unsafe, toxic arsenical effects appearing in about a sixth of the patients (Anderson and Reed, 1934; Bender, 1927). It is administered by mouth, 0.125 Gm. to 0.25 Gm. (½ to 1 tablet) two or three times daily for a week; then an intermission of ten days before a second course is given. It has been tried against *syphilis*, especially for oral administration to children, but its value is doubtful. It is less effective than arsphenamine and bismuth (Pillsbury and Perlman, 1939), and is also objectionable on account of its variable toxicity (Rosahn and Kemp, 1937). Good results are reported in *Vincent's angina* from local application of 10 per cent solution, supplemented by oral administration (C. H. Maxwell, 1936); and in *trichomonas* vaginitis, from insufflation of a 12.5 per cent powder diluted with kaolin and sodium bicarbonate (G. Gellhorn, 1933). Acetarsone is a white, odorless powder, stable at ordinary temperature, of a slightly acid taste. It is slightly soluble in water, freely if alkalinized. It is marketed as tablets of 0.25 Gm.

Phenarsone Sulfoxylate, N.N.R. (*Aldarsone*), consists chiefly of the sodium salt of 3-N-methanal sulfoxylic acid amino- 4-hydroxy phenylarsonic acid, containing about 18 per cent of arsenic. Its toxicity is relatively low, but it may produce untoward effects similarly to carbarsone. It is used locally against trichomonas vaginitis by insufflation of a powder containing 0.5 Gm. of phenarsone and 2.5 Gm. of kaolin. This may be supplemented by vaginal supposition, at 0.13 Gm. Phenarsone sulfoxylate is also employed to treat syphilis of the central nervous system, especially to supplement fever therapy. It is soluble in water and is injected intravenously, 1 Gm. in 10 cc. of sterile distilled water once a week, for forty or fifty weeks.

◆

DRUGS USED IN AMEBIC DYSENTERY

Infection by Entameba histolytica presents interesting problems in chemotherapy. The amebae establish themselves in the lumen and tissues of the intestinal tract, and may spread to the liver and produce hepatic abscess. As with other protozoan diseases, recent infections yield fairly readily and quickly to active chemotherapy, but may relapse after a time; chronic infections are easily improved, but difficult to eradicate. *Acute dysentery* with malignant onset and course calls for prompt and energetic treatment. *Emetine*, an ipecac alkaloid, is most effective in bringing the infection under control, arresting the diarrhea and alleviating the other symptoms; but the cure is generally incomplete, as it does not kill the cysts. In chronic dysentery it is the most useful agent for the amebic hepatitis and liver abscess. The other practically effective antiamebic drugs are the phenylarsonates, carbarsone and acetarsone, and the iodohydroxy quinoline compounds, chiniofon, vioform and diodoquin. Faust, 1946, considers *chiniofon* as the best agent, more effective and less toxic than *carbarsone*, which he ranks next, to be used especially if chiniofon has not cured after two full courses. It is as effective as acetarsone and is much better tolerated. Uncomplicated *chronic intestinal amebiasis* is the most frequent type in the United States, and carriers may be treated with carbarsone (or vioform as second choice). Emetine is the best remedy in liver abscess.

The *practical evaluation of amebicidal agents* has been greatly facilitated by experimental infection of animals; at first of cats (Dale and Dobell, 1917; Sellards and Leiva, 1924) and later and better, of monkeys (Leake, 1931; Anderson and Reed, 1934). The results concord qualitatively and fairly quantitively with those of the clinic. High doses are required, which with some drugs approach or infringe on the toxic, so that the "therapeutic index" is important.

In vitro tests of amebicidal potency have proved of little value, and as with other protozoal chemotherapy, it is not certain whether the amebicidal effect is direct; at least, the potency appears much higher and more specific in the body.

Amebicidal Action.—Entamebae histolyticae in the stools of dysentery patients are quite unaffected by contact with emetine in dilutions of 1:2000 for one or two hours; and even 1:250 often fails to kill in this time (Allan, 1920). The action is slow, so that some organisms, especially of the encysted forms, are likely to survive when most have been killed. Entameba buccalis often survives on contact with 1 per cent emetine hydrochloride. However, the inefficiency may be due largely to unsuitable conditions, for in liquid media buffered to pH 6.8 to 7.2, Bishop, 1929, found Entameba coli killed by emetine 1:300,000, and histolytica by even more dilute solutions, the toxicity increasing with the alkalinity. On the other hand, it is suggestive that Dale and Dobell, 1917, found that the emetine alkaloids affected the ameba less than quinine, although quinine has much less effect on the disease. Experiments with other protozoa are little more than suggestive. Pyman and Wenyon, 1917, and Walters, Baker and Koch, 1917, investigated the efficiency of emetine and its derivatives on cultures, especially of Ameba limax. Emetine and cephaeline were about equal. Psychotrine was much inferior. Some emetine derivatives with higher alkyl esters were more efficient than emetine. Papaverine and narcotine (to which emetine is probably related chemically) also kill protozoa (Pick and Wasicky, 1915). Emetine is a fairly efficient *bactericide in vitro*, but acts slowly and is therefore useless *in vivo* (Kolmer and Smith, 1916).

Ipecac, Emetine and Cephaeline.—The value of ipecac root in the treatment of amebic dysentery has long been known, but its emetic action makes its administration difficult and it has been displaced by its most effective alkaloid, emetine. This and a related alkaloid, cephaeline, are entirely responsible for the antiamebic action (Vedder). Emetine, which is methyl cephaeline, is preferred, as it is more effective and considerably less emetic than cephaeline. It was first suggested by Vedder, 1912, and used successfully by Rogers, 1913.

Adequate doses of emetine usually cause prompt disappearance of all clinical symptoms in which it surpasses the other drugs. Failure to obtain striking clinical improvement within two days indicates that the dysentery is not amebic. The amebae generally disappear completely from the stools, but in most cases only temporarily. The most complete and permanent effects are obtained by hypodermic injection of emetine in early acute cases (Ross, 1916). For the encysted amebae of chronic cases and carriers, this must be supplemented by oral administration, which is difficult on account of the emetic action. The hypodermic injection of effective doses of emetine may produce serious side actions, especially on the heart and kidneys, so that continued treatment is distinctly dangerous and has been largely displaced by other drugs, especially chiniofon and carbarsone; but emetine has a special field in amebic hepatitis, where it is useful especially in early stages of liver abscess, and where arsenical drugs should not be used; and in severe or malignant acute dysentery, because it gives more prompt symptomatic relief than the other drugs, by which it may be followed. It is the only drug known to eradicate extraintestinal amebiasis (E. C. Faust, 1946). It should not be used against mild intestinal infections.

Toxicity.—The effective dosage of emetine seriously overlaps the toxic range (Leake, 1932); indeed, toxic phenomena occur from effective treatment in 80 per cent of the monkeys used (Dobell and Bishop, 1929). Excessive use is followed by accentuation or recurrence of diarrhea, sometimes by nausea, peripheral palsy, edema from renal damage, weakness and irregularity of the heart, most commonly auricular extrasystoles, auricular tachycardia, and disturbance of intraventricular conduction leading to dilatation of the right ventricle. The cardiac action is cumulative, increasing with repeated injections (L. J. Boyd and Scherf, 1941). The *heart muscle* shows early histologic damage, cloudy swelling, shrinking and atrophy of the muscle fibers, which may be followed by scarring. The dangers are greater in diseased subjects (Pellini and Wallace, 1916).

Local and gastro-intestinal effects are relatively mild or absent, with hypodermic injections of the ordinary therapeutic doses of emetine hydrochloride. Larger doses produce some nausea, vomiting, depression and pain. Even 0.25 Gm. in a single dose caused only persistent nausea (Allan). Cephaeline is more emetic. If emetine solution should accidentally touch the conjunctiva, it is very irritant (Blue, 1915). *Bloody diarrhea* in consequence of therapeutic hypodermic emetine injection is probably more common than was formerly supposed; it may be mistaken for recrudescence of the dysentery. Kilgore and Liu, 1917, describe several cases of children who received excessive doses under the mistaken notion that they would be more tolerant than adults. The *liver* and *kidneys* are affected later, chiefly with congestion and fat infiltration (Chopra, Ghosh and De, 1924; Rinehart and Anderson, 1931).

Toxic and Fatal Dosage.—Emetine hydrochloride is toxic for most animals, with 10 to 25 mg. per Kg., hypodermically (Leake, 1932). Clinical fatalities have occurred from about 25 mg. per Kg. (Leibly, 1930). These accidents do not seem to be connected with variability in the commercial preparations (Lake, 1918), but appear to be explained by cumulative action. Walters and Koch, 1917, found in animals that doses only $\frac{1}{10}$ of the minimal single fatal dose became fatal when repeated daily for three weeks.

Excretion After Hypodermic Injection.—Emetine appears in the urine within twenty to forty minutes; but the excretion outlasts the treatment by five to nine weeks. It must therefore form stable deposits in the body (Mattei, 1920), perhaps at the site of injection.

Intravenous injection has been tried, but Vedder rightly cautions against it. Baehrmann and Heinemann, 1913, had no bad results with 60 to 200 mg.; 300 to 400 mg. gave severe effects in a few minutes; vascular paralysis, marked dyspnea, unconsciousness, vomiting and diarrhea, slow pulse. This exceeds the fatal intravenous dose for rabbits (2.5 mg. per kilogram). The fatal hypodermic dose is much higher (20 mg. for rabbits).

Administration.—Emetine hydrochloride is injected hypodermically, one dose of 65 mg. (1 grain) daily for six days, followed if necessary by daily doses of 30 mg. ($\frac{1}{2}$ grain) for six days. The ultimate total of the course must never exceed 10 mg. per Kg. (Reed, 1934). It should not be repeated within a month. The administration should be stopped immediately if untoward symptoms occur. After the third day, it is advised to add carbarsone (except with hepatitis), 0.25 Gm. three times daily by mouth, for seven days; then rest for seven days; then change to chiniofon, 1 Gm. three times daily. Patients should be in bed for the first few days, to avoid collapse (Chopra and Ghosh, 1922). The first few injections usually suppress all symptoms, and cause the living amebae to disappear from the stools, but unless the full "course" is given, or they are followed by another amebicide, the disease is likely to return in the resistant chronic form.

Oral Administration of Ipecac.—The oral administration of adequate doses of soluble preparations of ipecac or emetine is likely to produce vomiting. The emesis often diminishes in two or three days and can be controlled by 10 or 15 minims of Tr. Opii. The vomiting may be circumvented by the use of salol-coated pills or of difficultly soluble preparations. A careful technic must be followed (S. K. Simon, 1918).

Difficultly Soluble Preparations.—Two types of these have been introduced: emetine fuller's earth adsorbate, and emetine bismuth iodide; but they are no longer used.

Iodohydroxyquinoline compounds, originally introduced as wound antiseptics, are effective amebicides, clinically and experimentally. **Chiniofon** is recommended by E. C. Faust, 1944, as more effective than carbarsone. It is believed to act on the intestinal amebae through the blood stream, although it is administered by mouth and rectum, never intravenously. It is not effective against amebic liver abscess. It usually produces watery diarrhea, but rarely other toxic effects with therapeutic doses; liver damage has been reported (Dyckerhoff, 1935), and it should not be used when liver function is impaired.

***Chiniofon,** U.S.P. (*yatren*), is a mixture of 7-iodo-8-hydroxyquinoline-5-sulfonic acid, its sodium salt and sodium bicarbonate, containing about 27 per cent of iodine. It is soluble in about 25 parts of water, with effervescence; insoluble in organic solvents. Administered orally (not intravenously), preferably as enteric-coated tablets, 0.25 to 1 Gm. three times daily. It may be supplemented by rectal instillation of 1 to 5 Gm., freshly dissolved in 200 cc. of warm water. The combined treatment is continued for seven to fourteen days. *Chiniofon Tablets,* U.S.P.; usual size, 0.25 Gm.

Vioform, N.N.R., 5-chloro-7-iodo-8-hydroxyquinoline, also used as dusting powder for wounds, was highly recommended as amebicide (Reed, 1934), but is not used extensively (E. C. Faust, 1944). In contrast to chiniofon, it is almost insoluble in water. It is administered in gelatin capsules, 0.5 Gm. daily, for ten days. The course may be repeated after a ten day interval. About one patient in twenty has severe gastric distress, and iodism may occur, but no permanent ill effects have been reported. However, it would be unwise to use it if the liver or kidneys are diseased. It is too irritant for rectal administration.

Diodoquin, N.N.R., 5.7-diiodo-8-hydroxyquinoline, is used against intestinal amebic and Trichomonas infections. It is almost insoluble in water and is administered as tablets of 0.2 Gm., 7 to 10 tablets daily for fifteen to twenty days. The "course" is therefore longer than with chiniofon. Iodide toxiderma occurs occasionally (D. N. Silverman and Leslie, 1945).

Bismuth compounds are now but little used (Faust, 1941). James and Decks, 1925, claimed good clinical success with bismuth subnitrate. Anderson and Reed, 1934, consider bismuth valuable as adjuvant to any of the other treatments, but advise the *subcarbonate* to avoid nitrite poisoning.

Heptyl Resorcinol ("Dihydranol").—This was suggested by Faust, 1930, but it irritates the gastro-intestinal mucosa, and its effectiveness has not been determined, so that its use is not advised at present (Anderson and Reed, 1934).

Diamino Acridine ("Rivanol") was recommended by O. Wagner and by F. M. Peter, 1928, but its effectiveness was shown to be negligible by A. G. Biggam and Arafea, 1930 (Leake, 1931).

Kurchi alkaloids were introduced by Acton and Chopra, 1929, but discredited by Knowles, 1930, as relatively inefficient (Leake, 1931).

Chaparro amargosa (Simarubaceae), a Mexican plant (Castela Nickolsonii), has been used in amebic dysentery, with successful results and without bad effects. The bitter infusion is used. It kills entamebas (Nixon, 1914, 1916). It effected cures in cases refractory to emetine (Shepheard and Lillie, 1918). Sellard and McIver, 1918, isolated a product toxic to small animals, which is apparently glucosidal. They also give an abstract of the early literature. Faust, 1946, believes that "the results are not yet sufficiently advanced for critical evaluation."

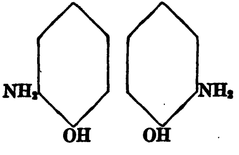
Experimental chemotherapy of rabies was attempted in mice by A. Hoyt, Fiske and Thienes, 1933, but quite unsuccessfully. The agents included organic mercurials and arsenicals, bismuth and antimony compounds, plasmoquin, optoquin, germanin, pyridium and sparteine.

THE ARSPHENAMINES

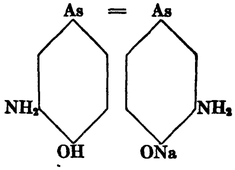
Arsphenamine (Salvarsan, 606, Arsenobenzol) and its derivatives combine a high degree of antisyphilitic action with relatively low toxicity. Various derivatives of the original arsphenamine are now used. They produce identical effects, but differences in solubility, in speed of oxidation and in toxicity are of practical significance. The arsphenamines are used with marked success in other protozoan and spirochetal infections: particularly in Vincent's angina, frambesia or yaws (Nichols, 1910), relapsing fever (Iversen, 1910), rat-bite fever and amebic dysentery (Wadhams and Hill, 1913). They appear less effective against malaria and trypanosomes, in man; and ineffective against yellow fever. Suggestive results have been reported in anthrax. They have been tried as *substitutes for ordinary arsenic,* in skin diseases, anemias, and so forth, but without great advantage. The introduction of arsphenamine accomplished a revolution in the treatment of syphilis; not the "therapia magna sterilisans" with which Ehrlich hoped to eradicate infection by a single injection; but the prompt control of the virulence of the infection, so as to stop its contagion and greatly to increase the chances of a permanent cure.

Historical.—The introduction of arsphenamine was the direct outcome of the systematic attempt of Paul Ehrlich (1854 to 1915) to combat parasites in the living tissues by chemical agents. According to Reid Hunt (U.S.P. Presidential Address, 1930) the starting point was a purely academic study of the vinyl linkage in quinine in relation to its toxicity (which led later to the development of cupreine esters against pneumonia and as wound antiseptics). In the course of this, quinine derivatives were studied on various protozoan cultures, then on trypanosomes in living animals. As quinine proved quite ineffective against these, many other agents were tried, including various arsenic compounds, first pentavalent and then eventually the trivalent arseno derivatives. The analogies of trypanosomiasis and syphilis led to the trial of the arseno-compounds against rabbit syphilis, and this culminated in "salvarsan" and the clinical cure of human syphilis. The substance was prepared by Bertheim and tested by Ehrlich and Hata. They found that a single injection of a harmless dose frees animals completely and permanently from spirillosis and certain other protozoan infections, including syphilitic spirochetes. The discovery was first described by Ehrlich and Bertheim, Oct. 10, 1909, in a German patent issued to Farbwerke Hoechst. The first scientific publication was early in 1910 by Hata, describing the trypanocidal and spirochetocidal actions. The first clinical trials were described by Alt in February, 1910, in a paper before the Magdeburg medical society. The chief report was made by Ehrlich, Hata, Schreiber and Hoppe in April, 1910, at the Congress of Internal Medicine at Wiesbaden. The first important clinical report on its use in the United States was by Nichols and Fordyce, Oct. 1, 1910, in the J.A.M.A. (review, Raiziss, 1930; the pharmacological literature was reviewed by Voegtlin, 1925).

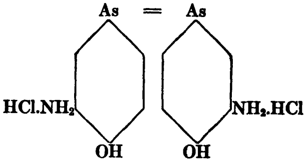
Composition.—*Arsphenamine* is the dihydrochloride of diamino-dihydroxy-arseno-benzene. The base itself (see structural formulae, below) has two amino and two phenolic groups, which confer basic and acidic characters respectively, so that the arsphenamines are amphoteric like the proteins. The addition of successive molecular quantities of an alkali, for instance, sodium hydroxide, to the dihydrochloride (*i. e.*, the commercial arsphenamine), removes first one and then both HCl groups, forming the monohydrochloride, and then the neutral base; further quantities of the hydroxide then neutralize the H of the phenolic group, yielding the mono- and then the disodium salt.



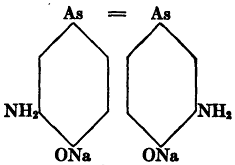
Neutral base



Monosodium salt.

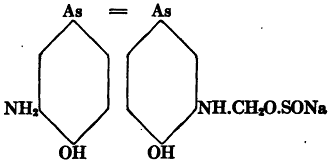


Dihydrochloride

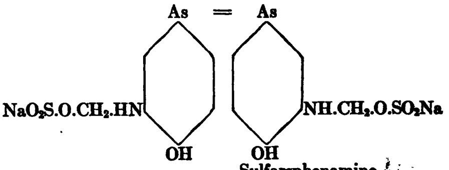


Disodium salt.

Neoarsphenamine and *sulfarsphenamine* are formed by substitution in the amido groups:

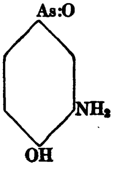


Neoarsphenamine
(arsphenamine-dimethanal-sulfoxylate)



Sulfarsphenamine
(Arsphenamine-diemethylene sulfonate).

In *trisodarsen*, NaO replaces one of the OH groups of sulfarsphenamine. *Oxophenarsine* (*marpharsen*, phenylarsenoxide, "arsenoxide," meta-amino-parahydroxy-phenyl arsenoxide),



is the first oxidation product of the arsphenamines. *Silver arsphenamine* contains silver, but its constitution is not established. It is possible that the silver is present merely as admixed colloidal metal (reference, Voegtlin). There are many other derivatives, but their present importance is slight.

Impurities.—Arsphenamine and its derivatives are so unstable that they cannot practically be prepared in pure form. The impurities vary with the method of preparation, and for the most part have not been identified. They are usually more toxic than the arsphenamines, so that it is necessary to determine the toxicity of each lot, by intravenous injection into rats or mice. Impurities may also develop on storage.

Colloidal Condition.—The arsphenamines exist in solution largely as hydrophilic colloids. They dialyze slowly; they are precipitated at the isoelectric point; concentrated solutions tend to gelatinize; they can be "salted out" by high concentrations of neutral salts (Raiziss, 1922; H. Freundlich *et al.*, 1923). The colloidal characters are especially marked with the acid arsphenamine salts, and are important as the cause of the immediate "nitritoid" and toxic reactions.

Reaction.—*Arsphenamine* (*i. e.*, the dihydrochloride) forms strongly acid solutions; its sodium salt, *i. e.*, the form which is administered therapeutically, is strongly alkaline; neutralization precipitates the insoluble base. Neoarsphenamine solutions are practically neutral. Sulfarsphenamine solutions are strongly acid. They and other derivatives formed by substitution in the amino group show a greater solubility in water through a wider range of *p*H, and have a higher degree of dispersion.

The typical *p*H of the 2.4 per cent arsphenamine salt, is for the dihydrochloride, about 2; monohydrochloride 2.7; monosodium salt, 11.4; disodium salt, 11.8 (Elvove and Clark, 1924). The isoelectric point is at *p*H 3.39 (Hunter and Patrick, 1925), but there is little ionization between *p*H 3 and 10; within this range, the base is practically insoluble. It cannot therefore exist in the blood in true solution, and even in colloidal solution only if it is stabilized by protective colloids. The acid solutions of arsphenamine have a relatively high *viscosity* which increases progressively as the isoelectric reaction is approached. The viscosity of the sodium salts is not much higher than that of water.

Oxidation is the main cause of the decomposition of the arsphenamines. The rate of oxidation varies with the access of oxygen, the temperature (Masucci, 1922) and the *p*H; and with the character of the compound. Arsphenamine hydrochloride and base are fairly stable; the sodium salts oxidize readily, the rate increasing rapidly with the alkalinity of the solution. Neoarsphenamine is unstable in the presence of oxygen, even in neutral solutions. Sulfarsphenamine in its acid solutions is more resistant to oxidation (Voegtlin and Johnson, 1922).

Absorption.—The arsenic of the arsphenamines is readily absorbed from the intestines (including the colon; Bargen, Osterberg and Mann, 1929); but probably only after decomposition. The compounds are therefore never administered by mouth.

Sojourn in the Blood.—After intravenous injection of arsphenamines, their concentration in the blood falls rapidly; clinically, for instance, the blood contained only 38 per cent of the arsphenamine immediately after the injection; this continued to fall rapidly, attaining a constant minimum in about an hour (Fordyce, Rosen and Myers, 1924). The disappearance is probably due chiefly to flocculation of the colloidal arsphenamine. Sodium cacodylate leaves the blood about as rapidly; sodium arsenate rather more slowly (d'Haenens, 1925).

Schreus and Hollaender, 1922, after the intravenous injection of 0.45 Gm., found the following concentrations of arsphenamine in the blood, by the diazo reaction, the values varying but slightly in different patients: after fifteen minutes, 25 to 33 mg. per liter; thirty minutes, 20 mg.; one hour, 13 mg.; three hours, 10 mg. In dogs at least three-fourths of the injected arsphenamines diss appeared from the blood stream within a few minute, (Kolls and Youmans, 1923); in rabbits, only one-twentieth remained in five minutes, one-thirty-fifth in an hour (Bulmer, 1923). With larger doses corresponding to 60 mg. of As, per rabbit, 99 per cent of the injected neoarsphenamine or cacodylate left the blood in ten to thirty minutes; but with sodium arsenate, also intravenously, corresponding to 60 mg. of arsenic, only 1 mg. disappeared in ten minutes, 14 mg. in thirty minutes, 38 mg. in two hours, and 50 mg. in three hours (d'Haenens, 1925). When added to blood *in vitro*, none of the arsenic passes into the corpuscles at body temperature within an hour; and only small proportions into the cells of pulped kidney, brain, muscle or heart (d'Haenens).

The **excretion** of the arsenic of the arsphenamines occurs chiefly by the bile. It is slow and incomplete, even after intravenous injection. The colloid fraction is retained longest

(F. B. Rodman, 1943). Very little is excreted unchanged.

Rate of Excretion.—Arsenic appears in the urine in a few minutes to two hours after the intravenous injection of arsphenamine (Abelin, 1911). The excretion rate is highest on the same or the next day (J. Webster, 1916) and becomes low in four days (Hoppe, 1910). Traces may be found up to three months (Heuser, 1911). After a single injection of 0.9 Gm. the urine contained less than 2 mg., the feces about 18 mg. of arsenic per day (Frenkel-Heiden and Navasartt, 1913). By the fourteenth day, the urinary level had usually fallen to 0.1 to 0.5 mg. per day (Weiss and Raiziss). The clinical urinary excretion in the first twenty-four hours for the organic arsenicals ranged as follows, in per cent of the injected arsenic (Lockemann, 1916): acid arsphenamine, intramuscular, 0.5 to 2.1 per cent; alkaline arsphenamine, by vein, 0.9 to 2.5 per cent; neoarsphenamine, by vein, 2.2 per cent; arsenophenylglycine, intramuscular, 0.1 to 7.5 per cent; arsacetin, hypodermic, 32 to 39 per cent; atoxyl, hypodermic, 88 per cent. Moderate renal insufficiency does not materially diminish the excretion of arsenic after neoarsphenamine, in contrast to the chloride and urea retention (Mathieu and Chatelain, 1926). *With repeated injections*, the excretion rises by both channels, so that nearly 60 per cent may be recovered within a week after the last injection (Underhill and Davis, 1922). The remaining 40 per cent is eliminated slowly (Mathieu, 1922). With intramuscular injections, the excretion begins more slowly and is likely to be less complete (Irokawa, 1914; Mehrtens, 1921). The excretion by rabbits is essentially similar to that of man (Burnascheff, 1912).

The *fecal excretion* of arsphenamine begins after three or four days (Underhill and Davis, 1922). It is four to ten times greater than by the urine; the difference is less marked for neoarsphenamine and for inorganic arsenicals (Pomaret, 1920; Voegtlin and Thompson, 1922; Bulmer, 1923). In dogs with permanent biliary fistula, an average of 40 per cent of injected neoarsphenamine was recovered from the bile in seventy-two hours; with oxophenarsine in forty-eight hours. Both excreted more in the first day, only traces after two or three days. Bile acids did not increase the amount excreted (J. H. Annegers *et al.*, 1944). If the common bile duct is ligated, the arsenic content of the feces is greatly lowered (Bulmer) and the toxicity and the trypanocide action is increased; ligation of the ureter increases the toxicity and potency of the pentavalent arsenicals which are excreted chiefly by the kidneys (Voegtlin, Dyer and Miller, 1922). None is excreted into the colon (Bargen *et al.*, 1929). With arsphenamine, the arsenic concentration in the bile (with dogs) may be forty times higher than in the blood (Kolls and Youmans), and thirty times higher than in the urine (Underhill and Dimick, 1927).

The *form of excretion* is not satisfactorily known (Voegtlin, 1925). A small part may be excreted unchanged, but this is doubtful. The arsenoxide-glutathione combination is tenaciously retained, while pentavalent aromatic compounds are rapidly excreted by the kidneys (Voegtlin and Thompson, 1922). From this it may be surmised that the urinary excretion occurs in the latter form. The surface tension of the urine is materially lowered (Kuroda, 1930).

The distribution has been investigated extensively in animals, after intravenous injection of the arsphenamine and neoarsphenamine. Histologic examination (obtained with reduction of silver) shows four types of localization: granular deposits in the reticulo-endothelial cells; similar deposits in the epithelium of the renal tubules and glomeruli; diffuse penetration of the mesenchymal structures, especially of the spleen; and arsphenamine emboli in the capillaries (Jansco, 1928). These localizations point to adsorption of the flocculated arsphenamines. The numerous chemical studies (Voegtlin *et al.*, 1923, rabbits; Kolls and Youmans, 1923, dogs; Bulmer, 1923, rabbits and dogs; d'Haenens, 1925, and E. D. Osborne *et al.*, 1932, rabbits; and others) show that the arsphenamine is most abundant in the organs in which the mechanical adsorption would be most extensive: in the spleen, liver and lungs and, to a somewhat less degree, in the kidneys. Arsphenamine apparently has a greater affinity for the liver, neoarsphenamine for the kidneys (F. B. Rodman, 1943).

The concentration in these organs rises soon after the injection to something like three times that of the blood. Within the first few days the concentration is higher in the spleen and liver than in the lungs; but within an hour (Bulmer) the liver begins to eliminate arsenic through the bile, and its concentration falls below the others, sometimes to a fiftieth of the spleen, on the fourth day after a single injection of neoarsphenamine or cacodylate. The lung concentration remains most constant during this period (d'Haenens). After intravenous injections of *neoarsphenamine* corresponding to 60 mg. of arsenic per Kg., into rabbits, the spleen, liver and lung together contain about a tenth of the total injected arsenic, fifteen minutes after the injection, decreasing but slightly in four days; the spleen and liver represent each about 2 mg., and the lung about 1.3 mg. of arsenic (d'Haenens). Of other arsenicals, administered intravenously in the same dosage, the *cacodylate* showed a similar distribution, but the quantity in the liver decreased more markedly, from 2.25 mg. five minutes after the injection, to 0.8 mg. in four days. *Sodium arsenate*, which would not be expected to flocculate, gave a quite different distribution. It proved fatal in two or three hours; the liver contained about 5 mg. of arsenic, double that of the other compounds; the spleen contained little, to 0.18 mg.; the lungs were intermediate with 0.35 to 0.75 mg. (d'Haenens). In a case of chronic poisoning by *arsenic trioxide*, the largest amount was also found in the liver and very little in the spleen (Underhill and Dimick, 1927), so that the latter evidently traps only the flocculated organic arsenicals. After serial injections of neoarsphenamine in dogs, which were killed by bleeding six hours after the last injection, Underhill and Dimick, 1927, found considerable individual differences in the various organs, with no direct relation to the dosage or to the number of injections. The spleen and kidneys, however, often contained more than the liver.

Other organs generally contain lower concentrations. The *bones* show perhaps the longest retention (Bulmer, 1923), but traces can be demonstrated in all the organs for months (Ullmann, 1912; Valenti, 1912; Usuelli, 1912). The *central nervous system* notably contains only traces at any time, in chronic as well as in acute poisoning, and with inorganic as well as with organic compounds; indeed, d'Haenens found less arsenic in the brain of rabbits after acute poisoning by intravenous injection of sodium arsenate than after cacodylate or neoarsphenamine. E. D. Osborne, Putnam and Hitchcock, 1932, found no appreciable amount of arsenic in the central nervous system of rabbits after arsphenamine or tryparsamide. The *cerebrospinal fluid* shows traces of arsenic within an hour after intravenous injection, in a fourth to a half of the patients, averaging 0.0036 mg. of arsenic per 100 cc. (Mehrtens and McArthur, 1919; Fordyce *et al.*, 1923). Sulfarsphenamine penetrates into the cerebrospinal fluid of rabbits much better than do the other arsphenamines (Voegtlin *et al.*, 1923). The *milk* also participates in the excretion (Caffarena, 1912); in the milk of mothers treated clinically with arsphenamine, the arsenic concentration was approximately that of the blood (Fordyce, Rosen and Myers, 1924). Traces of arsenic pass through the *placental circulation* to the fetus (Burnascheff, 1912; Underhill and Amatruda, 1923; human, Eastman and Dippel, 1933).

Oxophenarsine (mapharsen) and its related compounds also show a high arsenic content of the liver and kidneys of rabbits. Their passage into the cerebrospinal fluid is greater if the meninges are irritated, and still greater if they are infected with spirochetes (T. Hojo, 1940). Their urinary excretion is greater than the fecal (A. C. Chance *et al.*, 1945).

Chemical Transformations.—The changes the arsphenamines undergo are known only in part. The oxidation of arseno-compounds *in vitro* goes through arsine oxides to arsonic acid (with pentavalent arsenic); and the change may be reversed by reduction:

$$\begin{array}{ccccc} \text{Oxidation} \longrightarrow & & & & \longleftarrow \text{Reduction} \\ R.As = As.R & \rightleftarrows & R.As.O & \rightleftarrows & R.AsO_3H_2 \\ \text{Arseno-compound} & & \text{Arsine Oxides} & & \text{Arsonic Acid} \end{array}$$

The middle term, amino-oxyphenyl arsenoxide, oxophenarsine, briefly called "*arsenoxide*," has been isolated from the liver of animals several hours after the administration of arsphenamine, corresponding to 10 per cent of the administered arsenic; none was found in the spleen, kidneys or the serum. After administering neoarsphenamine, it was found in the kidneys, but not in the liver (S. M. Rosenthal, 1932). This compound acts more potently and more promptly on animals infected with syphilis or with trypanosomes than do the arsphenamines and the arsonic acids (Ehrlich and Bertheim, 1912). It appears probable that the arsphenamines pass through this form and that part or all of their actions are produced by this compound, although its actual concentration in the tissues appears too low to kill the spirochetes directly. Its oxidation would proceed further to the less potent arsonic acid and thence to inorganic compounds. Voegtlin has suggested that the toxicity of arsenoxides to parasites and host is due to combination with the sulfhydryl group, especially in the glutathione: $RAsO + 2HSG = RAs(SG)_2 + H_2O$, thus preventing it from fulfilling its function in the cellular oxidation-reduction system. Accordingly, the toxicity of arsenoxides is lowered if they are injected with sulfhydryl compounds, for instance, sodium thioglycollate (review, Voegtlin, 1925).

Evaluation of antisyphilitic potency on rabbits is indispensable in conjunction with the clinical trials as a qualitative and roughly quantitative index of therapeutic value. The determination of trypanocidal potency on rats (Raiziss and Severac, 1928; intraspinal, 1930) is without value for this purpose, as it does not run parallel with the antisyphilitic potency even in compounds so closely related as different lots of neoarsphenamine (Probey and McCoy, 1930).

A standardized procedure for testing antisyphilitic agents, described by Wakerlin, Lorenz and Loevenhart, 1925, determines (1) the fatal dose; (2) the "sterilizing" (therapeutic) efficiency, including the healing of the syphilitic orchitis, blood Wassermann test, and control by autopsy and by lymph node inoculation; and (3) the "prophylactic" efficiency, by intravenous injection twenty-four hours after intratesticular inoculation. Further experience with organic arsenicals and with mercurials showed a close parallelism between the prophylactic efficiency, which can be estimated on rabbits in three months, and sterilizing efficiency, which requires eight months (Wakerlin and Loevenhart, 1928). *Efficiency against neurosyphilis* appears to be a different problem. It has been studied in mice and on rabbits inoculated with spirochetes that have been passed through mice (Raiziss and Severac, 1933). Its practical value is questionable, since tryparsamide appeared to be less potent than arsphenamine and acetarsone, which is contrary to the clinical experience.

Spirocheticidal Action in Vitro.—H. Eagle, 1938, 1939, showed that treponemas from experimental syphilitic orchitis of rabbits are immobilized and rendered noninfectious by eight hours' contact with arsphenamine or neoarsphenamine, 1:250,000, or mapharsen, 1:1,000,000, concentrations, similar to those existing in the blood after clinical doses. Bismuth is also effective.

The time of contact may be greatly shortened by increasing the concentration (Kast *et al.*, 1939). The *in vitro* spirocheticidal action of arsenoxide and of bismuth compounds is not affected by removal of oxygen and is probably due to these compounds as such. Neoarsphenamine is only $\frac{1}{60}$ to $\frac{1}{25}$ as potent in the absence as it is in the presence of oxygen, so that its action is apparently due to oxidation products; arsphenamine and silver arsphenamine are intermediate; the anaerobic potency with all the arsphenamines may probably be attributed to oxidation products in the original specimen. *Sulfhydryl compounds* (cysteine, glutathione, thioglycollic acid) abolish the *in vitro* spirocheticidal action of arsphenamines, arsenoxide, bismuth and mercury almost completely. Presumably the —SH blocks the arsenical molecules so that it cannot act on the organism. Thiamine and methionine, which contain —S—, do not inhibit (Eagle, 1939). *Bacteria* in general are not very susceptible to arsphenamine, but according to Roos, 1912, it is directly germicidal to *anthrax*, even in living animals. It is ineffective in rabbits (Mejia, 1913).

In **human syphilis**, injection of the arsphenamines or oxophenarsine diminishes the spirochetes in the chancre and condylomata within a few hours, and causes them to disappear completely in twenty-four to ninety-six hours, suppressing the contagiousness of the local lesions more effectively than any other drug. A single injection of arsphenamine also produces marked and rapid improvement after the Wassermann reaction has become positive, so that the results of one administration may equal those of months of mercurial treatment. All the syphilitic symptoms regress at once, except those that have an anatomic basis. Surface lesions and ulcers are repaired with astonishing rapidity. Gummatous and periosteal lesions are usually much improved. Malignant cases, and those resistant to mercury, also cede to arsphenamine. The Wassermann reaction generally becomes negative after about five days (sometimes with a temporary exaggeration). However, the spirochetes would soon reappear and the condition would relapse, unless medication is kept up continuously for two or three years; or unless the administration is pushed energetically by massive doses. These are about as effective as penicillin, but not so safe. With *moderate doses*, "*clinical cure*," the complete and permanent suppression of the parasites (although not necessarily their complete eradication), requires early and unremitting treatment with alternating courses of the arsphenamines, and bismuth or mercury, until cautious omission of treatment is not followed by recurrence. The arsphenamine or orophenarsine *should be started as early as possible*, best in the pre-Wassermann primary stage, and should not be deferred for any reason whatever, since a few days of delay at this time may decide between success and failure. The *early treatment* should be as intensive as possible and should be kept up regardless of reversal of the Wassermann reaction. It is considered unsafe to administer arsenicals continuously over long periods, but courses of bismuth or mercury should be interpolated instead of intermissions or "rest periods" without medication, for these encourage relapses, and delay or compromise final success. "Even a few weeks of non-treatment in the first eighteen months of the disease is likely to be profoundly injurious" (Report of the American Cooperative Committee). Arsphenamine in ordinary doses should never be the sole treatment of early syphilis. Bismuth or mercury is required partly to maintain treatment between the arsphenamine courses, but probably also because they attack the parasites in directions not covered by arsphenamine. Conversely, no patient should be treated with heavy metals alone, not even bismuth; for one thing, these do not control the contagion. If the treatment was begun in the primary stage before the Wassermann reaction had become positive, and was carried out intensively and continuously, a clinical cure (nonrecurrence of any sign of the disease within two years after all treatment ceased) resulted in 86.4 per cent of the patients under continuous treatment in the clinics of the cooperative committee, and in 71.4 per cent of the patients with intermittent treatment. These figures were reduced by about 18 per cent if the treatment was started after the Wassermann reaction was positive, but before secondary lesions had developed. *Adequate treatment during pregnancy* practically prevents congenital syphilis, especially if it is started before the fifth month. In the series of Usilton *et al.*, 1938, it reduced the percentage of stillbirths by syphilitic women to half, and raised the percentage of normal babies from 16 to 65. Treatment during a previous pregnancy does not insure protection; it must be repeated. Pregnant women tolerate antisyphilitic treatment quite as well as nonpregnant (Cole, Usilton *et al.*, 1936). *Preventive treat-*

ment, before the appearance of the chancre, confuses the diagnosis and the treatment; if the latter is not energetic and prolonged, it may result in latent syphilis. Treatment for *prophylaxis*, after exposure, is unreliable. *In the late and latent syphilis* of patients who did not receive adequate treatment, and this is still a majority (Usilton *et al.*, 1938), the response to arsphenamine is much less striking, but none the less important for clinical cure (85 per cent of treated as against 25 to 30 per cent of untreated); the earlier cases respond best (Cooperative Clinical Studies, Moore, Cole *et al.*, 1932 to 1938; Stokes, 1937). Arsphenamine is much less successful against the fibrous and perivascular syphilitic manifestations, aortitis, tabes, general paresis, and the like. Presumably these are not so accessible to the arsphenamine or to its active decomposition products.

Response of the Wassermann Reaction.—Routine arsphenamine treatment renders the reaction negative in 90 per cent of the patients in the primary, and in 85 per cent in the secondary, stage; the corresponding percentages for bismuth treatment are 85 and 77 (Leri, Tzank and Peron, 1923). The early negative Wassermann reaction is not an indication of eventual cure, and the treatment must be kept up. In *latent* syphilis, the earlier the treatment is started the more readily does the reaction respond, *i. e.*, in a larger proportion of individuals (34 per cent in early latent cases, 24 per cent in late), and with fewer injections; but as regards the latter, practically all cases that become negative at all do so by the end of the first arsphenamine-metal sequence. After four months of treatment there is little or no further serologic response. If the reaction is negative, arsphenamine may turn it temporarily to positive, the "provocative Wassermann reaction," especially in early syphilis.

Spirochete Persistence.—Although clinical cure results as a rule from adequate treatment, so that all clinical manifestations are permanently suppressed, and the patients are completely noninfectious to others and may even themselves be subject to reinfection, this does not prove that all the parasites have been eradicated. Such is not the case with protozoan infections in general. Warthin, 1918, contended on the basis of histologic evidence that some of the spirochetes perpetuate themselves indefinitely after adapting themselves to the host so as to produce only slight but continued local reactions, resulting in fibrous degenerations.

The standards of treatment which have become practically universally accepted are laid down by the League of Nations Committee, 1934, and by the American Cooperative Committee, J. H. Stokes *et al.*, 1934. They include (1) the earliest possible start, in the seronegative primary stage if feasible; (2) strict supervision of mucosae, skin, kidneys and liver, to avoid toxic effects; (3) relatively heavy dosage of arsphenamines or preferably oxophenarsine in relatively rapid succession, especially at the start; (4) when moderate doses are used, persistent and continuous attack (or at least avoidance of long intervals, League of Nations), including at least 20 or, better, 30 injections of arsenicals (the first 5 to 9 being the most important), alternating in courses with 60 bismuth injections (Stokes, 1937). Bismuth or mercury should be continued for a year after all signs of the disease have disappeared. (5) Observation of the patient for at least three years; (6) spinal fluid examination at least before final dismissal.

An illustrative routine is as follows: In the first ten days, three intravenous injections of neoarsphenamine, 0.3, 0.45 and 0.6 Gm.; third to seventh week inclusive, each one injection of neoarsphenamine, 0.6 Gm.; eighth to eleventh weeks, bismuth injections; twelfth to nineteenth, A.*; twentieth to twenty-fifth, B.*; twenty-sixth to thirty-first, A.; thirty-second to thirty-ninth, B.; fortieth to forty-fifth, A.; forty-sixth to fifty-third, B.; fifty-fourth to fifty-ninth, A.; sixtieth to sixty-seventh, B.; sixty-eighth to seventy-third, A.; seventy-fourth to eighty-third, B. (*A. stands for 0.6 Gm. of neoarsphenamine; B. stands for bismuth injections.) Bismuth or mercury should be continued for a year after all signs of the disease have disappeared. *Oxophenarsine hydrochloride* or dichlorphenarsine hydrochloride may be used instead of neoarsphenamine in this sequence; making a trial injection of 30 mg. for women, 45 mg. for men, and continuing with weekly injections of 40 mg. for women and 60 mg. for men. *For prophylaxis in blood transfusions*, when syphilis of the donor is known or suspected, Kast *et al.*, 1939, urge the addition of arsphenamine or neoarsphenamine, 1:10,000 of the citrated blood, and letting the mixture stand fifteen minutes before injection.

Administration.—Most of the arsphenamine preparations are administered by vein. Intramuscular injections are effective, and are employed with sulfarsphenamine and acetylglycarsenobenzene (solusalvarsan), but most of the other compounds are too irritant. Rectal administration is unreliable. In making the intravenous injections, care must be used that none escapes into the subcutaneous tissue, since infiltration with arsphenamine (or neoarsphenamine) is painful and may incapacitate for a considerable time. *Shaking of arsphenamine* and neoarsphenamine solutions in contact with air should be avoided, since it may result in rapid oxidation with great increase of toxicity. This is particularly dangerous with neoarsphenamine and alkaline arsphenamine, but varies for different specimens

(Roth; Schamberg, Kolmer and Raiziss, 1922). The injection should be made slowly, at least two to five minutes. A few hours should have elapsed since the last meal, or this should have been light. The patient should rest for fifteen minutes after the injection and should not eat much, smoke or use alcohol for several hours, and avoid hard work for the day. He should be warned to watch for fever, digestive disturbances and skin irritation, and to remain in bed if there is marked malaise. The administration should be avoided when the patient has an acute fever or other upset.

As precaution against untoward reactions, a thorough physical examination should be made before the treatment is started, and any weaknesses adjusted. The state of health and the tolerance of the drug must be constantly watched. The patient should be specifically questioned before every injection as to his general health, colds, reactions to the previous injection (fever, digestive derangement, itching, angina). The skin should be examined for eruptions, the urine for protein, the skin and conjunctiva for icterus. Impaired organs should receive particular attention, especially the kidneys, liver, skin and cardiovascular system. Serious organic disease of these enjoins caution in the use of the arsenicals, as do also intercurrent infections and idiosyncrasy to drugs in general.

Intramuscular injections of arsphenamine and neoarsphenamine have practically gone out of use. Arsphenamine was employed as a 10 per cent neutral suspension; neoarsphenamine in the ratio of 3 cc. of water per 0.15 Gm. This yields an approximately isotonic solution. Neither drug should be injected into the subcutaneous tissue. Intramuscular injections must not be made too near the sciatic nerve, or they may cause neuritis (Kissmeyer, 1916). The absorption of arsphenamine from intramuscular injections is slow, some arsenic generally remaining at the site of injection for months (Schuebel, 1914). Neoarsphenamine is absorbed more rapidly (Ullmann, 1912, 75 to 85 per cent within a week; Swift, 1913).

Oral administration was tried in man (0.6 Gm.), and in animals, but the therapeutic effects are feeble (Schamberg *et al.*, 1916). Vomiting and diarrhea may result, but not serious intoxication (Kolmer and Schamberg, 1912). *Rectal administration* has been used (J. M. Joseph, 1918), especially for children (Araujo, 1918). A considerable amount of arsenic may be absorbed (Noeggerath and Reichle, 1921; Mehrtens, 1921), but it is not known in what form and the clinical results are unreliable (Littman and Hutton, 1924). *Subdural (spinal) injections* of arsphenamine were tried in cerebrospinal syphilis with the hope of reaching the spirochetes in the nervous system more directly, but without much result. The safest method is the injection of the serum of the patient himself, who has recently received an intravenous arsphenamine injection (Swift-Ellis, 1913; Fordyce, Rosen and Myers, 1923). Spinal injection of arsphenamine dissolved directly in serum was advocated by Marinesco and Minea, 1914, using not over 0.5 mg. of the drug. It is safer than the watery solutions, but not so safe as the Swift-Ellis method. Gennerich, 1913, and Schubert, 1914, used cerebrospinal fluid drawn from the patient for the solution of the arsphenamines. Spinal injection of watery arsphenamine solution causes severe irritation of the cord, and should not be attempted in man (Ellis and Swift, 1913; Marinesco, 1913; Swift, 1916).

Intensive massive dose arsenic methods greatly increase the speed of clinical cure in early syphilis. By introducing large doses almost continuously during a week they arrest the disease, its symptoms and the serologic reactions, so that further treatment appears unnecessary; relapses are no more common than with the ordinary method; toxic reactions are more frequent, and sometimes serious. The intensive method has no advantage in late syphilis and should be reserved for relatively acute cases (H. N. Cole, Heisel and Stroud, 1943).

Continuous intravenous drip administration of massive doses was introduced by Chargin, Leifer and Hyman, 1935, injecting 4 to 4.5 Gm. of neoarsphenamine within five days. Frequent occurrence of peripheral neuritis caused them to change to oxophenarsine, a total of 1200 mg. A smaller total tends to give incomplete results, a larger to be toxic (W. Leifer, Chargin and Hyman, 1941). All the current methods employ oxophenarsine or dichlorophenarsine.

Many *modifications* have been introduced, varying the total dosage of oxophenarsine hydrochloride from 250 to 1250 mg., the latter equivalent to 40 per cent of the maximal tolerated dose in dogs, adjusted to weight. The administration varies from slow drip (2000 cc. in seven to ten hours), rapid drip (1000 cc. in one to three hours) and multiple injections (one or more rapid intravenous injections by syringe in a small volume of solution), the frequency of injections from once a day to twice a week, and the duration of treatment from one day to twenty weeks (D. C. Elliott, Baehr *et al.*, 1941; H. Eagle, 1944). *Experiments with rabbits' syphilis* indicate that the total curative dose is not greatly influenced by the spacing of the doses, and that continuous drip is less effective than spaced injections. The toxicity, however, depends greatly on the speed and intensiveness of the treatment, and scarcely at all on the total dosage. The therapeutic index is therefore much more favorable for spaced injections (H. Eagle and Hogan, 1942). *Clinical results* also appear to be no better for continuous five day intravenous drip than for spaced methods that spread the total 1200 mg. dosage over twelve days, by daily injection of 100 mg. (D. C. Elliott *et al.*, 1941) or 2400 mg. spread over twenty weeks as forty semi-weekly injections of 60 mg. Serious reactions are much less common with the slower methods. The *Army routine* employs the forty injections with the addition of sixteen weekly intramuscular injections of bismuth subsalicylate, 0.2 Gm. in oil, extending the whole treatment to twenty-six weeks (T. B. Turner and Sternberg, 1944). H. Eagle, 1944, studied an extensive series of patients receiving about 60 mg. of phenarsine three times weekly for twelve weeks. He concludes that the therapeutic results were rather poor unless bismuth was also used; the combined treatment effected 85 to 90 per cent of "cures." The effectiveness can also be increased by combining it with fever therapy. The Cooperating Clinics of the U.S.P.H.S., 1944 (J.A.M.A., *126:* 554), conclude that the best results are obtained by using typhoid vaccine, with multiple syringe injections of oxophenarsine. They report 85 to 90 per cent of satisfactory results in primary syphilis, 70 per cent in secondary. Of the primary, 5 to 6 per cent relapsed; of the secondary, 10 to 13 per cent. A *one day treatment* by oxophenarsine and hyperthermia has been tried, but involves technical difficulty (W. M. Simpson *et al.*, 1942).

Untoward results are usually mild. They may show all the manifestations of arsphenamine therapy (see below) except nitritoid crises. Lighter reactions are rather common, even with spaced injections, but only about 2 per cent require interruption of treatment (H. Eagle, 1944). *Pregnancy* is not a contraindication. The *milder reactions* include nausea, vomiting, diarrhea, often some fever. Almost all patients develop significant but transient changes in the electrocardiogram, especially of the T wave, during or shortly after the treatment. These are not observed with the smaller doses of the older therapy (A. J. Geiger *et al.*, 1942). Secondary anemia may develop late (J. F. Sadusk *et al.*, 1942). The series of D. C. Elliott, Baehr *et al.*, 1941, showed no evidence of significant damage to the liver or kidneys; no exfoliative dermatitis; exceptional mild and transient neurites. The series of H. Eagle, 1944, with triweekly injection, records serious reactions, chiefly jaundice, in 0.8 per cent of the patients. *Fatalities* are generally due to hemorrhagic encephalitis and rate 0.25 to 0.5 per cent for intravenous drip; Cooperative Clinics, 1944, 0.02 to 0.08 for spaced injections (H. Eagle, 1944; T. B. Turner and Sternberg, 1944), and only 0.005 per cent for the older dosage (J. H. Stokes, 1942).

The excretion of arsenic during intravenous drip administration of oxophenarsine to dogs shows that 27 per cent of the daily dosage occurs in the urine, 35 per cent in the feces (H. J. Magnuson and Raulston, 1941).

Other treponemal diseases successfully treated by arsphenamine are frambesia, Vincent's angina, gangrenous balanitis and recurrent fever. In *frambesia* (yaws) the treatment and results are the same as in syphilis, both for neoarsphenamine and for bismuth (G. M. Saunders, 1937). *Vincent's angina and gangrenous balanitis* are promptly arrested by intravenous injection of neoarsphenamine, 0.3 to 0.4 Gm. The pain disappears in a few hours, and the inflammation subsides within a day. A second injection is rarely needed. Dry neoarsphenamine or arsphenamine dusted on the lesion is also effective; or painting with a 5 or 10 per cent solution of arsphenamine or neoarsphenamine in glycerin, at first twice a day, then daily (C. Barker, 1922). Intravenous injection is used in *treponemal pulmonary gangrene.*

Nontreponemal diseases in which more or less successful results from arsphenamine have been reported include malaria, intestinal protozoan infections, kala-azar, filariasis, anthrax, lichen ruber planus, lupus erythematosus. It proved *ineffective* in experimental trichinosis, as did also antimony and various other agents (J. J. Miller *et al.*, 1932).

Tertiary malaria is checked by oxophenarsine and arsphenamines; they have little effect on plasmodium species other than vivax. In *therapeutic malaria,* neo arsphenamine, 0.15 Gm. by vein, averts the paroxysm, but it must be repeated for two or three days. It cannot take the place of quinine for permanent arrest (C. W. F. Winckel, 1941). In *clinical vivax malaria,* oxophenarsine hydrochloride, 40 mg. by vein, may be used to increase the effect of quinine in resistant cases; it has little effect alone (W. H. Stewart, 1945).

Other Metals against Syphilis.—The usefulness of mercury, bismuth (and of iodide) is discussed under these headings. *Gold* was credited with some value by Fracastor (1530) and by many later writers, especially by Chrestien of Montpellier, 1811. Legrand of Amiens, in 1836, wrote a book on it, in which he claimed it to be more effective than mercury. A reaction against mercury was in vogue at that time and a number of other metals were credited with antisyphilitic effects: *Silver* by Serres, 1836; *platinum* by F. Hoefer, 1840; *iron* by Horn; *copper* by J. R. Koechlin; *zinc* by J. H. Hancke; antimony, lead, manganese, graphite by others. Arsenic was tried early, with and without mercury, but was feared and not used widely.

Systematic chemotherapeutic studies by modern methods led to the introduction of *bismuth* by Levaditi and Sazeran, 1920. Levaditi, 1931, also tried some thirty other metals against rabbit syphilis, spirillosis and trypanosomes. As, Hg, Bi, Te, Va, Pt, Au were found more or less effective; Sb, Se, Th, Pb, Ir and the others appeared ineffective. The *malaria treatment* of paresis was introduced by Wagner von Jauregg, 1920.

Toxic and Side Actions of the Arsphenamines.—The slow *intravenous injection* of the usual solutions does not give rise to notable local phenomena. There is sometimes intense but fleeting pain in the shoulder, possibly from endocardial irritation. A peculiar disagreeable odor and taste of garlic, ether, suet or strong peppermint candy is also often perceptible for a short time. There may be nausea, and sometimes vomiting, to be treated by gargling with cold water. Injection of solutions of arsphenamine or neoarsphenamine into the *subcutaneous tissue* produces severe burning pain, followed by painful irritation for several days. With acid and alkaline solutions this is due partly to the reaction, partly to the arsphenamine; acid arsphenamine causes severe and persistent pain; alkaline solutions of arsphenamine may produce corrosion, ulceration and gangrene. Neutral suspensions of arsphenamine also result in severe but slower irritation, and the absorption is incomplete (H. E. Robertson, 1913). *Neoarsphenamine* solutions, although neutral, produce severe inflammation, infiltration and fibrosis, which may proceed to abscess. If an injection should accidentally be made into the subcutaneous tissue, it should be aspirated and promptly diluted by injecting 10 to 20 cc. of normal saline solution into the site (Dietel, 1925). Thiosulfate solution, which is often used, acts similarly and appears to have no material advantage.

Intraperitoneal injection of neoarsphenamine into rabbits produces transient aseptic peritonitis, but no permanent injury, and is completely absorbed (W. Rosenberg, 1924). The incidence of adhesions is greatly reduced by adding 1 to 4 per cent of sodium bicarbonate to 1 per cent neoarsphenamine (B. G. Noble, 1929).

Toxicity by Mouth.—Neoarsphenamine, 0.3 Gm., has been taken by mouth for six successive days, with no other effect than some temporary gastric discomfort and diarrhea. The *Wassermann reaction* remained positive (M. Friedmann, 1920).

Toxic Frequency, Danger and Precautions.—Some degree of systemic reactions occurs in ½ to 15 per cent of all injections. They are annoying and alarming, but not often dangerous. The danger may be minimized by using reliable drugs; exact technic of preparation and administration of the solutions; and painstaking surveillance of the patient as described under administration.

American Statistics.—The data of Cole, DeWolf *et al.*, 1931, represent a uniformly supervised series, with conservative doses of arsphenamine and neoarsphenamine, which gave approximately equal incidence; and a smaller number of other arsenicals, of which sulfarsphenamine appeared to be distinctly more liable to serious complications. The entire series comprised about 78,000 injections on 1200 patients; nearly all the patients were under treatment for six months or longer. Toxic effects or complications were observed in 1:123 injections. The most common occurred in the following order of frequency: severe gastro-intestinal reactions, 1:700 injections (in round numbers); slight skin eruptions, 1:1000; pruritus, 1:1500; nitritoid, 1:1900; crustaceous and exfoliative dermatitis, 1:3000; icterus, 1:3500; death, 1:6500; the latter included: hemorrhagic encephalitis, 1:13,000; exfoliative dermatitis, 1:15,000; and hepatitis, 1:78,000. Nearly two-thirds of the patients had a single complication; a fourth showed two; an eleventh, three. Patients oversensitive to one arsenical are probably so to all. Arsphenamine and neoarsphenamine gave essentially the same percentage of toxic reactions, but purpura and hemorrhagic encephalitis were more common with sulfarsphenamine, as noted also by Stokes and O'Leary. The frequency of toxic effects is somewhat greater for women; Negroes rather less than white. Age is important, the toxicity being generally highest above forty years and lowest below twenty years; but encephalitis and exfoliative dermatitis are more frequent in young adults. Twenty-one deaths from arsphenamines were reported from New York City in 1937.

Physical (*Colloidal*), *Chemical* (*Arsenical*) *and Indirect* (*Immune*) *Factors.*—The *immediate and early reactions* are due mainly to *physical interactions* between the colloidal particles of the arsphenamine and of the tissues. They are therefore confined essentially to the intravenous injections, and vary quantitatively with the colloidal instability of the solutions. They are by far most serious with acid arsphenamine, much less with alkaline arsphenamine, slight and rare with neoarsphenamine, and practically absent with oxophenarsine. They should be avoided by dilution and slow injection, by stabilization of the colloids, or by selection of the more stable compounds.

Delayed reactions are partly chemical, owing to the formation of more toxic arsenic compounds or to the injurious effects of the products of the destruction of parasites, and of accompanying *immune reactions.* Too little is known about either of these to permit a sharp classification.

Immediate "nitritoid" reactions (angioneurotic symptom complex), due to flocculation or agglutination of the blood by the colloid arsphenamines, bear a general resemblance to vasodilatation ("vasoparesis"); the milder grades to nitrite action; the severer grades to anaphylactic reaction (Swift, 1912). The *symptoms* start during or within a few minutes after intravenous injection, with a burning ethereal taste; flushing of the face; injection of the conjunctiva; edema of the tongue and eyelids; anxiety, nausea and vomiting; then profuse perspiration. Cough, dyspnea, cyanosis and precordial distress are sometimes present. The pulse is full at first, then weak, with a pallid skin. In severe cases there is unconsciousness, with scarcely perceptible pulse. Occasionally there are attacks of severe lumbar pain during the injection. These symptoms may disappear in one-quarter to one-half hour, or they may be followed by later symptoms (Schamberg *et al.*, 1917). The immediate symptoms are rarely dangerous; even actual collapse (which is said to be more frequent after the second dose) usually ends in rapid recovery, rarely in death (Tomasczewski, 1913). The occurrence of the immediate reactions does not preclude continuance of arsphenamine therapy, but renders it advisable to use oxophenarsine, which is not liable to nitritoid reactions; although an exceptional case of severe crisis was reported by A. L. Shapiro, 1945.

These "reactions" occur in 0.05 to perhaps 5 per cent of the administrations of alkaline arsphenamine; the relative frequency depends mainly on the conditions of administration, especially on giving the drug with the stomach empty, and having the patient rest for an hour or more after the administration. The rate of injection and the proper alkalinization, are also important factors A few patients react even with the most careful technic,

Treatment of Nitritoid Reactions.—The injection should be stopped with the first sign of flushing. If the reaction does not subside immediately, epinephrine should be administered hypodermically, ½ cc. of 1:1000. This usually gives prompt relief, but if necessary, it may be followed by 0.1 to 0.15 cc., well diluted, by vein. Once recovered, the patient does not relapse. With those who tend to react to each injection, epinephrine may be used as a preventive, 0.25 cc. of 1:1000, hypodermically. Patients hypersusceptible to arsphenamine are sometimes also hypersusceptible to epinephrine, the effects of which may be as alarming as those of arsphenamine (Stokes, 1919; Cole).

Effects on Circulation.—The rapid injection of arsphenamine solution into the femoral vein of dogs produces a gradual but severe and persistent fall of blood pressure, *i. e.*, a shocklike state (Auer, 1911). This is preceded by rise of the pressure in the pulmonary artery (Jackson, 1923; Jackson and Raap, 1920) and dilatation of the right heart and swelling of the splanchnic organs (Jackson and Smith, 1918). The rise of the pulmonary pressure indicates that the actions are due chiefly to increased resistance in the pulmonary circulation; the heart is also depressed directly (Auer, 1911; Luithlen, 1913) as well as by the fall of coronary pressure; but the rise of the pulmonary pressure indicates that the cardiac impairment plays a secondary role. All these effects are diminished if the arsphenamine is much diluted, or if it is injected slowly, and they are slight if it is injected into the portal vein or into the femoral artery. The effects are greatest for acid solutions of arsphenamine, and least for strongly alkaline solutions. They are slight for neoarsphenamine and sulfarsphenamine, strong for silver arsphenamine (Jackson and Raap, 1920).

The reactions parallel the colloidal properties of these substances. Voegtlin, Johnson and Dyer, 1924, observed a direct correlation between the changes of toxicity and viscosity; for instance, warming alkaline arsphenamine solution, under conditions that preclude oxidation, decreases the toxicity (Hunt, 1921), with a corresponding decrease of viscosity. The less dispersed, more viscid and more coagulable colloid compounds tend to produce flocculates, precipitates or agglutinates with the blood, which would obstruct the nearest capillaries; *i. e.*, the pulmonary capillaries if the injection is made into a systemic vein (Joseph, 1911). This embolism cuts off a part of the pulmonary circulation and so causes the rise of pressure in the pulmonary artery and fall of pressure in the systemic arteries, which is the characteristic of the shock in animals and of the "nitritoid reactions" in man. The arsphenamines do not act on the muscle of the pulmonary vessels (Busacca, 1924); the systemic vessels of frogs are constricted (Luithlen). If the injection is made into the portal circulation, the pulmonary obstruction does not occur because the emboli are filtered out and broken up before they reach the lung; with injection into the femoral artery, this occurs in the leg. The phenomena are analogous to those of fat embolism. With dilute solutions, or slow injections, or with the more stable colloids, the precipitates are so scanty and dispersed that they can be washed through the capillaries without notable disturbance (Joseph, 1911).

Interaction of Arsphenamine and Blood.—Precipitation by mixing acid arsphenamine and serum can be demonstrated in the blood vessels as well as in the test tube (Joseph, 1911). Alkaline arsphenamine is much less precipitant, but there is at least a tendency to flocculation (Danysz, 1917), which varies perhaps with different bloods, as was claimed by Berman, 1918. The precipitates contain both arsphenamine and protein. Since arsphenamine is practically insoluble at the *p*H of the blood, it would necessarily be precipitated unless it is kept in colloidal solution by protective proteins. In alkaline solutions these would be formed by the action of the alkali (Oliver and Douglas, 1923), thus explaining the difference in precipitation. The protein precipitation by acid solutions may be due partly to adsorption, partly to the flocculent effect of the phenolic group of the arsphenamine. It may be recalled that the intravenous injection of phenol also produces shock phenomena (Pomaret, 1923). The characters of the proteins that remain in solution are also altered; fibrinogen, for instance, is rendered noncoagulable by thrombin, so that *arsphenamine prevents the coagulation of blood*, both *in vivo* and *in vitro* (Oliver and Douglas, 1922). Neoarsphenamine and sulfarsphenamine produce this effect only with doses much larger than the therapeutic (Anwyl-Davies and Mellanby, 1923). Arsphenamines alter the properties of the *blood corpuscles*, so as to produce agglutination, *in vitro* and *in vivo* (Oliver and Yamada, 1923). The importance of these in the lung embolism of acute fatalities was shown by Karsner and Hanzlik, 1920. Necropsy from fatal injection of *acid arsphenamine* shows ring-shaped hemorrhages widely spread in the white matter of the brain, which are attributed to embolism by agglutinated erythrocytes (G. C. Parker and Perkins, 1940).

Protection by Hydrophilic Colloids.—The agglutinating and anticoagulant effect of the alkaline arsphenamine may be prevented by the previous addition of hydrophilic colloids, as by mixing the arsphenamine solution with serum (Kritschewsky, 1921); or more practically with gelatin (Oliver and Yamada, 1922). These reduce the toxicity greatly (Oliver, Yamada and Kolos, 1923; Roick, 1915).

Hemolytic Action.—Alkaline arsphenamine solutions hemolyze slowly, by their alkalinity; acid solutions, or isotonic neutral solutions of neoarsphenamine, are not hemolytic (Corridi, 1912).

Leukocytes.—Arsphenamine injections are followed by leukopenia, and after several hours by leukocytosis, especially of neutrophile polynuclear cells (Tunnicliffe, 1922).

Excised Organs.—The effects were studied by Joseph, 1911 (skeletal muscle); Peruntz and Rosemann, 1923 (intestines); and Busacca, 1924 (autonomic system).

Sensitization by Repeated Injections.—If arsphenamine injections are repeated at intervals of several days to two weeks, the toxicity appears sometimes to be considerably increased (Flandin and Tzanck, 1921; Busacca, 1923; Launoy, 1923); but the result is uncertain (Berman, 1918), and it is doubtful whether it is analogous to ordinary anaphylaxis (Kolle *et al.*, 1920).

Early and delayed toxic reactions are common. They start within one to four hours, with a chill and *febrile symptoms*, headache, nausea, vomiting and diarrhea of varying severity. The temperature is usually between 100° and 102° F. Occasionally there are severe pains in the legs or back; sometimes polyarthritis (Tzanck *et al.*, 1936). These reactions need not cause alarm (Ormsby, 1917) and do not demand interruption of the arsphenamine treatment. They occur especially in the presence of infections even if slight (Wechselmann, 1910). The symptoms usually recede in twelve to twenty-four hours, leaving some lassitude and weakness. More rarely, the temperature, vomiting and diarrhea may continue for several days. In some cases, the urine is scanty and contains albumin and casts (Schamberg *et al.*, 1917).

The fever is generally attributed to the products of the massive destruction of spirochetes (Neisser, 1910), It may also result from pyrogenic water (Wechselmann: 1911). Various other explanations have been proposeds Ehrlich's, that the bacterial products sensitize the tissue to arsenic; Yakimoff, 1912, a colloidoclastic react on between the bacterial proteins and arsphenamine; Luithlen and Mucha, 1913, destructive action of arsphenamine on pathologic tissues.

Herxheimer reactions are exacerbations of the local syphilitic manifestations, usually in secondary or late syphilis, which may follow the first few injections. They are attributed to liberation of the treponemal endotoxins. They are harmless in the secondary stage; in tertiary syphilis they may be dangerous if vital organs are affected. They are prevented by starting the treatment with one or two small doses (0.15 Gm. of neoarsphenamine) or by a preparatory course of bismuth or mercury.

Kidney Involvement.—A few casts and a trace of albumin are not uncommon on the day after the injection, and the phthalein output may be somewhat diminished, the blood urea a trifle increased (J. A. Elliott and Todd, 1920). This renal impairment is generally temporary and has little significance. It does not demand interruption of the treatment unless the albumin or casts persist. In that case, the arsphenamine (and mercury or bismuth) should be stopped until the renal irritation has disappeared and then be resumed with great caution. Serious nephritis develops especially in connection with the skin lesions, but sometimes also independently.

Marasmus.—Occasionally the arsphenamine appears to lower the general health, without definitely ascertainable cause. In such case, it is generally advisable to discontinue the administration until the health has been restored. Anemia has been described by Moore and Keidel, 1921. Ordinarily, the blood picture is not changed, even in chronic intoxications (rabbits, Herzog and Roscher, 1923).

Metabolism.—The effects resemble those of arsenic (Postoiev, 1912). Syphilitic patients, under treatment, show some nitrogen loss on the day after the injection; otherwise the changes are inconstant (Cappelli, 1911).

Exanthemata.—Rather exceptionally, various types of skin eruptions, ranging from mild to dangerous exfoliative, may appear in a few hours to several days, generally accompanied by renal irritation. The more common types are patches of urticarial, scarlatinoid and morbilliform erythemas; herpes; or rarely purpura (Labbe and Langlois, 1919). Sometimes there is only itching. The eruptions generally subside in a day or two. They do not absolutely contraindicate continuation of the arsphenamine treatment, but it may be advisable to go slower. Recurrent urticaria may be prevented by changing to oxophenarsine, or by prophylactic injection of epinephrine, 0.5 cc. of 1:1000, hypodermically, five minutes before the arsphenamine. Persistent pruritus usually turns into severe dermatitis if the injections are continued. Sulfarsphenamine sometimes induces purpura hemorrhagica and occasionally aplastic anemia.

Dermatitis may develop in one to fourteen days. It takes various forms and may turn into exfoliativa, the latter generally with severe nephritis, with slow recovery, and often with fatal outcome (J. E. Moore and Keidel). These severe effects are probably direct arsenic actions. If there is vesication, exfoliation or marked and persistent itching, arsenical treatment must be permanently abandoned.

Sodium thiosulfate is often injected in treating the dermatitis (Ravaut, 1920), 1 Gm. in 10 cc. of water intravenously, daily or on alternate days, for one or two weeks; sometimes supplemented by oral administration of 1 Gm. in water, three times daily. Its value is questionable (Voegtlin, 1923).

Whatever action it has is probably on the dermatitis rather than on the arsenic; for it does not decrease the toxicity of arsenoxide (Voegtlin) and scarcely at all that of sodium arsenite or arsenate; *i. e.*, it does not protect against superfatal doses, and only partly against just fatal doses. It appears rather to decrease the urinary elimination of the arsenic, but this has no relation to the improvement of the dermatitis (A. G. Young, 1928). It causes some decrease in the trypanocidal efficiency of arsenicals, *in vivo*. The action has been attributed to the formation of colloidal arsenous sulfide (Kuhn and Loevenhart, 1925).

Severe Late Intoxications.—Occasionally, severe and even fatal reactions set in three days to several weeks after administration, with phenomena referable either to the kidneys or skin, or to the brain or liver. They may be due to direct actions of the arsphenamines, or to the inorganic arsenic compounds formed from them; and to special susceptibility to either.

Parenchymatous Degeneration.—Fatty and necrotic changes are of inconstant occurrence, clinically and in animals. They resemble ordinary arsenic lesions, and involve especially the liver (acute yellow atrophy); then the kidneys, heart, nervous system (encephalitis hemorrhagica) and spleen (Morel *et al.*, 1912). Mucha and Ketron, 1912, claimed that even small doses damage the renal vessels and glomeruli. The intestines may also show hemorrhagic and inflammatory changes (Saccone, 1912). The lesions occur especially after repeated injection, and are increased by mercury, uranium, epinephrine or roentgen treatment (A. Loewy and Wechselmann, 1913). Luithlen, 1913, emphasized the greater toxicity of arsphenamine to animals subjected to these vascular injuries, and believes them analogous to the Herxheimer reaction; *i. e.*, that this is a specific effect on vessels previously injured by the luetic process. In a series of *phenylarsenoxides*, the systemic toxicity was found to parallel the amount bound by the red corpuscles, liver and kidneys, *in vivo*, and inverse to the rate of excretion (R. B. Hogan and Eagle, 1944).

Hepatitis.—Rather exceptionally, the syndrome of jaundice, generally accompanied by fever, may appear from three days to several weeks or even six months after treatment. It occurs usually only after one or two courses of intravenous injections. It is less frequent with oxophenarsine than with neoarsphenamine. Its incidence is higher when epidemic hepatitis prevails. The symptoms start with sudden intense icterus. Most cases recover in a few days to three months (Wosegien, 1923); others run rapidly to a fatal ending, with vomiting, hemorrhagic phenomena in the viscera, tubular nephritis and the general typical symptoms and autopsy findings of acute yellow atrophy (Severin and Heinrichsdorf, 1912). The hepatitis is probably caused directly by the arsenical, for icterus was rarely observed in syphilis before arsphenamine was introduced; it has occurred from the use of the drug in nonsyphilitic conditions (Filliol, 1930). When icterus appears, arsenical treatment should be discontinued. In severe cases the diet should be light or liquid; fluids should be forced, and a saline cathartic administered. Caution should be used when resuming the arsenical, as is usually advisable especially in early syphilis.

Diet on Incidence of Hepatitis.—Dogs are susceptible to arsphenamine and oxophenarsine hepatitis. The susceptibility is increased by diets poor in meat protein or by abundance of fats. They are protected by carbohydrates, and especially by high protein diets (not by casein) and by feeding methionine or cysteine (W. J. Messinger and Hawkins, 1940; J. P. B. Goodell *et al.*, 1944). The effect was also noticeable, but not very significant, in clinical postarsphenamine jaundice (R. A. Peters *et al.*, 1945).

Hemorrhagic purpura is not uncommon with sulfarsphenamine, and is relatively rare with the others. It may develop twenty-four to forty-eight hours after the injection. If it is severe, it may be necessary to abandon arsenicals.

Polyneuritis is infrequent and may be syphilitic rather than arsenical. *Optic neuritis* is a rare sequel of arsphenamine and neoarsphenamine. It is generally classed with the neurorecurrences; but Arganarez, 1914, reported a series of cases which he attributed directly to the drug and not to the spirochetes. *Optic lesions* in animals require much larger doses than those concerned in clinical amblyopias. With rabbits, they require the presence of an amino group in the para position. They occur both with tri- and pentavalent arsenic; but they may be made more intense with the pentavalent, because their lower systemic toxicity permits larger doses (A. G. Young and Loevenhart, 1923).

Hemorrhagic encephalitis is a rare but most dangerous reaction. It occurs especially after large doses, or when ordinary doses are given in close succession. It is more frequent in young adults. The symptoms begin in two to four days, with headache, weakness, vomiting, muscular twitching, epileptiform convulsions, suppression of urine, dilatation of pupils, absence of reflexes, coma and death within three or four days, generally in a few hours after the onset. Paralytic symptoms may be observed (Chiari, 1913). The necropsy generally shows edema of the brain or hemorrhagic encephalitis; often also degenerative parenchymatous changes in the kidneys, liver, heart muscle, spleen, and so on. (Busse and Merian, 1912; Corlett, 1913). The encephalitis appears to be more frequent with sulfarsphenamine. It is probably a direct arsenical action, for similar phenomena may be observed in nonluetic patients (Lube, 1914), and in animals (Marschalko and Veszpremi, 1912). It is not inconceivable, however, that some cases may be Herxheimer reactions (Laredde and Jamlin, 1914).

Neurorecurrences.—Severe nervous manifestations sometimes follow arsphenamine injections after an interval of weeks or months, by epileptiform convulsions; acoustic, more rarely optic, facial and other neuritis. These do not appear to be due to the arsenic, for similar effects may occur in mercurial treatment, and they recede on further arsphenamine or mercury medication. The explanation of Ehrlich, 1911, is generally accepted, that they are caused by the incomplete destruction of the parasites, those which escape being then less exposed to the normal restraining influences, and assuming a greater virulence. Their occurrence calls for more vigorous arsphenamine medication.

Choice of Preparations.—The trend of clinical practice is toward oxophenarsine hydrochloride (mapharsen), or the dichlorophenarsine hydrochloride, which forms oxophenarsine in the body. These can be marketed as practically pure preparations which keep well, especially the dichlorophenarsine, while arsphenamines contain or form derivatives, which are often more toxic and must be limited by bio-assay. Therapeutic results with oxophenarsine are fully as good as with the arsphenamines; nitritoid reactions are absent; other toxicities are about the same. Of the arsphenamines, neoarsphenamine is used five or ten times as often as all the others combined (H. H. Hazen, 1929). It is preferred especially in general practice chiefly because its administration is much simpler, and less liable to acute fatalities from errors of technic. Although somewhat less potent than the old arsphenamine, which is therefore preferred by some specialists, it is sufficiently effective in practice. The other arsphenamines—sulfarsphenamine, trisodarsen—represent rather superficial modifications which still have a somewhat experimental status. Sulfarsphenamine can be administered intramuscularly (Stokes and Behn, 1924). Silver arsphenamine and bismarsen are attempts to combine metals which it would seem better to give separately as circumstances may indicate. *The clinical valuation of antisyphilitic agents* is discussed by H. N. Cole, 1938. In general, they are best compared in early syphilis, as the effects are then most definite.

Comparison of Arsphenamine and Neoarsphenamine.—Arsphenamine gives an acid solution which requires careful alkalinization or serious and fatal accidents ensue; neoarsphenamine forms a neutral solution with water, which can be injected directly. It is not hemolytic in ordinary clinical solutions, but only when very dilute or very concentrated; arsphenamine hemolyzes with practically all concentrations. Arsphenamine is less oxidizable in air and forms more stable solutions, and gives more uniform and prompt therapeutic results.

The data compiled by A. B. Cannon and Karelitz, 1931, showed that old arsphenamine averaged about a third fewer injections than neoarsphenamine to accomplish the healing of primary and secondary lesions and to reverse the Wassermann reaction, and the percentage of relapses was only an eighth as great. Toxic reactions of all kinds were at least as frequent with the neoarsphenamine (Pearce and Brown, 1917).

Ascorbic acid, when added to arsphenamine solutions, decreases their toxicity and prevents the increase of toxicity on standing (J. Dainow, 1939) by retarding their oxidation of the o-aminophenol (McChesney, 1945). H. N. Bundesen *et al.*, 1941, confirmed that this extends also to neoarsphenamine and oxophenarsine; the proportion of one part of ascorbic acid to three of the arsenical inhibits the toxic oxidation for a week and suppresses the patch test. E. W. McChesney *et al.*, 1944, showed that injection of ascorbic acid also protects against the toxicity of neoarsphenamine. The effect is greatest if the two are mixed, but some protection occurs if they are injected at different sites. The therapeutic efficiency does not appear to be decreased. Para-aminobenzoic acid and some other organic acids also confer protection.

Preparations.—Oxophenarsine Hydrochloride, U.S.P., *Mapharsen*, "*arsenoxide*," the hydrochloride of 3-amino-4-hydroxyphenylarsine oxide, containing about 31 per cent of trivalent arsenic; a white powder soluble in water, alkalis and acids. Usually distributed in air-free ampuls with buffering agents and other substances to render its solution compatible with human blood. It should not be stored longer than two years. Discolored solutions should not be used. Average dose, 45 mg. dissolved in 10 cc. of water and injected rapidly by vein. The solution as buffered contains oxophenarsine base. It is not precipitated by mineral acids (difference from neoarsphenamine) or by alkalis (difference from arsphenamine). It appears that the actions of the arsphenamines are due to their oxidation to this substance in the body (Rosenthal and Probey, 1933). When it is injected directly into syphilis-infected animals and patients, it appears fully as effective as arsphenamine, and acts much more promptly (Tatum and Cooper, 1934; Gruhzit, 1935). The treponemas disappear from the open lesions in less than twenty-four hours. Originally it was considered too toxic for therapeutic use, but in proper dosage (which is about a tenth that of arsphenamine) it is probably safer than the arsphenamines since it is a definite and uniform chemical substance and does not flocculate with plasma protein. No nitritoid reactions have been reported (E. A. Levin and Keddie, 1942). Only six fatalities had been reported for some twelve million injections by the ordinary routine (G. D. Astrachan and Cornell, 1943).

The *fate of oxophenarsine* was studied by H. N. Wright *et al.*, 1937, for intravenous injections on rats; fifteen minutes after the injection 34 per cent of the total arsenic was recovered from the skeletal muscles, 22 per cent from the blood, 12 per cent from the kidneys and 7 per cent from the liver. Two hours later, the blood content had fallen to 7 per cent, but that of the other organs was not greatly changed. With three injections per week for two to ten weeks there was but little retention and therefore little opportunity for cumulation.

Dichlorophenarsine Hydrochloride, U.S.P. (Chlorarsen phenarsine), the hydrochloride of 3-amino-4-hydroxyphenyl dichlorarsine, containing about 26 per cent of trivalent arsenic; a white powder, soluble in water, alkalis and dilute mineral acids. Usually in air-free ampuls as a mixture analogous to oxophenarsine. It is more stable than oxophenarsine, but should not be stored longer than three years. It is transformed to oxophenarsine when it is dissolved in water and acts as such. It is usually distributed with buffering agents. Dosage, as for oxophenarsine. Animal experiments and clinical studies were reported by R. R. Tompsett *et al.*, 1941.

***Neoarsphenamine, U.S.P.**, a product obtained by the action of sodium methanal sulfoxylate on arsphenamine, consists chiefly of sodium 3, 3′-diamino-4, 4′-dihydroxyarsenobenzene methanal sulfoxylate. It contains about 20 per cent of As, two-thirds as much as arsphenamine, and the dosage accordingly is 50 per cent higher. Neoarsphenamine is distributed in air-free ampuls. A yellow powder, readily oxidized on exposure to air, becoming darker and more toxic. Very soluble in water. Solutions of neoarsphenamine must be freshly prepared when required for use, using 2 cc. of cold distilled water per 0.1 Gm. of neoarsphenamine. This gives a neutral 5 per cent solution. It should not be shaken, and should be injected immediately to avoid toxic oxidation. The intravenous injection should not take less than five minutes. Average *dose*, 0.45 Gm. The ampuls should be stored in a cool place. The commercial ampuls contain the usual dosages. "The ampule containing the drug is immersed in alcohol; then carefully wiped off; the neck filed across and broken off; and the contents sprinkled on the surface of cool, sterile distilled water and allowed to dissolve *without shaking* the solution. Any product incompletely soluble should be discarded. Solutions of neoarsphenamine must be injected *immediately* after their preparation. Neoarsphenamine must not be warmed and the temperature of the injected fluid should not be more than 20° to 22° C. (68° to 71.6° F.)." "The drug may undergo deterioration in the ampule, and care should be exercised to use the drugs of normal color and free solubility"—N.N.R. (G. B. Roth, 1922). *Peritoneal injection* of neoarsphenamine has been used in infants with congenital syphilis; it appears to be effective and fairly safe (Grulee *et al.*, 1928).

Arsphenamine, U.S.P. (3, 3 diamino 4, 4 dihydroxyarsenobenzene dihydrochloride), contains not less than 30 per cent of As. A light yellow powder; odorless, or slight odor; hygroscopic. Oxidizes on exposure to air, becoming darker and more toxic. Sol. in water, alc. and glycerin. Marketed in sealed glass containers, free from air, containing the ordinary doses. Dose, *Caution!* Intravenous, 0.3 Gm.; less for debilitated patients. The first test dose should be of 0.2 Gm. The dosage should never exceed 0.6 Gm. *It must never be injected as a simple solution*, but must be converted into the alkaline salt by adding for each 0.1 Gm. of arsphenamine, dissolved in 25 cc. of water, 0.85 cc. of exactly titrated normal NaOH solution. This should stand thirty minutes before using. It should not be shaken. Further directions accompany the packages. It is inadmissible to use the contents of damaged tubes or remnants of powder from previously opened tubes. To prevent the injection of acid arsphenamine, it is advisable to add two drops of a 1 per cent alcoholic solution of phenolphthalein, which gives a deep yellow color if the solution is properly alkaline (S. Chambers, 1928).

Sulfarsphenamine, U.S.P., Sulfarsenobenzene, 20 per cent As (the same as neoarsphenamine), is a yellow, dry powder; odorless; freely sol. in water. More stable than neoarsphenamine, but slowly oxidizes on exposure to air, becoming darker and more toxic. Dose (by intramuscular injection), usually 0.4 to 0.6 Gm. for men, 0.4 Gm. for women, dissolved in sterile, freshly distilled water in the proportion of 0.1 Gm. to 0.3 cc.; for intravenous injection, 0.1 Gm. to 2–5 cc. It is employed mainly when intravenous injection is undesirable, as in children. Its therapeutic potency is satisfactory. Though originally credited with special efficiency in neurosyphilis, it was discredited by further experience. *Untoward reactions* are about the same in kind and frequency as with neoarsphenamine; purpura hemorrhagica is more frequent with sulfarsphenamine, icterus with neoarsphenamine (T. F. Probey *et al.*, 1944). Children appear to tolerate it better than do adults. The toxicity for animals is about the same as for neoarsphenamine. *Trisodarsen*, formerly Triarsen, trisodium arsphenamine disulfonate (with some inert diluent), has been investigated chiefly by Stokes and Beerman as a substitute for neoarsphenamine. It is more stable in air than are neoarsphenamine and sulfarsphenamine. Its therapeutic potency is reported as between neo- and old arsphenamine. The frequency of reactions is about the same as with neoarsphenamine; its toxicity for animals is somewhat lower (Report, Council on Pharmacy and Chemistry, 1937, J.A.M.A., *109:* 1125). *Acetylglycarsenobenzene*, sodium diacetylaminohydroxyarsenobenzene glycolate, SS371, solusalvarsan, has been introduced as a water-soluble arsphenamine derivative suitable for intramuscular injection. It appears promising, but requires further study. It is a yellow, odorless powder, readily soluble in water, and contains 28.3 per cent of As. It appears to be less effective than neoarsphenamine

Its intramuscular injection is often painful, and arsenical toxic reactions appear to be rather common (L. W. Harrison, 1939; Report, Council on Pharmacy and Chemistry, 1940, J.A.M.A., *115:* 1635). *Silver arsphenamine,* N.N.R., is a combination of sodium arsphenamine and silver, containing 20 per cent of arsenic (the same as neoarsphenamine) and about 13 per cent of silver. Readily soluble in water. Dose, 0.25 to 0.3 Gm. for men, 0.2 Gm. for women, as 0.5 per cent solution intravenously. It may produce argyria, although rarely. It was introduced especially for neurosyphilis, with the claim that the silver enhances the potency (Kolle, 1920), but it is doubtful whether it has any special value. *Bismarsen,* N.N.R., bismuth arsphenamine sulfonate of sodium, contains about 13 per cent of arsenic, 24 per cent of bismuth. It is used intramuscularly and acts more slowly than sulfarsphenamine.

◆

TELLURIUM

The pharmacological actions of tellurium and selenium are rather similar to those of inorganic arsenic, especially the toxic effect on the capillaries. Tellurium is relatively nontoxic, however, being rapidly reduced to the metallic state. Its most conspicuous effects are suppression of sweat, and a persistent garlic odor, especially of the breath, due to methyl telluride. These effects are noted in the industries dealing with tellurium. Sodium tellurate has been used to suppress the night sweats of phthisis. It is somewhat spirochetocidal in rabbits (Levaditi and Nicolau, 1926).

The *relative toxicity of the salts of the metals of the arsenic group* was investigated for rats by intraperitoneal injection by K. W. Franke and Moxon, 1936. The M.F.D. mg. per Kg. to kill 75 per cent of the animals in forty-eight hours was as follows: Na_2SeO_3 = 3.25 to 3.5; Na_2SeO_4 = 5.35 to 5.75; Na_2TeO_3 = 2.25 to 2.5; Na_2TeO_4 = 20 to 30; Na_2HAsO_3 = 4.25 to 4.75; Na_2HAsO_4 = 14 to 18; $NaVO_3$ = 4 to 5; $(NH_4)_6Mo_7O_{24} > 160$. *For ingestion with food,* at levels of 25 to 50 ppm, they found the toxicity to decrease in the sequence of As>Mo>Te>V>Se.

Compounds.—The more important are tellurous oxide, TeO_2; telluric oxide, TeO_3; sodium tellurite, Na_3TeO_3, and sodium tellurate, Na_2TeO_4; hydrogen telluride, H_2Te; methyl telluride, $(CH_3)_2Te$; and tellurium tartrate, $Te(C_4H_5O_6)_4$.

Solubility.—The sodium salts are soluble in water; but the tellurite would be transformed into insoluble tellurous oxide by the acidity of the gastric juice. The alkalinity of the intestine, however, would restore the tellurite. Tellurous oxide itself would therefore be dissolved in the intestines.

Absorption from the alimentary tract is incomplete, since all the compounds are rapidly reduced to metallic tellurium, which is eliminated by the feces, imparting a blue or gray color to these. A small proportion, however, is easily absorbed, apparently even from the intact skin, for even a trace adhering to the skin imparts the garlic odor to the breath.

Reduction in Body.—All living cells rapidly reduce all tellurium compounds to the metallic state, recognized by the greenish, blue-green, blue, or dark gray-blue color, according to the quantity (Kunkel). After intravenous injection, this is found in all the organs, particularly abundant in the liver and kidneys; the lungs, spleen and adrenals are relatively free. Hofmeister, 1894, pointed out that the distribution of this reduction is quite different from that of dyes. The reduced metal is in an ultramicroscopic state. Beyer claimed that it is in the cell nuclei. The deposition of the reduced metal throughout the body occurs also with oral administration. It remains in the cells for a long time, but part is continuously transformed into methyl telluride. This explains the persistence of the odor.

Reduction by Micro-Organisms.—Gonis, 1905, showed that living bacteria and other micro-organisms reduce tellurite (also selenite). As dead organisms do not effect this reduction, potassium tellurite may be used as an *indicator of living bacteria,* yeasts, molds, and so forth. When incubated for twenty-four hours with a concentration about 1:50,000, living cultures of all the more common micro-organisms reduce the tellurite, as indicated by the appearance of a black precipitate. This concentration is practically harmless when injected into animals (W. E. King and Davis, 1914).

Excretion.—With oral administration, the major part is reduced to the metallic state, and is excreted as such unabsorbed by the feces. That which is absorbed is excreted partly as methyl telluride by the breath, urine and feces, and partly as a soluble form in the urine and bile (Mead and Gies, 1901).

Methyl Telluride.—A pronounced odor of garlic, due to methyl telluride $(CH_3)_2Te$, appears in the breath within five minutes after administration by any channel and in all animals. It persists for several days up to eight months after a single dose, according to the quantity taken. In man, it has been noted after as little as 0.0005 mg. (Reisert). The odor was described by Gmelin, 1824, and by Hansen, 1853, who made the first pharmacologic investigations of tellurium. The odor is also present, though less marked, in the urine, feces, epidermal excretions, blood and viscera. Hofmeister found that methyl telluride is produced by all tissues; also when tellurite is digested with finely mashed organs *in vitro;* but that it is prevented by any agents that tend to disorganize protoplasm, even by water or normal saline. Saponin has little effect, and quinine restrains only in fairly high concentrations. There is no parallelism between the formation of methyl telluride and the reduction to metallic tellurium. Methyl telluride is also produced by cold-blooded animals and invertebrates (earthworms), not by the higher plants (Knop, Bokorny; quoted from Gies and Mead). "*Bismuth breath*" has been attributed to contamination of bismuth preparations with tellurium; the two substances often occur in association.

The *toxicity* is low for oral administration, higher for hypodermic injection. The tellurite is perhaps ten times more toxic than the tellurate. Commercial tellurate, however, often contains tellurite. Colloidal tellurium is also much less toxic. Martelli, 1914, claimed that the toxicity to rabbits is greatly increased by coccidiosis of the liver. Berzelius found hydrogen telluride and selenide more irritant and toxic than hydrogen sulfide. The toxic and fatal doses may be found in the papers of Mead and Gies; Brutti; Martelli; Czapek and Weil; and de Angelis.

Metallic Tellurium.—Hofmeister showed that this is gradually converted into the active form in the tissues, for the garlic odor occurred after intravenous injection of the finely powdered metal.

Colloidal tellurium was investigated by de Angelis. He found it much less toxic than the tellurite. Indeed, the effects were not proportional to the dose. He attributed this to limited power of the organism to transform it into hydrogen telluride, which he assumed to be the really active agent.

Acute Toxic Phenomena in Mammals.—The essential features were described by the earliest investigators, Gmelin, 1824, and Hansen, 1853. Czapek and Weil, 1893, made a comprehensive study and pointed out the close resemblance to selenium and arsenic; the effects of tellurium, however, are slower and less virulent. They start with somnolence; restlessness, tremors, vomiting and diarrhea; asphyxial convulsions and death. The muscles and nerves remain irritable to the end. The *pathological lesions* are: severe gastro-enteritis, intense hyperemia of viscera and lungs, hemorrhage from mucosae, fluid in the serosae, parenchymatous nephritis (Martelli, 1914).

Symptoms in Man.—The inhalation of tellurous oxide in fairly large quantity results in nausea, metallic taste, the garlic odor, somnolence, depression and constipation (Mead and Gies). The same symptoms are described for hydrogen telluride. Hansen took a total of 0.34 Gm. of potassium tellurate, distributed over a long period. He recorded unusual sleepiness, nausea, anorexia and abundant salivation.

Toxic effects on frogs are interpreted by Czapek and Weil mainly as paralysis of the central nervous system. Skeletal muscle shows fibrillary twitching, even at a distance from the site of injection. With tellurite, there is also a curare action (Labes, 1929). The heart becomes paralyzed late in the poisoning.

Effects on Circulation.—Czapek and Weil observed characteristic arsenic effects, attributed to paralysis of the capillaries: profound fall of blood pressure and dilatation of splanchnic vessels, with good pressure response of the heart and vasomotor system. The *cardiac vagus* remains excitable late in the poisoning.

Digestive Tract.—Czapek and Weil found that dogs and cats respond to large doses by vomiting and diarrhea, the stools becoming of a rice-water and finally mucous character. The necropsy shows the mucosa of the duodenum and jejunum congested, swollen, with small hemorrhages, covered with a pseudomembrane; the epithelium is desquamated. The ileum and colon are usually quite normal. Rabbits generally die without gastro-intestinal symptoms. Subemetic doses do not interfere with digestion. Even fairly high concentrations do not affect gastric and pancreatic digestion *in vitro*. Ptyalin is perhaps somewhat checked (Mead and Gies).

Blood-Forming Organs.—The changes in these are analogous to those from arsenic. Martelli studied especially the bone marrow in rabbits and guinea pigs. With *small doses*, there is hyperplasia. *Moderate doses* cause leukopenia and hypoplasia. The animals tend to put on fat and increase in weight. With *fatal doses*, the bone marrow appears red, with hyperplasia of the white and red cells. If the animal survives, the picture is as for moderate doses. The *blood picture* also corresponds with that with arsenic. Small doses produce some leukocytosis, with diminution of hemoglobin. Moderate doses cause leukopenia. With rapidly fatal doses, the whites increase; the reds decrease, their resistance is lowered, and some hemolysis occurs spontaneously (de Angelis).

Hemolysis.—Luzzato found that sodium tellurite is also hemolytic *in vitro*. He believed that the action is not due to the tellurite as such, nor to the metallic tellurium to which it is reduced, but to an intermediate product, perhaps H_2Te. In confirmation, Brutti found that colloidal Te is not hemolytic *in vitro*.

Sweat.—Neusser, 1890, apparently first observed that sodium tellurate, 20 to 60 mg. per day, suppresses the night sweats of phthisis patients. The observations were confirmed by others, and this application was endorsed especially by Combemale, 1891. These doses produced no notable bad effect, except slight dyspepsia and the marked garlic odor. The latter was probably mainly responsible for the abandonment of the tellurates, for but little has been written about them since that time. Dryness of the skin and skin eruptions were noted by Shie among industrial workers. Czapek and Weil found in kittens that subtoxic doses suppress spontaneous sweating of the paws and weaken or abolish response to sciatic stimulation. Pilocarpine provokes a feeble secretion. The gland cells do not show anatomic changes They claimed that arsenic had a similar effect, selenium not.

Other Secretions.—The statements as to *saliva* are contradictory. The workers of Shie's series complained of dry mouth. Hansen recorded abundant salivation. Only little work has been done on animals; none on the saliva or mucus; little on other parasympathetic innervation. Mead and Gies reported mucus secretion markedly increased in the stomach and intestines. They found the quantity and acidity of *gastric juice* markedly diminished in dogs, even by small doses. The vomitus was never acid. *Bile* was frequently regurgitated into the stomach.

Kidneys.—Czapek and Weil often observed casts, leukocytes and sometimes red cells in the urine. Mead and Gies also record albumin after hypodermic or toxic oral doses. De Angelis, on the other hand, claims absence of albumin, unless the urine contained hemoglobin.

Metabolism.—Mead and Gies fed subtoxic doses of various Te compounds to dogs, for a week, without notable effects. The *urine* became dark colored from the reduced tellurium. Brutti, 1910, found that 30 to 50 mg. of sodium tellurate per Kg. of rabbit or guinea pig produced in about half the animals severe *glycosuria* (3 to 10 per cent of sugar), with decrease of blood sugar. Mead and Gies did not find any glycosuria after toxic oral doses. Intravenous injection of 25 to 50 mg. of colloidal tellurium into rabbits produced marked increase of *urobilin* in the blood and urine, which de Angelis attributed to the hemolysis.

Autolysis.—Fasium found that salts of Te and Se activate ordinary autolysis, while they hinder the autolysis of mouse sarcoma.

Industrial Tellurium Poisoning.—Tellurium occurs as an impurity of lead and copper ores and is encountered industrially in the purification of these metals, especially in the electrolytic refining of lead. Here it occurs in the fumes as hydrogen telluride, and in dust as tellurous oxide and tellurates. The direct industrial use is not extensive. It is employed in the glass industry, to impart a blue, red or brown color to glass. It is being tried in steel making as a reducing agent in place of coke. It vaporizes when added to melted iron in foundry practice (H. Steinberg *et al.*, 1942). Shie, 1920, and Deeds examined twelve lead workers exposed to tellurium. Eight of these showed *symptoms* that might be attributable to tellurium, and these were of about the same frequency and degree with those who had been exposed only two weeks, as with those who had worked for a year. The frequency of the symptoms among these eight affected workers was as follows: seven—garlic odor, metallic taste, dry mouth; six—dry, itching skin and rashes; five—suppression of sweat; four—constipation; three—poor appetite, nausea, vomiting, somnolence; one—loss of hair. None showed albuminuria or malnutrition.

◆

SELENIUM

This element is closely related to tellurium chemically and in some of its actions, but is much more toxic. Chronic poisoning produces unique effects that were overlooked in the earlier investigations, as those of Czapek and Weil, 1893, and Woodruff and Gies, 1901. These were concerned chiefly with the acute effects of relatively large doses, which seemed to have only a moderate theoretical interest. Selenium had some notoriety as a possible specific treatment of cancer, but this proved a disappointment. Relatively recently it was recognized that "alkali disease," a peculiar stock disease prevalent in certain regions of the North Central Great Plains, in Wyoming and South Dakota, is due to the ingestion of selenium in the forage and cereals grown on the volcanic soils of these regions, which are relatively rich in selenium (review, A. L. Moxon and Rhian, 1943).

Historical.—Marco Polo (1254–1327), in his account of travels in Western China, in the thirteenth century, recognized this peculiar form of stock poisoning and assigned it correctly to the forage, "a poisonous plant growing there, which if eaten . . . has the effect of causing the hoofs of the animal to drop off. Those of the country, however, being aware of its dangerous quality, take care to avoid it." The connection of selenium and alkali disease was shown by the chemists of the U.S. Department of Agriculture. The toxicology and pharmacology have been extensively investigated by M. I. Smith and his associates of the National Institute of Health.

Toxic Selenium Soils.—Selenium is widely distributed in the soil of arid and semi-arid regions throughout the world (K. T. Williams and Byers, 1934) and passes into the plants grown upon them. Soils containing more than 0.5 parts per million or vegetation with more than 5 ppm are potentially dangerous to live stock (H. G. Byers, 1935). The actual danger depends somewhat on the form in which the selenium is present, and on climatic and other conditions (H. G. Knight, 1935, 1937). It was reported that the passage of selenium into the plants could be materially reduced by treatment with sulfur or calcium sulfate (Trelease and Trelease, 1938), but this does not seem to have worked out well. The raising of cereals has been abandoned in regions where selenium abounds.

Insecticidal Contamination.—Citrus orchards in which selenium sprays had been used for five years contained a maximum of 2 ppm in the upper six inches of soil (W. M. Hoskins *et al.*, 1938), a quantity that does not appear negligible. Selenium applied directly to soils destroys red spiders and some other insects on plants, but some insects are not susceptible (review, A. L. Moxon and Rhian, 1943).

Occurrence in Vegetation.—Plants grown on selenium-containing soils take up considerable of the element. Its connection with the disease was first suspected from its isolation by W. O. Robinson from South Dakota wheat which had proved toxic to animals. It is the only mineral element known to be absorbed from the soil by food plants in sufficient quantity to render them lethal to animals. It accumulates much more in some plant species than in others, and in a few varieties, such as Astragalus, it appears to be essential to growth, so that the occurrence of these plants indicates its presence in the soil (Trelease and Trelease, 1938). In commercially purchased wheat grain from various parts of the world, its concentration ranged from 0.1 to 1.9 mg. per Kg. In that grown in soils of the selenium region it may be as high as 26 mg. per Kg. It is mostly in the gluten, and gluten from wheat grown on artificially selenized soil may contain up to 340 mg. per Kg. (W. O. Robinson, 1936). Crystallizable selenium-containing amino acids, similar to cystine, have been isolated from seleniferous grain (Horn and Jones). The concentration in most vegetables from selenium regions is rather low, except with onions, cabbage and rutabaga; in onions it may run up to 17.8 mg. per Kg. Its concentration in meat is up to 8.0 mg., in eggs to 9.14 mg., in milk to 1.28 mg. per Kg. These are the chief sources of income for man. Water is rather low, not above 0.33 mg. per liter. The bread used in selenium regions contained only up to 0.1 mg. per Kg., as it is made from imported flour. The locally grown wheat averaged 18.8 mg. per Kg., maize 14.9 mg. The seleniphile plants, such as Astragalus, may contain 150 mg. per Kg., a half more than the soil. About half of the latter is water soluble, while none of that in wheat is extracted by water.

Fate.—Extensive studies of M. I. Smith, Westfall and Stohlman, 1937, with hypodermic and oral administration of sodium selenite to animals, acutely, and continuously for two weeks to half a year, show that 30 to 90 per cent, usually 50 to 75 per cent, is excreted chiefly by the urine (although the concentration in the feces may be higher). A smaller amount is exhaled as methyl selenide $(CH_3)_2Se$. With hypodermic injection of sodium selenate (radioactive isotope) into rats, 3 to 10 per cent is excreted through the respiration within twenty-four hours (K. P. McConnell, 1942); with sodium selenite the respiratory excretion reaches 17 to 52 per cent (J. Schultz and Lewis, 1940). The urinary concentration runs closely parallel to the intake. Selenium organically bound in plants gives a considerably higher retention (about five times), as would be expected from its slower absorption. When the administration of selenite is discontinued, the excretion falls as a parabolic curve, becoming practically horizontal in about two weeks. With organic selenium the descent is slower and the horizontal higher. The quantitative determination of selenium in tissues and feces is described by R. Gortner and Lewis, 1939.

The *selenium content of the urines* in selenium regions was studied by M. I. Smith, Franke and Westfall, 1936, and M. I. Smith, 1941. Of the rural population, 92 per cent showed selenium above 0.002 mg. per 100 cc.; 73 per cent ran below 0.05 mg.; the others to 0.133 mg. The urinary concentration in animals with selenium symptoms ranges from 0.06 to 0.3 mg. per 100 cc., which would correspond to a daily intake of about 0.1 mg. per Kg. of body weight. They incline to consider concentrations above 0.02 mg. per 100 cc. as indicative of potential damage. Random urine samples of persons not exposed to selenium contained 0.001 to 0.016 mg. per 100 cc., 0.02 to 0.1 mg. per day (J. H. Sterner and Lidfeldt, 1941).

Organ Distribution.—Selenium administered as inorganic or organic compounds is distributed through all the tissues with special predilection for the liver and kidneys, and in descending order: pancreas, spleen, heart, lungs, brain. Hair contains considerable selenium in chronic poisoning and is perhaps an index of the amount of exposure. The blood concentration is usually low, the corpuscles much higher than the plasma. It passes into the fetus (H. C. Dudley, 1936; Gortner and Lewis, 1939; M. I. Smith, 1941). After discontinuing the exposure of sheep, the organ content falls to a harmless level in about two months (I. Rosenfeld and Beath, 1945).

Phenomena of Selenium Stock Poisoning ("Alkali Disease").—The chronic form ordinarily seen causes emaciation, stunted growth, stiff gait, loss of hair, especially of the tail and mane, and a peculiar deforming atrophy of the hoofs, leading to transverse ridging, erosion and separation at the coronary band. There is also a peculiar hepatic change. Reproduction is impaired. The disease is especially injurious to young animals. The hoof condition may occur in the fetus, which may be born without hoofs. Horses imported into a virulent selenium region develop the condition in about three months. It is exacerbated in spring and autumn. More intensive poisoning leads to incoordination, "loco" or "blind staggers," but it is questionable whether selenium is responsible for all cases of these ill defined conditions. Acutely fatal poisoning may ensue from liberal consumption of plants with especially high selenium content, but these are not eaten by the animals unless forced by hunger—probably not by an antiselenium instinct, but because they happen to have a strong odor or taste. *Chickens* are peculiarly resistant to selenium poisoning, but their *eggs* develop only partly and do not hatch, and the embryos are greatly deformed. The production of eggs is not materially decreased. Turkey eggs show the same changes. This effect occurs when the soil contains 1 ppm of selenium, or even less, and is a delicate index that a farm is selenium tainted. It is diminished by adding arsenic, 5 to 10 ppm, to the feed (B. Ivory, 1945). Small quantities of selenium injected into normal eggs lead to deformed embryos (K. W. Franke, Moxon *et al.*, 1936). *Goldfish* kept in water containing sodium selenite equivalent to 2 ppm develop anorexia and die in eighteen to forty-six days (M. M. Ellis *et al.*, 1937).

Chronic selenium poisoning in the human inhabitants of selenium districts is unlikely, as their food does not come exclusively from the region. However, the urinary output of about a fourth of the inhabitants is about a third of that of animals with selenium disease, so that the margin is not wide. Smith, Franke and Westfall, 1936, found no serious illnesses attributable to selenium, and not a conspicuously high incidence of minor gastric, hepatic, neuritic, finger-nail, dental or other disturbances that might be attributable to selenium, but which are not characteristic.

Industrial chronic selenium poisoning is a potential hazard, as selenium is given off in lead, zinc and copper smelters and is widely used in ceramics, paints, steel, copper alloys and rubber manufacture. The domestic consumption in 1935 was 412,000 pounds, four times that of 1921. The urine of workers in a copper refinery contained from traces to 0.69 mg. per 100 cc. (the maximum being over twice that in selenium stock poisoning). Gastro-intestinal disturbances, nervousness, pallor and garlic odor were observed. The selenium content of the air and of the urine of the workers should be watched (H. C. Dudley, 1926, 1938). Acute sore throat was observed by Motley *et al.*, 1937, in *laboratory workers* handling animals treated with selenium compounds (possibly exhalation of methyl selenide). The dogs showed marked edema of the lungs and concentration of the blood.

Typical chronic selenium poisoning is produced experimentally in rats and guinea pigs by feeding grain grown on artificially selenized soil (H. C. Knight, 1934). Severe toxic effects occur with 15 mg. per Kg. of food, corresponding to a daily intake of 1 to 1.5 mg. per Kg. of body weight. Organic selenide is about half as toxic as the selenium in grain (O. G. Fitzhugh *et al.*, 1944). The phenomena have been studied with sodium selenite especially on rats. These are peculiarly resistant to the acutely fatal action so that it is possible to continue relatively large doses which produce cumulative pathological lesions; but if the rats are given a choice of foods they avoid the selenium. At the threshold dosage of 0.1 mg. per Kg. of body weight per day (corresponding to about 0.1 to 0.5 mg. per 100 cc. of urine), these lesions include injury to the gastric mucosa, focal destruction and fatty necrosis of liver cells, anemia and focal cardiac degeneration, with symptoms of anorexia, vomiting and lowered liver function. They progress to gastric ulcers; severe necrosis and degeneration of the hepatic parenchyma, with periportal cirrhosis; similar but less severe renal changes; preliminary anhydremia followed by progressively severe hyperchromic anemia; hyperplasia of the reticulo-endothelial system; serous effusions; epiphyseal erosions of the bones; cachexia and malnutrition, diminished fertility (K. W. Franke and Potter, 1936; M. I. Smith, 1941). J. Seifter, Ehrich *et al.*, 1946, describe the production of thyroid hyperplasia and adenomatous liver by an organic selenium compound. The unique hepatic cirrhosis occurs in about 70 per cent of the rats that have been on selenium diet for three months (O. G. Fitzhugh *et al.*, 1944). It may be followed by adenoma or low grade carcinoma (A. A. Nelson *et al.*, 1943). It is preventable by the administration of sodium arsenite and arsenate; tungstate is less effective; other elements, including molybdenum and vanadium, are ineffective or increase the damage (Moxon and DuBois, 1939; K. P. DuBois *et al.*, 1940). Sodium arsenite also decreases the general toxicity of selenium. The detoxication applies to all forms of selenium and is not due to interference with intestinal absorption, for it is independent of the route by which either the selenium or the arsenic is administered (A. L. Moxon *et al.*, 1945). Various proteins in food protect against chronic selenium poisoning. This is not related to their cystine or methionine content (Smith and Stohlman, 1940). Rats with symptoms of selenium or tellurium poisoning show marked decrease of the *ascorbic acid* content of the liver and adrenals (Svirbely, 1938). Similar chronic poisoning is observable in *dogs* when 7.2 ppm of natural organic selenium, or 10 ppm of sodium selenite, are added to the diet; with similar protection by arsenic (M Rhian and Moxon, 1943).

The *acute toxicity* of selenium compounds is high. For dogs, 4 mg. of sodium selenite or selenate per Kg. of body weight, by oral, hypodermic or rectal administration, are usually fatal in a few minutes. The powdered metal is much less toxic by mouth. Even 4 Gm. per dog are nontoxic, being mainly excreted by the feces (Czapek and Weil, 1893). For cats, rabbits and rats, the M.F.D. ranges from between 1.5 and 3 mg. per Kg., the selenite and selenate usually alike, and oral about half as toxic as intravenous (Smith, Stohlman and Lillie, 1937). *Selenium oxychloride*, $SeOCl_2$, is highly vesicant, producing painful, slow-healing burns. Rabbits die within twenty-four hours after the application of 0.01 cc. to the skin, with Se demonstrable in the liver and blood (H. C. Dudley, 1938). Organic selenium compounds are much less toxic (Moxon *et al.*, 1938). The toxicity of *selenium cystine* was studied by A. L. Moxon, DuBois and Potter, 1941.

Embryos.—A small amount of a selenium salt injected into the air sac of hens' eggs, after incubation, gives rise to monstrosities similar to those that form in the eggs of hens fed on selenium grain. Arsenic, fluoride and lead do not produce monsters (K. W. Franke *et al.*, 1936).

A specific effect on cancer in rats was claimed for intravenous injection of selenium compounds by Wassermann, Keysser and Wassermann, 1911, 1912, but it proved unreliable (Keysser, 1914). Czapek and Weil found sodium selenite practically nontoxic for *protozoa* or *ciliated cells.* It checked alcoholic and bacterial *fermentations*, being reduced to the red metallic selenium. The *oxygen uptake* of living yeast cells is markedly inhibited by low concentrations of sodium selenite (V. R. Potter and Elvehjem, 1936). The *metabolism of tissue slices* of rats' liver, brain and kidneys (but not of muscle) is decreased by dilute solutions of sodium selenite (H. A. Schneider, 1936) and by diseleno-diacetic acid (C. I. Wright, 1939). Sodium selenite inhibits oxygen consumption by tissues *in vitro,* apparently by poisoning succinic dehydrogenase (M. E. Collett, 1924), not on the cytochrome oxidase component (E. A. Stotz and Hastings, 1937). It, and selenate, inhibit urease at *p*H 5, but not arginase of rat's liver, *in vitro* (C. I. Wright, 1940). The inhibition of urease is probably through oxidation of its sulfhydryl group, and the removal of this group is perhaps involved in the general toxicity (Smith, 1941; E. P. Painter, 1941).

Hemoglobin.—Hydrogen selenide acting on ferri-hemoglobin solutions produce a compound analogous to hydrogen sulfide hemoglobin (R. D. Barnard and Neitzel, 1938).

Higher Plants.—The presence of selenium in soils is deleterious to most plants, including cereals, decreasing their growth rate, and higher concentrations cause extreme chlorosis and death. *Tellurium* is similarly toxic (A. L. Martin, 1936, 1937; Hurd-Karrer, 1937). The addition of a sulfate to the soil reduces the selenium content of plants and thereby renders it less toxic. Certain species of Astragalus (not all) and a few other "indicator" plants take up selenium selectively and are stimulated to increased growth by concentrations that kill wheat or buckwheat (S. F. Trelease, 1940).

◆

VANADIUM

Chronic vanadium poisoning occurs clinically in workers exposed to it, in its production, through its industrial use as a mordant and by the wearing of dyed fabrics. The symptoms are those common to other chronic metal intoxications (Dutton, 1911). The lungs, kidneys and digestive canal are especially affected. Dust and fumes cause irritation of the exposed mucosae, bronchitis with a characteristic dry paroxysmal cough, sometimes so severe as to cause hemorrhage; emaciation; increased susceptibility to tuberculosis. Anemia and a peculiar cachexia are early symptoms. Digestive derangements, vertigo, hysteria, melancholia may develop; also fine tremors of the hands and failure of sight. Hemorrhagic nephritis has been reported. *Experimental chronic poisoning* in animals shows similar symptoms (Ballotta, 1931; E. P. Daniel and Lillie, 1938. Symanski, 1939, claims that industrial exposure, chiefly to the dust of the pentoxide, V_2O_5, causes only local irritation of the exposed mucosae, and no systemic effects).

The *distribution* of vanadium in biological material is reported by E. P. Daniel and Hewston, 1942. When sodium tetravanadate was injected intravenously into man, 81 per cent was *excreted* in the urine in seven days, and 9 per cent in the feces (N. L. Kent and McCance, 1941).

The **acute symptoms** produced in rats by oral administrations of sodium meta- or orthovanadate are similar to those of chronic poisoning: immediate intense distress, hemorrhage from the nose and intestines, marked diarrhea, often paralysis of the hind legs, dyspnea, convulsions. Postmortem examination shows acute desquamative enteritis. Continued administration of tolerated doses does not produce cumulation (E. P. Daniel and Lillie, 1938).

Circulatory Effects.—With intravenous injection of sodium orthovanadate, D. E. Jackson, 1912, found rise of blood pressure due to systemic vasoconstriction, by direct action on the arterial muscle or vasomotor endings. The heart is not strengthened. The pressure in the pulmonary artery also rises by the systemic and pulmonary vasoconstriction. Perfused lung vessels are strongly constricted (Baehr and Pick, 1913). *Bronchial muscle* also shows moderate but prolonged constriction (confirmed by Baehr and Pick, 1913).

Vanadium chloride and bromide (VCl_3 or VBr_3), investigated by Luzzato, 1903, cause the usual anatomic lesions of metals in the kidneys, liver, intestines and stomach. No lesions are found in the central nervous system. The blood pressure is raised and the excitability of the vagus is depressed. Death occurs through respiratory paralysis.

Spirocheticidal action has been reported for rabbits (Levaditi *et al.*, 1928), and clinically by Pereira, 1939 The latter injects vanadium sodium tartrate, 0.15 Gm. in 2 cc. of water, intramuscularly, twice a week. He reports prompt disappearance of the spirochetes and secondary lesions, and of gummas that had been refractory to bismuth and arsphenamine. It is also effective in frambesia. The toxicity is low; stomatitis, erythema and hepatic disorders are rare sequels.

Therapeutic Use.—The pharmacologic actions do not point to any definite therapeutic usefulness. Vanadium has been tried as an alterative similar to arsenic, in tuberculosis, diabetes, and so forth, but the results are not convincing. It was administered as *sodium metavanadate*, a white, almost tasteless powder, sol. in water. Dose, 1 to 8 mg. ($\frac{1}{60}$ to $\frac{1}{8}$ grain).

TUNGSTEN

The toxicity for rats on oral ingestion is reported by F. W. Kinard and van de Erve, 1941; the effects and excretion after hypodermic injection by Selle, 1942; its organ distribution by F. W. Kinard and Aull, 1945.

◆

TITANIUM

Titanium dioxide, TiO_2, is applied to the skin as ointment or wash to protect against sunburn. It produces no local irritation or systemic effects (Ballotta, 1931). The oxide or orthotitanic acid can be administered to rabbits by stomach tube in considerable doses for several weeks. They are absorbed without apparent effects. M. C. L. Bernheim, 1940, reported changes in the sulfur metabolism, *in vitro*, and with intraperitoneal injection, probably by inhibition of the oxidative enzymes. The *distribution* of titanium in man was reported by Maillard and Ettori, 1936.

◆

MOLYBDENUM

Molybdenum occurs normally in the tissues of all animals examined; in vertebrates it averages 2 mg. per Kg. of dry weight; in invertebrates, 0.8 mg. (D. Bertrand, 1942). It is not very toxic even when inhaled as dust or fumes in industry (review, L. T. Fairhall, 1945). The pharmacological effects of molybdenates were studied by Agnoli, 1933.

◆

URANIUM

The salts are corrosive, readily absorbed, and highly toxic. They injure the capillaries and cause a characteristic nephritis, both tubular and glomerular; hepatitis; glycosuria and acidosis and a unique edema. The renal and hepatic epithelium regenerates readily. Acute poisoning stimulates and then paralyzes the respiration, resembling cyanide. Animals survive the lethal dose of uranium nitrate if a liberal amount of sodium citrate is injected by vein, even three days later (G. L. Donnelly *et al.*, 1944).

Oral Intoxication by Insoluble Uranium Compounds.—Although uranium oxide and uranyl nitrate are nearly insoluble in water, they are highly toxic when given by mouth (to guinea pigs), since they are fairly soluble in dilute hydrochloric acid (Karsner *et al.*, 1918). Hypodermic injection of colloidal uranium is less toxic than nitrate (Maloney and Burton, 1938).

Influence of Light.—The resistance of guinea pigs to uranium poisoning is decreased if they are kept in the dark, but this is reversed by the injection of eosin (Karsner, Shen and Wahl, 1922).

The **excretion of uranium** occurs mainly by the kidneys (Karsner, Reimann and Brooks, 1918); none in the bile.

Distribution.—Retained uranium is deposited chiefly in the renal cortex. About a fifth (1 to 50 per cent) is contained in the liver. Very little is found in the other organs (Eitel, 1928; H. D. Jones and Goslin, 1933).

The **acute effects** were studied, especially by Woroschilsky, 1890, and D. E. Jackson, 1910. The respiration is first increased, then paralyzed. This results in asphyxial phenomena, stimulation of the vasomotor center and rise of blood pressure. The respiratory paralysis is the cause of death. The blood is rendered noncoagulable by an unknown mechanism. **Sublethal doses** are followed in a few days by albuminuria and glycosuria; parenchymatous degenerations; gastro-intestinal disturbances; paralytic symptoms and changes in the blood vessels.

The **anatomic changes in uranium nephritis** affect both the tubular epithelium and the glomeruli (Fleckseder, 1907). The vascular mechanism is involved first, but the tubular changes progress longer and finally predominate. The anatomic and functional changes are more severe in old animals, and are increased by anesthetics, especially chloroform (MacNider, 1914). Sodium citrate administration confers some protection, increasing the uranium excretion up to four times (G. E. Gustafson, 1944). Dogs are more resistant than rabbits (O'Hare, 1913). The epithelium shows fatty changes; the glomeruli are congested; or the glomeruli shrink, with enlargement of the glomerular space (Tribe *et al.*, 1916). Christian *et al.*, 1911, described characteristic hyaline droplets in the vessel walls of the glomerular tufts. These do not occur in other vessels of the kidneys or in other organs. The tubular epithelium regenerates completely within two weeks, and the regenerated epithelium is much more resistant to uranium (W. C. Hunter, 1928). The nephrotoxic action also extends to the fetus (M. Bodansky *et al.*, 1933). Repeated injections of small doses produce chronic interstitial nephritis with fibrous changes, not so severe as with chromates (R. M. Smith, 1911). The histologic lesions are similar to human chronic diffuse nephritis, but not quite identical. They are not associated with arterial lesions (Dickson, 1912). Some samples of uranium produce extensive *arterial calcification* in rabbits; in the kidneys this also involves the microscopic vessels and the glomerular capsules (P. Dominguez, 1926, 1928).

Regeneration.—Liver and kidney cells injured by relatively large doses of uranium, mercury or chloroform are replaced by less differentiated but more resistant cells of embryonic type, which probably are in turn replaced by normal cells (McNider, 1919, 1942).

Urine Changes.—In the early (vascular) stages, the quantity and specific gravity of the urine are increased. Albumin, glucose and acetone substances appear especially in older dogs (MacNider, 1914). A further increase of urine flow may be secured by caffeine or salines, although the response is slower than normal (Mosenthal and Schlayer, 1913). With the appearance of the epithelial changes, the urine decreases, the tubules being obstructed by the swelling and desquamation of the cells. This is not relieved by diuretics, although the vascular response to the diuretics may be preserved (MacNider, 1915). The excretion of chlorides and urates is diminished in acute, somewhat increased in the subacute, nephritis; *i. e.*, it varies in the same direction as the urine flow. Pohl described a subacute nephritis in rabbits, with polyuria until death, and with increased excretion of nitrogen and diminished chloride output. Dünner, 1915, found this inconstant. The intravenous injection of calcium or of hypotonic NaCl converted this subacute nephritis into an acute form. Isotonic saline had no effect. In this stage, the renal vessels are engorged and the blood flow through the kidneys is increased, but the oxygen consumption is diminished (Tribe *et al.*, 1916). A similar hyperemia exists in the spleen and other organs (Brull, 1934). The excretion of endogenous *creatinine* is diminished in both stages; but injected creatinine is completely excreted in the subacute, retained in the acute (Kraus, 1913). The *phenol-s-phthalein excretion* also varies in the same direction as the urine flow (Eisenbrey, 1913). It bears no definite relation to the histologic lesions (Smith, 1911). The most marked effect of uranium nephritis is a depression of the factor: urine urea divided by plasma urea. This is fairly parallel to the anatomic injury (Watanabe *et al.*, 1917). The nonprotein *nitrogen retention* in the blood goes parallel to the phthalein retention; both increase and recover together, except that the phthalein responds more promptly (Frothingham *et al.*, 1913; Karsner and Denis, 1914). However, Mosenthal, 1914, pointed out that the increase of nonprotein nitrogen in the blood is not necessarily proof of retention, but could be explained by increased protein destruction or by inspissation of the blood through polyuria.

Hepatic degeneration was studied on dogs by MacNider, 1919, 1935. It is similar to that seen after mercury, and is parallel to the acidosis, rather than to the dose.

Uranium glycosuria develops on the first or second day. The action consists partly in increased permeability of the kidneys for sugar, for it may occur without hyperglycemia (Franck, 1913), and may even relieve hyperglycemia when this is due to decreased permeability of the kidney cells (Pollak, 1911). The sugar does not bear any definite relation to the other urinary constituents, except albumin, which goes fairly parallel (Wallace and Myers, 1914). Uranium may itself cause hyperglycemia, however, even when the kidneys are excised, so that part of its action must be extrarenal (Fleckseder, 1906). *Nephritic glycosuria* without hyperglycemia occurs with many nephritic poisons. With cantharides, it is attributed to increased permeability of the vessels; with uranium, chromium, tellurium, mercury and aloin, to lesions of the tubular epithelium (Luzzato, 1914).

Acidosis.—MacNider, 1916, found the toxicity of uranium associated with acidosis, sodium bicarbonate having a distinct saving effect. It also protects the uranium kidneys against anesthetics, so that these produce much less epithelial degeneration. These findings were confirmed by Goto, 1917. Karsner, Reimann and Brooks, 1918, also found that uranium poisoning is almost always accompanied by acidosis, and that this is more severe in older animals. The albuminuria always precedes the acidosis, so that the acidosis is not the cause of the nephritis. The acidosis is not due to retention, for it occurs even when the excretion of acid is increased. It is due to overproduction or inadequate combustion of organic acids (Brull and Roersch, 1934).

Uranium Hydrops.—Hypodermic administration of uranium salts produces general anasarca and ascites (Le Bret, 1854; Richter, 1904), a highly albuminous fluid transuding mainly into the serous cavities but even into the other tissues, and extending even to the fetus in the uterus (Bibergeil, 1905). Nephrectomy alone does not produce hydrops, so that the anuria does not furnish the explanation. On the other hand, the uranium hydrops occurs in nephrectomized animals, so that the kidneys are not concerned in its production (Fleckseder); nor do the histologic kidney lesions bear any relation to the edema (R. M. Smith, 1911). The fundamental change consists presumably in an altered permeability of the capillary walls (Richter, 1904). The injection of the blood of uranium animals into chromate animals also produces edema (Heinecke, 1905; Blanck, 1906). Edema, however, occurs only in animals which are freely supplied with water—otherwise the uranium causes anuria without hydrops (Fleckseder). Retention of salts is not connected with its production (Richter, 1905). In acute uranium poisoning, the *lymph flow* is not increased (Jackson, 1910). Uranium poisoning interferes with the restoration of the blood volume after saline infusion (Bogert, Underhill and Mendel, 1916).

Therapeutic Uses.—The soluble uranium nitrate was tried in diabetes mellitus and in phthisis in doses of 75 mg. (1 grain), largely diluted. The results do not justify the further employment of so dangerous an agent. *Uranium Nitrate*, $UO_2(NO_3)_2$. $6H_2O$, occurs as light yellow prisms of bitter, astringent taste. Freely sol. in water (1:1.2) or in alc. Dose, 0.01 Gm, $\frac{1}{6}$ grain, diluted, with caution.

◆

ANTIMONY

The actions of antimony resemble those of arsenic, differing chiefly by greater local irritation and more difficult absorption. When given by mouth, doses can be chosen whose only action is that of producing nausea or, if somewhat larger, vomiting. The intravenous injection of inorganic and organic antimony compounds is effective against various tropical protozoan infections. Excessive doses, intravenously or by mouth, produce toxic symptoms resembling those of acute and subacute arsenic poisoning. Application of antimony preparations to the skin results in local inflammation.

Antimony has an interesting *history*. Paracelsus in the sixteenth century used it as a panacea, and it was employed against the plague. Numerous deaths caused its formal proscription.

Applied to the skin, antimony chloride is a strong caustic. Antimony and potassium tartrate (tartar emetic), when applied over long periods, produces a pustular eruption. This is due to the decomposition of the double salt, which is but slightly irritant, by the acid secretion of the follicles into the more irritant antimonious oxide, Sb_2O_3, and other compounds. Such salves were formerly used for counterirritation, but have been abandoned as too destructive and toxic.

The **nauseant and emetic effects** are due mainly to the local action. "Tartar Emetic," the tartrate of antimony and potassium, is the compound usually employed internally. As an *emetic* (dose, 30 mg., $\frac{1}{2}$ grain), its action is rather slow and too depressing. As a *nauseant* it has the advantage that the dose required is only about one-tenth of that which produces vomiting. Its continued use, however, may become dangerous. It is employed mainly as a depressant expectorant in the first stages of acute bronchitis; often in the form of Wine of Antimony, 1 cc. = 4 mg., $\frac{1}{15}$ grain; or smaller doses (1 mg.) may be repeated every hour with precaution against excessive depression. It also enters into a number of compound expectorants, such as Compound Mixture of Opium and Glycyrrhiza, N.F. (8 cc. = 2 mg. of tartar emetic and 1 cc. of paregoric) and Compound Syrup of Squill (2 cc. = 4 mg. of tartar emetic).

The *mechanism of emetic effect* is chiefly reflex, for while emesis occurs both by gastric and venous administration, the latter requires much larger doses and the vomiting occurs much more slowly (Kleimann and Simonowitsch, 1872). Among animals, antimony is emetic for dogs and pigs, but not for horses, beef or sheep. The nauseant action and the increase of the salivary and bronchial secretion are also reflex (V. E. Henderson and Taylor, 1910). Like other irritants, antimony is said to increase *uric acid excretion* (Abl, 1913).

Toxicology.—Overdoses produce the same effects as arsenic, but vomiting is always a prominent phenomenon. Death may occur after 0.15 Gm. of tartar emetic. Long-continued small doses lead to a train of symptoms of *subacute poisoning*, analogous to those produced by arsenic in the same manner (Gaehtgens, 1876), including the metabolic changes. Even small amounts retard the growth of rats (Flury, 1927). Intravenous injection of antimony and potassium tartrate into rabbits causes leukopenia, with recovery in twenty-eight hours without secondary leukocytosis. The erythrocyte count is not affected (Lucia and Brown, 1934). In distinction to arsenic, selenium and tellurium, antimony is not converted into volatile compounds by molds (Knaffl-Lenz, 1913). *Chemic antidotes* are eggs, milk; and tannic acid (tea and the like) or, in its absence, magnesia. Potassium hexatantalate precipitates antimony compounds, even in the tissues; but it could be utilized only orally, since its hypodermic injection is too toxic (Rosenthal and Severin, 1912).

The *excretion* of various types of organic compounds has been studied polarigraphically by L. G. Goodwin and Page, 1943. Thirty to 40 per cent of their antimony is excreted in the first two hours after injection.

Industrial and Domestic Poisoning.—Antimony has rarely been recorded as giving rise to industrial poisoning, except through contamination with arsenic. However, the pentasulfides used in the rubber industry are fairly soluble in human gastric juice (Carlson, 1915). Industrial exposure to antimony oxide vapor resulted in skin eruption, itching and pustulation; sore gums, conjunctivitis and laryngitis; headache, anorexia and anemia (A. Feil, 1939). Antimony is sometimes used in the glaze of cheap granite ware. This should be prohibited by law (as it is in some European countries), since some samples yield from 3 to 14 mg. of dissolved antimony in a single cooking test (E. W. Miller, 1916).

Continued exposure of guinea pigs to inhalation of antimony trioxide produces moderate fall of leukocytes, especially granulocytes, pulmonary irritation, and fatty infiltration of the liver (C. V. Dernehl *et al.*, 1945).

Habituation.—The continued administration of antimony to mammals does not lead to tolerance, as is reported for arsenic, nor does arsenic habituation confer tolerance to antimony. This difference is explained by the observation that the absorption of antimony is not diminished (Cloetta, 1911); on the contrary, it is rather increased (Brunner, 1912; he claims some tolerance for 3-valent, but not for 5-valent). Protozoa also do not become immune so readily as with arsenic (Rowntree and Abel, 1912). Antimony immunity can be induced in infusoria and does not extend to arsenic (Neuhaus, 1910). Bacteria immunized to arsenic are also resistant to antimony (Marks, 1910).

Differences in Antimony Compounds.—The toxicity and trypanocidal potency of a series of organic antimony compounds are reported by L. G. Goodwin, 1944. As with arsenic, the 3-valent is more toxic (to ten times) than the 5-valent. The organic derivatives show similar relations, the side chains being relatively unimportant (Brunner, 1912; G. Bock, 1927). The relation of the *chemical constitution and therapeutic action* is discussed by Brahmachari, 1928. Cloetta found the *pyrostibiate* much less toxic than tartar emetic. *Urea-stibamine*, injected by vein, produces fall of blood pressure, by cardiac depression and splanchnic dilatation; with large increase of the liver and spleen volume (Chopra, 1927).

Stibine, SbH_3, antimony hydride, is a potent hemolytic agent. Dogs and cats are especially susceptible and die in a few hours (S. H. Webster, 1946).

Trimethylstibine, $(CH_3)_3Sb$, is far less toxic than ordinary antimony compounds. It produces mild inflammatory reactions on local application to the skin and mucosae. It lowers the blood pressure gradually, analogous to arsenic. Large doses paralyze the central system, but do not cause encephalopathy as do the methyls of bismuth, lead and tin. Dilute solutions depress the excised heart and smooth muscle; but have no effect on skeletal muscle or motor endings (J. Seifter, 1939).

Antimony Chemotherapy.—Intravenous injection of tartar emetic is highly effective against a number of tropical diseases due to animal parasites; especially against kala-azar, bilharziasis, filariasis, Schistosoma and other flukes, Delhi boil and granuloma inguinale; good results have been obtained in leishmaniasis, sleeping sickness and frambesia. The efficiency against spirochetal and malarial infections is low, presumably because the antimony is too rapidly excreted. A number of *organic compounds* have been introduced as less toxic and less irritant, but it is doutbful whether they are materially superior.

Urea-stibamine, ethylstibamine, N.N.R. (neostibosan) and sohistibosan are now preferred in kala-azar; stibophen, antimony, lithium thiomalate and neostibosan against schistosoma (E. C. Faust, 1946).

Antimony and bismuth, as well as arsenic, are highly toxic to *trypanosomes*, but not to all protozoa. As with arsenic, the trivalent form of antimony, in inorganic or organic combination, is much more toxic to protozoa, bacteria and yeast than is the pentavalent form (Friedberger and Joachimoglu, 1917).

At the suggestion of Cushny, various investigators (Plimmer and Thomson, 1907; Mesnil and Brimont, 1908; Camac, 1911, and others) successfully used injections of antimony sodium tartrate in experimental and human trypanosome infections. Rowntree and Abel, 1910, advocated certain organic compounds, such as sodium antimony thioglycollate. The trypanocidal activity of tartar emetic is greater in the presence of serum; this does not hold for arsenicals (Shilling and Goretti, 1914). Tartar emetic has proved inefficient against *malaria*, even in large intravenous doses (J. W. W. Stephens *et al.*, 1917). *In leprosy*, antimony appeared in some cases to improve the response to chaulmoogra treatment (W. H. Hoffmann, 1927), but its value appears doubtful.

Antimony potassium or sodium tartrate is too irritant to be administered intramuscularly. Intravenously, they are injected as 1 per cent solution in normal saline. The initial dose is 40 to 60 mg., $\frac{2}{3}$ to 1 grain. In bilharziasis, this is followed every second day with 0.12 Gm., stopping the course when a total of 2 Gm. has been injected (*i. e.*, about the fifteenth injection). Delhi boil requires from $\frac{1}{3}$ to $\frac{1}{2}$ Gm.; kala-azar, 3 Gm. As much as 0.24 Gm. have been given at one dose, and a total of 5.85 Gm. in eighty-six days (Christopherson); but the therapeutic dose is not far from the toxic, and is usually followed in a few hours by irritating cough, metallic taste, salivation and nausea, colic, sometimes diarrhea and occasionally by skin rashes. Electrocardiograms may show considerable changes, especially chronic bradycardia from toxic changes in the cardiac muscle, and this may result in auricular fibrillation (F. Mainzer and Krause, 1940). The icteric index rises progressively with repeated administrations, indicating a degree of liver injury (Faust).

There is less danger of cumulative poisoning than with arsenic, since the antimony is more rapidly excreted. After intravenous injection of 0.12 Gm. of tartar emetic, 30 per cent of the antimony is excreted by urine in forty-eight hours; of 1.7 Gm. injected in a six weeks course, 1 Gm. was recovered from the urine. No data are available for the feces. Antimonious oxide may be injected intramuscularly, $\frac{1}{2}$ per cent suspended in a mixture of equal amounts of glycerin and water.

PREPARATIONS.—***Antimony and Potassium Tartrate,** U.S.P. (Tartrated Antimony, Tartar Emetic); K(SbO)-$C_4H_4O_6$. $\frac{1}{2}$ H_2O; occurs as colorless, transparent crystals or white granular powder. Sweet, then metallic taste. Efflorescent, should be preserved in well closed containers. Slightly acid to litmus. *Incompatible* with alkalis and tannins. Sol. in water (1:12). Insol. in alc. Expectorant dose, 2 to 5 mg., $\frac{1}{30}$ to $\frac{1}{12}$ grain. An obsolete "Wine of Antimony" contained 0.4 per cent. *Antimony and Sodium Tartrate* is preferred for intravenous therapy (0.03 to 0.12 Gm., $\frac{1}{2}$ to 2 grains).

Antimony Lithium Thiomalate ("*Antithiomaline*"), intramuscularly, is reported to give good results in filariasis (H. W. Brown, 1944).

Antimony Sodium Thioglycollate, which contains about 37 per cent of antimony, is used against granuloma venereum, kala-azar and filariasis. It is reported to be less irritant than the tartrate, less depressing to the circulation, and less toxic parenterally (C. Pak and Read, 1939). It is used intramuscularly and intravenously. The average dose is 50 mg.; the watery *Injection*, U.S.P., is usually available as 50 mg. in 10 cc., and as 100 mg. in 20 cc. *Antimony Thioglycollamide*, N.N.R., containing about 30 per cent of antimony, is a similar compound, rather more stable and more toxic.

Stibamine glucoside ("neostam"), a relatively nontoxic antimony compound used against kala-azar (Napier, 1929), has also given good results against filaria in cotton rats (J. E. Culbertson and Rose, 1944).

Stibophen, N.N.R. ("*Fuadin*", "Pyrostib", Sodium-antimony III bis-catechol-2.4-disulfonate, containing 13.6 per cent of trivalent antimony, was introduced in Egypt against bilharzia. It appears to be the preferred agent against schistosomiasis flukes, and it is also used against granuloma inguinale (Williamson *et al.*, 1933), and kala-azar. It is administered intramuscularly, rarely intravenously, as the commercial 6.4 per cent solution, 1.5 cc. on the first day; 3.5 cc. on the second; 5 cc. on the third; then 0.5 cc. on alternate days for seven injections.

◆

BISMUTH

The ordinary basic bismuth salts are practically insoluble in water and very sparingly soluble in tissue fluids. They are therefore poorly absorbed, practically not at all from the skin and mucous membranes, and very little even from wounds or injections. They occur as fine powders which tend to adhere to surfaces, and are therefore used to furnish mechanical protection and to exclude irritants; externally on ulcers, burns and fistulas; on inflamed mucous membranes; by oral administration in gastro-intestinal inflammations and ulcers. They were introduced into medicine in 1785 by Odier of Geneva. Soluble preparations do not accomplish these objects. Bismuth compounds are also employed against intestinal amebae. They have been used as an opaque medium in roentgenoscopy, but barium sulfate has practically displaced them from this field. Because of the insignificant absorption of bismuth compounds from these surfaces they do not usually produce systemic effects. Except for a few special compounds, these occur only from application to extensive burns or ulcers, from prolonged sojourn in fistulas, and from intramuscular and intravenous injections. They resemble subacute or chronic poisoning from other metals, especially arsenic, mercury and lead. Conspicuous black spotting of the buccal and colonic mucosae, due to precipitation of bismuth sulfide, is characteristic. They may produce fatal nephritis. Soluble bismuth salts change readily to insoluble basic salts, and their intravenous injection may cause acute flocculation collapse. The *absorbed bismuth* checks treponema infection. It has largely displaced mercury as adjuvant to arsphenamine since it has material advantages of quicker action, greater potency and less toxicity. A variety of new preparations for intramuscular injection have been introduced, differing widely in speed of absorption and in the local effects.

Local Actions and Uses of Insoluble Basic (oxy) Bismuth Salts.—These form fine adhesive powders. The subcarbonate, subsalicylate and hydroxide (magma) are insoluble in water. The subnitrate and subgallate are somewhat hydrolyzed and therefore very slightly soluble (Bouček, 1910; Stingel, 1911). They have a healing effect on inflamed mucous surfaces and wounds, drying the secretion and forming a protective covering or scab. This action is partly mechanical (H. H. Meyer, 1885), and other indifferent powders have a similar effect. A small amount of bismuth goes into solution, however, and is astringent and mildly antiseptic. The insoluble bismuth compounds are *applied* as dusting powder or ointment (30 per cent) in inflammations of the skin; and to small ulcers and burns, but in these the dry powder tends to form hard crusts which prevent effective cleaning. The application to large surfaces may result in poisoning (T. Kocher, 1882). With mucous membranes, the catarrhal mucus may prevent effective contact. Suspensions containing 10 per cent of bismuth subnitrate may be injected in urethritis. The injection of *Beck's bismuth-petrolatum paste* (1:2) into chronic abscesses and suppurating sinuses is often effective, but bismuth and nitrite poisoning may occur. The technic and precautions are described by E. G. Beck, 1916. There is little difference between the actions of the *subcarbonate and subnitrate;* on the whole, the subcarbonate deserves the preference, since it cannot give rise to nitrites. Although the subnitrate consists of sharp-pointed microscopic crystals, it does not cause mechanical irritation even when dusted on the conjunctiva.

The *soluble bismuth salts* lack the soothing qualities which constitute the main value of the insoluble products. The double citrates are indeed partly precipitated in the acidity of the stomach; but the quantity of the precipitate is too small to be effective. Various *organic salts* have been introduced as substitutes, such as subgallate (Dermatol), especially for dusting powders, but it is questionable whether they are superior to the more economical older products.

Use in Digestive Disorders.—The basic bismuth salts form a protective coating over the mucous surface of the gastro-intestinal tract. The subcarbonate (not the subnitrate) is a slowly acting antacid. They bind hydrogen sulfide (Stingel, 1911), so that the stools are black; they are among the most effective of the nonirritant intestinal antiseptics (Sollmann, 1908). These actions render bismuth subnitrate, or preferably the subcarbonate (0.5 to 2 Gm., 8 to 30 grains, every two or four hours), useful for allaying *diarrhea* (x-ray observations, Hesse, 1913) and *gastritis* and sometimes against vomiting. The bismuth powders are similarly useful in *gastric ulcer* (1 to 2 Gm. suspended in fluid, before each meal), diminishing gastric secretion and acidity (Bastedo). In *intestinal amebiasis,* bismuth subcarbonate is an adjuvant to the more active amebicides (Anderson and Reed, 1934). In normal individuals, bismuth is only moderately *constipating* since the action is on the inflammation, and not directly on the peristalsis. The continued use of these large doses may become detrimental by covering the intestinal mucosa with bismuth concretions. A small amount of the basic bismuth salts is dissolved by the acid gastric juice, is *absorbed,* and excreted by the urine (Dorner and Weingaertner, 1909), mouth and large intestines. The quantity is not sufficient to produce systemic effects.

The *use of bismuth in gastro-enterological roentgen diagnosis* is obsolete. About 50 Gm. (2 ounces) of bismuth subcarbonate (not the subnitrate) were administered, suspended in buttermilk or thick soup. Best and Cohnheim, 1911, found that the bismuth meal delays the emptying of the stomach by an hour.

Nitrite Poisoning.—The use of the relatively enormous doses of bismuth subnitrate for radiodiagnostic purposes caused several intoxications, with methemoglobinemia, intense cyanosis, diarrhea, dyspnea and death by arrest of respiration. These effects are not due to the bismuth, but to the production of nitrite by the reducing action of putrefactive fecal bacteria, especially in the large intestines and rectum (Zadek, 1914). Methemoglobin poisoning with recovery has been reported from a total of 12 Gm. prescribed against digestive disorders (G. E. Miller, 1945). E. J. Stieglitz, 1930, suggested *therapeutic utilization* of this continuous nitrite formation against arterial hypertension, administering bismuth subnitrate, 10 grains, three times daily, but carefully controlled cases failed to show benefit, even with prolonged use of fairly large doses (Ayman, 1932).

Effects on Syphilis.—Bismuth, when absorbed in small, nontoxic quantities from the intramuscular injections of its compounds, checks and suppresses treponemal infections. It was first used against the spirochetosis of fowl, by Robert and Sauton, 1916; its efficiency against syphilis was demonstrated on rabbits by Sazerac and Levaditi, 1921; and on man by Fournier and Guenot, 1921. M. F. Balzer of Paris narrowly missed making the discovery in 1889. He had actually planned to try bismuth against syphilis, but abandoned the idea because of toxic effects on dogs.

In the clinical use of bismuth by intramuscular injection, the treponemas disappear from the primary lesion in three or four days and the chancre undergoes rapid cicatrization; the contagious syphilides heal almost as rapidly as under arsphenamine; the cutaneous and visceral lesions, gummata and bone changes begin to recede after three or four injections; the response of the neurosyphilitic phenomena is about as with arsphenamine and better than with mercury; the serologic reactions respond more slowly and less frequently than with arsphenamine, especially in the primary stage where the Wassermann reaction remains positive in about a tenth of the patients under arsphenamine and in a sixth under bismuth. In the secondary stage, the difference is less marked (arsphenamine 1:6, bismuth 1:4.3; Lèri, Tzank and Pèron); but half the cases in which the Wassermann reaction resists arsphenamine and mercury become negative under bismuth. Others have estimated the relative antisyphilitic efficiency of bismuth as seven to eight-tenths that of arsphenamine, and that of mercury as four to six-tenths. The promptness and degree of the antisyphilitic action of bismuth are intermediate between that of arsphenamine and mercury, somewhat nearer to the former; and it may be substituted for either of these, especially with patients in whom these drugs are contraindicated or not tolerated, and in whom they have failed. The action of bismuth on spirochetes is probably closely analogous to that of arsphenamine, since the combined potency of both drugs in rabbit syphilis is not potentiated; it is, however, fully additive, while the toxic action is less than additive, so that the margin of safety is increased (N. M. Clausen *et al.*, 1942). Syphilis may be treated by bismuth alone, but this is not advisable; alternation of at least two agents is preferable, and one of those should be an arsphenamine. Bismuth is inferior to arsphenamine in fresh infections, and increases in value in the second stage. It has displaced mercury almost completely chiefly because it is not so likely to become injurious. Infants with congenital syphilis tolerate bismuth better than mercury. The injections are also generally less painful. In neurosyphilis it is useful along with arsphenamine, and is sometimes valuable in tabetic crises, at least symptomatically; in general paresis, the results are poor. The *contraindications* are sepsis, severe nephritis (nonsyphilitic) and septic conditions in the mouth. Caution is indicated in diabetes, tuberculosis and hepatitis.

As prophylactic against syphilitic infection, bismuth is highly successful in rabbits, as long as intramuscular injections are continued (Levaditi *et al.*, 1926 to 1928). Efficient clinical protection by intramuscular injections of bismuth subnitrate in oil (1 cc. of 10 per cent weekly) has been reported (E. Sonnenberg, 1935). Hanzlik, Lehman *et al.*, 1940, suggest oral sobisminol.

Experimental Syphilis.—The antisyphilitic action of bismuth was first ascertained on rabbits. Eagle, 1938, showed that it is directly spirocheticidal *in vitro.* Levaditi, 1933, showed that the protective value correlates with the urinary concentration. Injecting a single large dose (100 mg.) as biliposol into a rabbit, he found it insusceptible to inoculation in ten days when the daily urinary excretion was 0.12 mg., but susceptible in thirty days when the excretion level had fallen to 0.012 mg.

Other Protozoan Infections.—Bismuth is effective against *frambesia,* although not so potent as arsphenamine (G. M. Saunders, 1937). In *Vincent's angina,* favorable results have been reported from one to three intravenous injections of thiobismol, in conjunction with the usual local treatment (Giese and Briskman, 1930). Bismuth is of slight value against experimental *trypanosome infections* (Sazerac and Levaditi) and recurrent spirillosis. The clinical dosage of the quickly absorbable thiobismol (0.2 Gm. intramuscularly) causes mitigation or temporary arrest of therapeutic *malaria.* This may be applied clinically to keep therapeutic malarial reactions under control. It acts more promptly than quinine, and enhances the effectiveness of this and of atabrine (H. N.

Cole *et al.*, 1940; C. E. Watson, 1939; Brunsting and Love, 1940). Other bismuth compounds do not easily reach the effective concentration level (W. F. Schwartz, 1939).

Administration.—In the treatment of syphilis, the bismuth preparations are administered by intramuscular injection, preferably into the gluteal muscles, since this appears to give better absorption (Cole, Farmer and Miskjian, 1926; Gruhzit, Tendick and Sultzaberger, 1927). In making the injection, "the needle should be inserted in the upper and the outer third of the buttocks, deep down into the muscular tissue; with the syringe tip inserted into the needle, the physician should aspirate back with the plunger of the syringe in order to be sure that the needle is not in a vein or in an artery. This will go far toward obviating many of the distressing venous emboli and arterial emboli that have been reported" (N.N.R.). The dosage is usually adjusted between 80 and 100 mg. of Bi per week, administered as a single weekly injection, with the suspensions and oil solutions; and divided into two or three injections for the watery solutions, to avoid excessive irritation. The injections are continued for six to ten weeks, unless stomatitis or other toxic effects appear. The bismuth is then intermitted for a month (or alternated with arsphenamine) before the course is repeated; this is especially necessary for the oil suspensions. *Intravenous injection* is practically precluded even for soluble bismuth compounds, since they tend to flocculate. Injection into the subcutaneous areolar tissue tends to form abscesses. *Oral administration* is ineffective except with sobisminol.

The *choice of the bismuth preparation* involves efficiency, local irritation and convenience. The close correlation of toxic and therapeutic action on intramuscular injection indicates that the potency in both respects is determined by the concentration of bismuth and not by the nature of the original compound (Longley, Clausen and Tatum, 1942). The potency can therefore be judged approximately by the *rate of absorption*, and this by the level of urinary excretion. Any preparation which maintains a urinary excretion level of 2 to 4 mg. of bismuth per day is potentially effective; levels materially above are potentially deterimental, depending upon how long they are continued. Temporary peaks of 10 to 15 mg. are apparently harmless. *Watery solutions*, such as sodium bismuth tartrate, iodobismitol or sobisminol and especially thiobismol, attain the effective levels most promptly, but decline so rapidly that they must be injected two or three times a week, which is painful and inconvenient. Oil suspensions of bismuth salicylate or sodium potassium bismuth tartrate reach the effective level slowly, generally by the cumulation of successive weekly injections which establish multiple absorption depots; but the effect is sustained correspondingly longer, and the weekly spacing is more convenient. Oily solutions are intermediate and should be injected every five to seven days (H. N. Cole, Sollmann, Henderson *et al.*, 1939). It is possible to combine the advantages and to avoid the disadvantages of the watery solutions and oil suspensions by administering a graded sequence of watery solutions(three injections in the first week, two in the second, one in the third, none after) during the early weeks of the suspension injections (Sollmann, Cole and Henderson, 1938).

Oral administration of sobisminol avoids the pain and inconvenience of the injections, and it can be made quite effective, but requires close supervision, including approximate estimation of the excretion level. A clinical method for this has been devised by Hanzlik, Lehman *et al.*, 1937.

The treatment of syphilis by oral administration of sobisminol was reviewed by the Council on Pharmacy and Chemistry, 1939, J.A.M.A., *113:* 2235. It is effective in patients as well as in rabbits, clearing the lesions about as rapidly as with intramuscular injections. Gastrointestinal upset is a frequent side action, sometimes so severe as to preclude its use. Stomatitis occurs occasionally. The *Sobisminol Mass* used for this medication is a complex organic bismuth product obtained by the interaction of sodium bismuthate, triisopropylamine and propylene glycol. It is marketed in capsules containing the equivalent of 150 mg. of bismuth. The adult dose is 2 or 3 capsules three times daily; a "course" extends over ten to twelve weeks.

Local Irritation and Pain.—The interaction of bismuth compounds with the tissues generally results in irritation and pain. Since the reaction is slow, the immediate pain is chiefly that of the trauma, even with the soluble preparations. It can be obviated by injecting a few drops of 1 per cent procaine solution. As the reaction proceeds, with the soluble preparations generally on the second day, somewhat later with the insoluble, there is more or less coagulation of the muscle fibers, edema, leukocytic infiltration and circumscribed necrosis (Gruhzit, 1929), with swelling, induration and pain, which may last for some days. The pain ranges from negligible to such severity that it has greatly restricted the use of the watery solutions. It varies not only with the sensitiveness of the individual, but also in the same person, according to the region involved and the spreading and the dosage of the injection. The smaller volume of concentrated solutions is an advantage. The addition of sugar diminishes the pain somewhat, perhaps because the viscosity hinders spreading. However, there is little difference practically between the various water-soluble preparations except that the rapidly absorbed thioglycollate (thiobismol) produces markedly less irritation, sensory or histologic (Gruhzit). With suspensions, the local changes may be more intense, but they develop so slowly, and are so much more circumscribed, especially with oil suspensions, that the discomfort is generally slight. Watery suspensions spread more freely and therefore are more painful; with the hydroxide, the irritation increases with the fineness of the particles, which promotes their solution (Lomholt, 1928). The reactions to the oil solutions have not been adequately studied, but the irritation is relatively slight.

Absorption, Distribution and Excretion of Injected Bismuth.—Success with bismuth requires the prolonged maintenance of maximal nontoxic concentrations of the active substance. The technic has been worked out chiefly by empiric trial, checked by studies of the absorption, distribution and excretion, clinically and in animals. *Studies on animals* should not be transferred too directly to the clinic, because of the differences in dosage as well as in the mineral metabolism; but when used with discrimination they lead broadly to the same conclusions. The absorption may be studied at the site of the injections, roughly by roentgen pictures and dissection, more accurately by the chemical determination of the remaining bismuth; and indirectly by the analysis of the excreta. The latter has the advantage that it can be done accurately *on patients;* and while it is not an absolute index of absorption, it reflects the concentration of actively circulating bismuth, which is of much greater practical, therapeutic and toxicologic importance than the fraction of bismuth which has been fixed in the tissues, for as with mercury, the patient relapses as soon as the excretable metal falls, and while considerable quantities are still unexcreted. Since there must be an equilibrium of diffusible bismuth between the tissues, the blood and the urine, the magnitude of the *urinary excretion* is determined directly by the concentration in the body. The few existing analyses of the blood indicate that the concentration of its bismuth is of a similar order of magnitude as that of the urine. The volume of the urine and the permeability of the kidneys doubtless have some effect on the excretion, but this appears of minor importance, altering only the detail, and not the general direction of the correspondence. The *fecal excretion* is variable and much smaller, generally less than a tenth of the urinary bismuth, but it follows the same direction.

The level of bismuth in the blood of patients receiving therapeutic intramuscular injections of water-soluble bismuth potassium saccharate attains 5 to 7 gamma per 100 cc. during cumulative administration. It goes fairly parallel to the daily urinary excretion; each gamma per day of urinary bismuth generally corresponds to approximately one gamma per 100 cc. of blood (M. H. Delp, Walker and Sondern, 1943).

The absorption of bismuth from intramuscular injection starts promptly and slows progressively, with considerable differences in the speed, duration and completeness for the various compounds. They depend chiefly on the solubility of the original compound or of its reaction products in the presence of tissue fluids; on the absorbing area, and therefore on the spreading of the injections; on the number and frequency of the injections; and on the dosage of bismuth. These differences determine both the systemic effects and the local actions, and therefore the clinical usefulness. The *solubility* is perhaps of the first importance in the speed and completeness of the absorption; however, the clinical solubility is not merely that in water, for *insoluble bismuth compounds* are gradually converted into soluble products, especially by interaction with the proteins, so that all bismuth compounds are "tissue soluble." The oily suspensions delay these reactions by restricting the contact; they are therefore liable to become encapsulated before absorption is completed. On the other hand, the *water-soluble compounds* tend to precipitate more or less rapidly on contact with the tissues, and then behave like the "insoluble" compounds.

Observations in the test tube and in the living eye (injection into the anterior chamber) show that the *precipitation* of the tartrate begins immediately, as it reacts with the *p*H and many ions of the tissue fluids; a part, however, remains in solution, so that the absorption is prompt as well as prolonged. The citrate is not precipitated by serum *in vitro;* in the eye also it does not precipitate immediately, but only after some hours, presumably by the dissociation of the sodium citrate through diffusion (von Oettingen, 1931). The sodium bismuth thioglycollate, because of its rapid absorption, appears least subject to precipitation in the tissues (Gruhzit, 1929).

Oily suspensions of water-soluble compounds are absorbed more slowly than their watery solutions, but more rapidly than insoluble compounds. The *oil solutions* have not been adequately studied as to their physicochemical reactions; but their absorption appears in general as good as or better than that of the watery solutions, slightly slower, but considerably more prolonged. The *absorbing area* depends on the spreading and on the number of the injections. Roentgen and anatomic studies (von Oettingen, Todd and Sollmann, 1927) show that the watery solutions spread in a thin sheet along the intermuscular fasciae, giving a large surface favorable to absorption and unfavorable to encapsulation. Oily solutions would probably spread in a similar manner. Suspensions, because of their viscosity, remain in large part in and near the track of the needle, offering a small surface and favoring encapsulation by local fibrosis (Mueller, 1922). With oily suspensions, diffusion is also hindered by the film of oil, until this is gradually broken down by the saponification and oxidation of fat. Mineral oils which do not undergo these changes allow the least absorption.

Repeated Injections.—The concentration of bismuth can be maintained at the effective level by repeated administrations, or by the establishment of depots of difficultly soluble bismuth for gradual mobilization. Both factors enter into the clinical use of all bismuth preparations, since the soluble compounds, with the possible exception of the thioglycollate, form precipitation depots; so that weekly injections suffice to maintain the concentration. Repetition of the injections does not merely replenish the concentration, however, but results in marked progressive increase in the concentration, as reflected in the excretion level, almost proportional to the number of injections; *i. e.*, after ten injections, the weekly excretion level would be over five times as high as after a single injection. This holds for all the compounds, and may be attributed to the increased absorption area. The repetition of the injections therefore amounts not merely to prolongation, but to intensification of the dosage and action.

The thinning of the *roentgenographic* shadow at the site of the injections does not distinguish sharply between absorption and spreading. It is therefore especially unreliable for aqueous solutions; but even with the suspensions, it is difficult for comparisons. For instance, in the clinical studies, quoted in von Oettingen's review, the shadow of the tartrate-oil injections had disappeared with some patients in a week, in others not even in seven months; with some salicylate-oil injections, the shadow was gone within a month, with others it was still present after a year.

Chemical analysis of the site of the injection gives quantitative data, but sacrifices the animals with one determination, so that the further course of the absorption cannot be followed. However, it permits comparison of different compounds. Using dogs (which seem more suitable than rabbits for this purpose), generally forty-eight hours after intramuscular injection of the full clinical dosage, the ranking of the various bismuth preparations correlates well with that of the clinical excretion studies, with few exceptions. Bismuth thioglycollate is practically completely absorbed in two hours; the others are incompletely absorbed at this time, 30 to 80 per cent for watery and oil solutions, 20 to 22 per cent for suspensions. The absorption proceeds actively for more than three hours, and much more slowly after eighteen hours, when there is still considerable unabsorbed. If the compounds are arranged in the order of absorbability (the reciprocal of the amount unabsorbed at forty-eight hours), thiobismol stands alone in the highest rank; other watery solutions are in the second and third rank; oil solutions in the second, third and fourth ranks, and oil suspensions are all in the fourth or lowest rank. Increase of dosage increases the amount of bismuth absorbed, but the percentage absorbed is not materially altered by doubling the dosage (Sollmann and Henderson, 1938).

The clinical urinary excretion, which reflects the level of the therapeutic effect, has been studied especially by Lomholt, by Hanzlik and his associates, and by Sollmann, Cole and Henderson, for its general course and for the comparison of the various bismuth preparations. The studies have given concordant results, although the details vary according to the difference in the administration. In general, with the ordinary clinical dosage, the urinary excretion reaches 2 to 8 mg. on the peak day; the weekly excretion ranges between 4 and 40 mg.; the total urinary excretion is between 15 and 50 per cent of the amount injected; the fecal excretion is 0.6 to 4.5 per cent of the injection, except for iodobismitol (to 18 per cent) and thiobismol (to 35 per cent); between one-third and nine-tenths of the injected bismuth is retained at the site of the injection and in the organs.

Single injections give the simplest picture of the *excretion curve;* repeated injections differ only by starting from progressively higher levels with succeeding injections. The excretion begins promptly, but varies in steepness of ascent, according to the absorption velocity. The thioglycollate stands at one extreme, with rapid ascent and descent of the curve; the subsalicylate at the other, with slow rise and prolonged descent. The other preparations are intermediate, with the watery solutions nearest to the thioglycollate, and the oil solutions somewhat nearer the suspensions. There is considerable overlapping, however, and the differences between individual patients are often greater than the differences between preparations. In general, the *peak* is sharp with the watery solutions, and is attained on the first to third day; with the oil solutions it is reached about the fifth to tenth day; suspensions do not have a sharp peak, but reach their maximum about the twelfth day after the injection.

The *steepness of the descent* decreases with the duration of the absorption. Since it forms a logarithmic curve without sharp end point, the rapidity of the descent may be compared by the time when it has fallen to half of the peak level. For a given preparation, this is reached in practically the same period from a high and from a low level, whether the injection was single or multiple; with watery preparations, about the second day after the last injection; with oil solutions, about the fifth day; with suspensions, about the tenth day. The *percentage* of the injected amount of bismuth excreted in a given time is a fairly constant characteristic of each preparation, largely independent of the amount injected, whether one or multiple injections, depending largely upon the rate of the absorption, varying therefore somewhat for each patient. With the clinical dosage, at the end of three weeks, the urinary excretion amounts to nearly 50 per cent of the injection for iodobismitol, 15 to 30 per cent for other watery solutions, oil solutions and tartrate suspension, and about 5 per cent for salicylate suspension. *The total amount of bismuth retained* at the end of three weeks of clinical injections (subtracting the urinary and fecal excretion from the total quantity injected) amounts to 73–258 mg. of bismuth, median about 180 mg., for all preparations, the grouping being rather immaterial.

The *amount excreted* depends upon the absorbability of the preparation and upon the amount injected at one time and in the entire course. The level reached at the peak represents intensity of action; the weekly or total excretion shows sustained action. Both are probably concerned in the therapeutic effect, and clinical data are not yet sufficient to decide which is the better index. The rapid absorption of the thioglycollate gives it a unique position, reaching the highest peak of about 0.85 mg. of Bi per hour, three hours after intramuscular injection corresponding to 75 mg. of bismuth, but only for a short time. To sustain such a level would presumably soon become dangerous. For the other preparations, the *peak excretion* may be figured for twenty-four hours. In the third week of treatment with the ordinary clinical dosage they run about 6 mg. for the watery solutions; 2 to 6 mg. for oil solutions; 3 to 3.5 for tartrate suspension; and about 1.2 for salicylate suspension. *Continued action* is perhaps best reflected in the average daily urinary excretion of the third week, which is near the middle of the course, and therefore presents an approximate average of the whole. For the clinical dosage, this amounts to 5 to 5.5 mg. for watery solutions, 2.5 to 3.5 for oil solutions, 1.5 to 2.5 for tartrate suspension and about 0.7 for salicylate.

Late Bismuth Excretion.—When the injections of bismuth cease, the daily excretion descends as a parabolic curve, which is steeper for high than for low excretion levels. When it reaches 1 mg. per day, it has become practically horizontal, and continues about this level indefinitely, at least over half a year, through the gradual remobilization of bismuth that had been deposited in the tissues (Sollmann, Cole and Henderson, 1937). This has no therapeutic effect.

The *fecal excretion* of bismuth constitutes a relatively small proportion of the total excretion, 4 to 10 per cent with oil solutions, 6 to 22 per cent with watery solutions, 12 per cent with oil suspensions. With thiobismol, however, it averages 56 per cent of the total excretion. Its relation to the blood concentration is less direct than the urinary (Sollmann, Cole and Henderson, 1937).

An unusually large but nonfatal dose of bismuth salicylate (equivalent to 675 mg. of bismuth, nine times the ordinary amount, by a single intramuscular injection) was followed by the urinary excretion of 246 mg. in two weeks; the daily peak was 16 mg. (J. Seifter and McDonald, 1943).

Excretion studies in animals are significant chiefly for toxic doses. *With relatively enormous doses, in rabbits,* Leonard, 1926, recovered 2 to 10 per cent from the urine when death occurred within a week, and up to 33 per cent within two weeks. These severe intoxications, which include marked nephritis, have little relation to the clinical conditions. These limitations apply also to the studies of Gruhzit *et al.* on dogs. The latter, however indicate that the fecal excretion in such dogs is considerably higher than under clinical conditions. According to the Thiry fistula experiments of Bargen, Osterberg and Mann, 1929, considerable bismuth is excreted directly into the colon of dogs, after intravenous injection of the sodium citrate.

The *absorption and excretion with oral administration* of most bismuth preparations is too small and uncertain for syphilis therapy. However, *sobisminol*, a soluble preparation derived from sodium bismuthate, is absorbed more liberally, promptly and with fair uniformity (Hanzlik *et al.*, 1936, 1937; confirmed by Sollmann, Cole and Henderson, 1937) so as to give urinary excretion curves resembling closely those of intramuscular injections of watery and oil solutions, in degree and in course, and to produce equally satisfactory therapeutic results. The dosage, however, must be considerably higher (420 mg. of Bi daily), as only a fraction is absorbed, the urinary excretion amounting to about one-half per cent of the quantity administered.

Rectal absorption of bismuth was claimed for a bismuth salt of heptadiene carboxylic acid (diallyl acetic acid); but no bismuth was found in the organs of patients who died as a result of the suppositories, death being due apparently to the hydrocarbon (J.A.M.A., 1947, *133;*962).

The **organ distribution of the retained bismuth** in autopsies from patients who underwent clinical treatment, and in dogs sacrificed forty-eight hours after intramuscular injection of clinical doses, is much like that of other metals, with a still greater predilection for the kidneys. The liver ranks next, but at some distance; it contains relatively more with chronic than with acute administration. The chief factor in the bismuth concentration in clinical cases is the total dosage. About half of the retained bismuth is excreted in the first three weeks after the administration is stopped. The remainder is retained tenaciously. These factors affect all organs similarly, and the distribution of the different preparations appears identical. Newborn infants whose mother had been treated show the same concentration as adults, so that the bismuth passes freely across the placental circulation (Sollmann, Cole and Henderson, 1938). Passage into the amniotic fluid had been reported by Kraul and Bodmer, 1926. Leonard and Love, 1928, found the distribution in the fetus similar to that in the adult. Bismuth is also excreted into the milk, but in lower concentration than in the urine (Cordaro, 1934; von Kennel, 1931).

The clinical series of Sollmann, Cole and Henderson comprised twenty-two patients who had received courses of bismuth, generally the salicylate, and three newborn infants of such patients. The median concentrations, as mg. of Bi in 100 Gm. of undried tissue were (in descending sequence): kidneys, 3.33; liver, 0.68; bile, 0.39; spleen, 0.155; ileum, 0.118; colon, 0.115; lungs, 0.085; jejunum, 0.083; brain, 0.06; blood, 0.05. If the total amount or bismuth administered is materially greater or less thay 750 mg., the average content varies in simple proportion. Dosage and time affect the storage similarly in all the viscera, including the blood. Some individual data differ considerably from the median, often without apparent reason. The *total amount of bismuth stored* in the body was calculated as 4 to 770 mg., median 82 mg., about 7.4 per cent of the amount administered. The liver and kidney each contained about a ninth of the total. The metal concentrations of the organs in clinical *poisoning by mercury and lead*, acute or chronic, fell within the range of the bismuth concentrations; the medians are about a third lower for chronic mercury and lead poisoning and three or four times higher for acute. The kidney ranks conspicuously highest for bismuth and mercury concentration, not especially high for lead. The liver ranks highest for lead, second for mercury and bismuth, but the latter at a considerably lower level. The spleen has its highest concentration in acute lead, next in acute mercury. The intestines are lower than the spleen and the lungs rank relatively low in all. The brain is generally of the same order of magnitude as the lung and a fifth to three-fourths higher than the blood, which is relatively low in all.

Distribution studies on animals permit changing the experimental conditions, particularly to compare different preparations. It was found, however, that the distribution of various types of preparations is similar forty-eight hours after the clinical doses have been injected into dogs. This holds for the oil-soluble as well as for the water-soluble compounds, and for the brain as well as other organs. Although these experiments were much shorter than the clinical administration, the bismuth concentration in the various organs fell within the range observed in the human patients and ranked in the same order, with the notable exception of the liver, which averaged distinctly higher, approaching the kidney concentration, indicating that the liver bismuth accumulates slowly. The retention by the tissues was found relatively more efficient for smaller than for larger quantities of absorbed bismuth. The total quantities retained in the tissues under these conditions (forty-eight hours after injection) was calculated as nearly two-thirds of the quantity actually absorbed from the injections (Sollmann and Henderson, 1938).

With intravenous injections, the bismuth leaves the blood rapidly, following a parabolic curve. The kidneys and lungs store it more rapidly than the liver and spleen (Sollmann and Seifter, 1941). With flocculating preparations, relatively larger quantities are retained in the reticulo-endothelial system, liver, spleen and lungs (E. Frankel, 1923).

The published data on the *distribution after toxic doses* are reviewed by Forst, 1935, in Heffter's Handbuch der exper. Pharmakol., Vol. 3, part 4. *The bismuth concen-*

tration of the brain and cerebrospinal fluid has been especially investigated with a view to the treatment of neurosyphilis. The brains of animals have not shown any distinctive differences for the various preparations (Sollmann and Henderson, 1938), and the available analytical methods are not reliable for the small quantities found in amounts of cerebrospinal fluid that can be collected.

Bone.—It is doubtful whether bismuth is concentrated in trabecular bone analogous to lead. Anatomical changes in bone have been described as the result of bismuth injections in children and in puppies (Caffey, 1937), and osteoporosis has been reported in adults (Racouchot, 1939). These need not be due to bismuth concentration, but may be more analogous to the bone changes produced by arsenic. Similar changes have been reported in the long bones of fetus if the mother received bismuth injections during the time of her pregnancy (J. Whitridge, 1940).

Tumor tissue was reported to show selective deposition of bismuth, and it was suggested to use the bismuth isotope, Radium E, to localize radiation in the tumors (Zadik, 1931).

Precipitation of Bismuth Sulfide.—Bismuth forms a black and insoluble sulfide. Since H_2S is always present in the large intestine, the feces are colored black when absorbed bismuth is circulating in the blood; this precipitation also occurs in and around the capillaries in situations in which hydrogen sulfide is formed by putrefactive processes. The black blotches are characteristic around the alveolar margin of the gums ("bismuth line") and the adjacent mucosa and tongue (Warfield, 1912); in the colon, rectum, cecum and appendix (none in the small intestines); in the urinary bladder if this is infected with coli; rarely in the reticular layer of the skin (Lueth, Sutton *et al.*, 1936). It gives rise to some stomatitis; and in severe poisoning to capillary embolism and ulceration of the large intestine, with the clinical symptoms of vomiting, diarrhea, cramps, colic and colitis—the latter rarely as severe as with mercury (Cabot, 1912). Bismuth has been demonstrated spectrographically in the gum margin (R. Probst, 1932).

M. Wachstein and Zak, 1946, found bismuth discoloration of the colon in about 1 per cent of consecutive routine autopsies.

The form in which bismuth is present in the tissues is imperfectly known. The serum bismuth appears united with the protein, since it can be salted out with all the fractions and does not pass ultrafilters (Lomholt's review, p. 243); but formation of bismuth sulfide deposits indicates that it is ionized. That stored in the tissues is largely nonionized, for histochemical methods fail when destructive methods show considerable bismuth (Levaditi and others). The *histologic demonstration of bismuth* in organs is discussed by H. Brabant, 1941; Castel's method, 1936, is described by Wachstein and Zak, 1946. Renal cells contain refractile granules which give equivocal bismuth tests (Pappenheimer and Maeckling, 1934). Levaditi and Nicolau, 1924, assumed the formation of a hypothetical "*bismoxyl*" because the toxicity of bismuth for trypanosome and spirillosis cultures appeared increased by incubation of bismuth with extracts of organs (especially those rich in glutathione, Levaditi and Howard, 1929; not with serum). Fournier *et al.*, 1929, attempted to apply the idea clinically, but the observations seem to lack adequate confirmation.

Diuretic Action.—Clinical injections of bismuth tend to produce some diuretic effect, analogous to mercury, but generally not so extensive (Mehrtens and Hanzlík, 1928; Hanzlik, Bloomfield *et al.*, 1929). This is also seen in dogs, with injection of 1 to 4 mg. of bismuth ammonium citrate per Kg. (Kisch, 1934).

Toxic Effects.—Because of the limited gastro-intestinal absorption, oral administration does not lead to toxic bismuth effects, even if continued over long periods. Large doses of the subnitrate, however, may give rise to nitrite poisoning. Serious and sometimes fatal poisoning, presenting the features of subacute or chronic arsenic, mercury and lead intoxication, may occur with the injection of large doses into closed cavities, and with extensive application to burns. The literature was reviewed by J. Phillips, 1917. With the gradual dosage of intramuscular injection in syphilis therapy, serious phenomena are rare, if the administration is stopped with the first warning symptoms. In animals, functional and histologic renal injury requires doses equivalent to more than nine times those used in human therapy (H. Brown, Saleeby and Schamberg, 1926). The therapeutic dosage may produce foul breath, *black "lead line"* at the alveolar margin and sometimes black spots on the buccal mucosa and throat; and annoying but not serious *stomatitis.* These phenomena usually occur when the total dosage reaches 2 to 2.5 Gm., but occasionally even with 0.5 Gm. The gum line is said to be present in practically all patients who have had six or more injections (J. E. Moore). Salivation is relatively less than with mercurial stomatitis. The administration should be stopped when gingivitis appears. A blue gum line is not a contraindication. The black discoloration generally fades in two to three months. Blue generalized *discoloration of the skin* resembling argyria has been described, but is rare.

If the warning is not heeded and the bismuth is continued, serious ulcerative stomatitis is likely to result, and other toxic effects develop: *malaise* (nausea, loss of appetite, loss of weight, headache, sleeplessness, depression, asthenia, joint pains); *diarrhea; albuminuria; skin reactions* (pruritus, herpes zoster, purpura); sometimes serious exfoliative dermatitis and rarely *jaundice. Conjunctival hemorrhage* is a rare sequel of bismuth injection (E. L. Cohen, 1945). The mouth, digestion, skin and urine should be watched, and the bismuth stopped with the first sign of disturbance. These precautions render bismuth treatment practically safe. Oral hygiene should be prescribed, to prevent undue stomatitis. In any case, the stomatitis is usually less severe than that of mercury, the cutaneous eruptions are more rare than with arsphenamine, and milder and renal irritation (albuminuria) is less frequent than with mercurials. If bismuth symptoms develop with *Beck's paste*, this should be removed with warm olive oil, curetting if necessary (Zollinger, 1912).

In a series of 2750 patients who had received courses of bismuth injections, recorded by Brittingham, 1933, thirty developed stomatitis, three watery diarrhea and two renal symptoms. *Jaundice* is rare; the patients recorded by Nomland *et al.*, 1938, all recovered and were subsequently again treated with bismuth, without harm. *Fatalities* recorded in the literature (Beerman, 1932) comprise six acute deaths from intravenous injections, and seventeen delayed deaths in which the share of bismuth is somewhat doubtful.

The *toxicity for rabbits* was investigated by Sazerac and Levaditi, 1921. Intravenous injection proved fatal in a few days with the dosage of 5 mg. of the potassium bismuth tartrate per Kg., but with intramuscular injection 60 mg. per Kg. was well tolerated, 100 mg. was toxic and 200 mg. was fatal in four days. The histologic lesions involve mainly epithelial degeneration of the convoluted tubules of the kidneys and cloudy swelling of the liver cells Lucke and Klauder, 1923). The toxicity and urinary elimination of various bismuth preparations was studied by C. L. Leonard, 1926, and the toxicity for rabbits by Raiziss *et al.*, 1934. The *speed of intravenous injection* influences the fatality; slow injections nearly double the tolerated dose. Acute deaths present the phenomena of flocculation; delayed deaths those of uremia, without cerebral symptoms (Sollmann and Seifter, 1941). Slow-drip injections are about twice as toxic to rabbits infected with syphilis. This is apparently related to the lower ascorbic acid content of their blood. The largest doses that were survived were ineffective against the syphilis (F. P. Ludueña, 1943). The prompt fall of blood pressure by the intravenous injection of soluble bismuth salts was described by Meyer and Steinfeld, 1885, who considered it analogous to that of arsenic. In contrast to this, however, the bismuth fall is generally followed by prompt recovery, if it is not immediately fatal. It closely resembles the fall produced by other flocculating agents, including most metals. According to G. A. Masson, 1926, it is chiefly cardiac, owing to disturbed conduction and heart block, which may also be produced in perfused hearts.

Trimethyl Bismuth $Bi(CH_3)_3$, volatilizes readily and oxidizes easily to bismuth oxide. It is a very active poison when administered by inhalation, or orally, or through the intact skin. It produces inflammatory reactions (vasodilatation, edema, extravasation, necrosis and ulceration) on local application to the skin and mucous membranes; and after absorption or parenteral administration, in the lungs, gastro-intestinal tract and kidneys. It has little or no effect on nonvascular structures, such as the cornea. These characteristics resemble those of arsenic, and it also causes a similar gradual fall of *blood pressure*. Acutely fatal doses paralyze the cerebral centers, partly at least by aliphatic narcosis. Repeated administration of sub-lethal doses leads to marked *encephalopathy* resembling lead poisoning. Very dilute solutions depress excised smooth muscle and the excised heart. Even saturated solutions have little effect on skeletal muscle and motor nerves and endings. The kidneys in acute poisoning contain relatively less bismuth than with ordinary bismuth compounds. *Triethyl bismuth* resembles the trimethyl in all respects but is unmanageable because it is spontaneously inflammable (Sollmann and Seifter, 1939).

Bismuth Compounds Used in Syphilis Therapy.—Practically all the numerous compounds introduced for this purpose are effective when properly administered (in courses of ten weeks, alternating with arsphenamines). The practical differences are in the rapidity of absorption, which governs the frequency of administration and tendency of cumulative effects, which in turn depends on the solubility of the compounds and the medium in which they are administered. This brings them under the following groups:

Aqueous solutions of anionic bismuth salts of complex composition. The solvent may contain sugars, glycerin or glycols. They must be administered about twice weekly, in doses corresponding to about 33 mg. of Bi per injection. Sodium bismuth thioglycollate, *thiobismol*, is by far the most quickly absorbed and the most quickly excreted (Gruhzit *et al.*). *Sobisminol* (sodium bismuthate derivative) probably ranks next in absorbability, but at some distance. It is also active by oral administration, in capsules, but this requires much larger doses (Hanzlik *et al.*, 1937, 1938, 1939; report, Council on Pharmacy and Chemistry, 1939, J.A.M.A., *113:* 2235). Iodobismitol (sodium iodobismuthite) has about the same rank for intramuscular injection, but is not suitable for oral administration (Hanzlik *et al.*, 1932; Gurchot *et al.*, 1932; C. C. Johnson *et al.*, 1932). *Potassium bismuth tartrate* is marketed as a solution in 40 per cent sucrose. *Sodium bismuth citrate* was investigated extensively by Sollmann *et al.*, but was deemed to cause too much local induration. *Oily solutions* include basic bismuth salts of certain large-molecule organic acids (biliposol, bismo-cymol) and quinobine, an oil-lecithin solution of bismuth iodoquinate. These are injected every fifth to seventh day. *Oil suspensions of water-soluble compounds*, especially the potassium bismuth tartrate, may be injected every three to seven days, in doses of 0.1 to 0.2 Gm. Settling of suspensions may cause considerable inexactness of dosage (Cole *et al.*, 1931). *Oil suspensions of insoluble (or sparingly soluble) compounds*, bismuth salicylate (subsalicylate), iodoquinate (quinby), benzoate and oleate and metallic bismuth. The salicylate is used extensively for sustained effects; they are mild at first, but become cumulative. It is injected weekly, generally 0.13 Gm., which attains a urinary excretion of 1 mg. per day in about three weeks. By using 0.26 Gm., a urinary level of 2 mg. per day is attained in one week (Sollmann, Cole and Henderson, 1938). *Watery suspensions of insoluble compounds*, hydroxide (Lomholt's magma), metallic bismuth (neotrepol), and semicolloidal bismuth (bismol). These are rarely employed in this country.

PREPARATIONS.—Bismuth compounds are generally *incompatible* with mercuric chloride, tannic acid, iodides and sulfur.

***Bismuth Potassium Tartrate,** U.S.P.; a basic bismuth potassium bismuthotartrate, containing about 61 per cent of bismuth. Granular white powder, freely soluble in water (1:2). Dose, 0.1 Gm., intramuscularly. *Bismuth and Potassium Tartrate Injection*, U.S.P., may be prescribed either as *Aqueous Solution*, 30 and 60 mg. in 2 cc., or *Oil Suspension*, 100 and 200 mg. in 2 cc.

***Bismuth Subcarbonate,** U.S.P. (Bismuth Oxycarbonate), yields not less than 90 per cent of Bi_2O_3. White powder; odorless and tasteless. Insol. in water or alc. Dose, 1 Gm., 15 grains; in powders or suspension. *Bismuth Subnitrate*, U.S.P., has similar properties. *Bismuth Subgallate* (Dermatol), yielding not less than 52 per cent of Bi_2O_3, is an amorphous, bright yellow powder, odorless and tasteless. Insol. in water or alc.

***Bismuth Subsalicylate,** U.S.P., yields about 64 per cent of Bi_2O_3. A white or nearly white, amorphous or crystalline powder; almost insol. in cold water. Dose, gastro-intestinal, 1 Gm., 15 grains; anti-syphilitic, 0.125 Gm., 2 grains, by intramuscular injection of 10 per cent suspension in oil. *Bismuth Subsalicylate Injection*, U.S.P., in oil; usual sizes, 100 mg. and 120 mg. in 1 cc.

Iodobismitol with Benzocaine, N.N.R., a solution of sodium iodobismuthite, N.N.R. *Dose*, 2 cc. (containing 25 mg. of bismuth), intramuscularly every three days for 16 to 20 injections.

Sobisminol Mass, N.N.R., a complex product obtained by the interaction of sodium bismuthate, tripropanolamine and propylene glycol. Marketed as capsules of 0.75 Gm. containing 150 mg. of bismuth. *Dose*, two or three capsules three times daily for ten to twelve weeks. *Sobisminol Solution* contains about 20 mg. of bismuth per cc., dissolved in a mixture of propylene glycol and water. *Dose*, 2 cc. twice a week, intramuscularly.

Thio-Bismol, N.N.R., sodium bismuth thioglycollate, chiefly Bi $(SCH_2CO_2Na)_3$, containing about 38 per cent of bismuth. A yellow granular substance, freely soluble in water, but solutions are unstable. Marketed in ampuls of 0.2 Gm. Dose, 0.2 Gm. intramuscularly three times per week for twelve to fifteen doses. A single injection arrests therapeutic malaria temporarily.

◆

IRON

Iron occurs widely distributed in the body, in several more or less firm and nonionizable combinations. It is found in all chromatin and therefore in all cells; in hemoglobin of the blood; and in granular form as "reserve iron" in the blood-forming and destroying organs. It is important chiefly in relation to blood formation. When administered to normal animals, it has no systemic action, but increases the "reserve iron." In most anemias, the administration of iron tends to restore the hemoglobin to the normal and therefore improves nutrition. The soluble ionizable salts exert local astringent effects.

Direct systemic actions may be secured by the intravenous or hypodermic injection of nonprecipitating salts, or by the absorption of corrosive preparations. The effects resemble those of arsenic (H. Meyer and Williams, 1881; Jacobj, 1887). Toxic effects occur with 60 mg. per kilogram, hypodermically or by vein, but not with therapeutic hypodermic doses (Lépine, 1897). E. J. Stieglitz, 1921, found that injected iron is deposited party in the kidneys, and that this is midly nephrotoxic. The *intravenous toxicity* is due largely to flocculation. The double salts are not directly precipitant, and therefore are much less toxic than the simple salts (Sabbatini, 1926). Even ferric chloride, however, can be injected by vein without harm, if it is diluted to 0.25 per cent. In rabbits infected with tuberculosis, it accumulates in the *tuberculous tissue* and appears to retard the progress of the disease. Menkin, 1937, injected 20 to 30 cc. of a 0.0625 per cent solution in isotonic saline, two or three times a week, for over a hundred injections into patients with advanced tuberculosis, without untoward systemic effects, although there was sometimes temporary local thickening of the vein.

Intravenous injection of calcium salts protects mice against intravenous fatality of iron salts, but fails in rats and rabbits (E. Rothlin and Schalch, 1946).

Astringent Action and Uses.—The soluble salts, especially the ferric, precipitate proteins readily and are therefore styptic, astringent, irritant and even corrosive. The Tincture of Ferric Chloride is employed as an astringent, especially in gargles (1:10), but discolors and corrodes the teeth. This and other iron salts, particularly the Iron Subsulfate Solution, are used as local styptics for capillary bleeding; but the efficiency of coagulant astringents in hemorrhage is low, even under favorable experimental conditions (Hanzlik, 1918), and they are likely to devitalize the wound and impede repair. In *ringworm*, Garrett, 1913, recommended painting the scalp with undiluted Ferric Chloride Solution.

In the alimentary tract the local actions of iron salts may produce some gastric irritation, usually mild, and sometimes diarrhea or constipation. The stools turn black through the formation of iron sulfide.

Large Doses on Phosphate Metabolism.—Continued feeding with large doses of ferric salts (as also of alum) to guinea pigs or rabbits precipitates the alimentary phosphate in the digestive tract and prevents its absorption, and thus lowers the blood phosphate (to 15 per cent of the normal) and reduces the ash calcium and phosphorus of the bones; the urinary excretion of phosphate almost ceases. These effects can be prevented by adding an excess of phosphate to the diet (G. J. Cox *et al.*, 1931). Similarly, 2 per cent of reduced iron, which has no effect when added to the normal diet, produces, when added to a rickets-producing diet, anemia and retardation of growth, and these effects are counteracted by vitamin D (K. Waltner, 1929).

Income and Output of Iron.—The body of an adult man contains about 3 to 3.5 Gm. of iron, of which about 2.4 to 2.7 Gm. are in the form of hemoglobin (mammalian hemoglobin contains 0.34 per cent of iron; blood about 50 mg. per 100 cc; plasma about 0.5 mg. per 100 cc.). On a normal diet, he excretes daily about 20 mg. of iron; even in starvation the excretion averages about 8 mg. (Cetti and Breithaupt, 1893). This is normally replaced by the absorption of iron from the food. The iron content of the ordinary daily American diet may vary between 7 and 35 mg., generally between 11 and 19 mg., 16 mg. being the mean value. This amounts to about 1/200 of the total iron of the body, and is ordinarily about twice the minimum requirement. It is more than sufficient even in otherwise poorly nourished individuals, since vegetable diets are relatively rich in iron and 90 per cent of this is "available," in contrast to less than half for meats. However, the iron income may fall much lower on restricted and "freak" diets; Exclusive "tea and toast" may lower it to 2–5 mg. White bread is poor in iron; cow's milk contains 0.5 mg. per liter, so that it would require 20 liters to supply 10 mg. of iron (Sherman, 1907; extensive bibliography).

Iron Equilibrium.—Various careful investigations concur that this is attained in adult men or women with a minimum dietary income of 5 to 8 mg. (Retznikoff *et al.*, 1934; Farrar and Goldhamer, 1935; Vahlteich *et al.*, 1935). Doubling this income does not create a positive balance, unless an iron debit exists, as in anemia. Otherwise, the excess is merely excreted or not absorbed (McCance and Widdowson, 1938). The loss of iron in menstruation is not sufficient to affect the balance. Pregnancy, however, requires a larger income, 15 to 20 mg. per day (Coons and Coons, 1935). Young children also require more iron, but 0.6 mg. per Kg. per day, equivalent to 40 mg. for adults, should suffice for normal growth and maintenance (M. S. Rose *et al.*, 1930; A. L. Daniels and Wright, 1934).

The *loss in a menstrual period* is from 6.6 to 180 cc. of blood, 0.7 to 23.6 Gm. of hemoglobin, 2.3 to 79 mg. of Fe. The majority, however, range between 20 and 30 cc. of blood, 3 and 6 Gm. of hemoglobin, 10 and 15 mg. of Fe; divided by twenty-eight days this gives ⅓ to ½ mg. of Fe per day, 0.1 to 0.15 Gm. of hemoglobin (L. H. Gilette *et al.*, 1918; Ohlson and Daum, 1935; Vahlteich *et al.*, 1935; Barer and Fowler, 1936).

The *normal hemoglobin level* is maintained for long periods with an iron income of 5 mg. per day (Farrar and Goldhamer, 1935), and only a part of this, perhaps a third, is absorbed and *utilized.* Lintzel's work (1929) suggests that the actual utilization of iron in normal adults may be somewhat less than 1 mg. per day. Large increase of iron income by the administration of ferrous iron, the form best utilized, scarcely alters the hemoglobin of males; that of women in England, which is often somewhat low, is raised by 4 to 17 per cent (Widdowson and McCance, 1936). Healthy young women who for three to eight months consumed controlled diets with a daily iron income of 6.55 mg., averaged a daily retention of 2.14 mg., so that 6.5 mg. is more than adequate: 4.5 mg. led to iron loss (R. M. Leverton, 1941).

The **utilization of iron,** its absorption, storage and conversion into hemoglobin, are closely adapted to the needs of the organism. Income in excess of that needed to maintain normal hemoglobin level is eliminated by the feces without being absorbed, except for a small fraction which is added to the reserve stock of iron laid down loosely bound in granules within the cells, especially of the liver and spleen. If the hemoglobin level is low, however, iron is freely absorbed and is built promptly and directly into hemoglobin. In any case, the absorption appears to occur only as dissolved ionized iron, which can exist only as ferrous iron salts in the duodenum; other iron compounds are changed into this form in digestion, but only in part, so that larger quantities must be taken to secure the same absorption. Reduction and oxidation of iron occur readily and the absorbed iron circulates in the plasma in ionic form, probably ferric. In the organs it is again reduced to ferrous. The synthesis into hemoglobin is a more complicated process.

Historical.—The study of the utilization of iron has been complicated by the fundamental difference between the normal and anemia; by the small quantities involved in the normal utilization; and by theoretical preconceptions of the implications of synthesis of a protein from an inorganic element in the animal organism. The treatment of anemia with iron was practiced in antiquity and probably had a symbolic origin, the patients drinking water in which swords had been allowed to rust, with the idea that the strength of the steel would pass into the patient. However, Celsus (about 25 A.D.) advised to treat enlargement of the spleen by drinking the water in which the glowing iron is drenched in the smithies (and which presumably contains colloidal iron oxides), because, he avers, domestic animals raised about smithies, that drink this water, have abnormally small spleens ("quod animadversum est in his animalibus, quae apud hos fabros educata exiquos lienes habent;" liber IV, Cap. IX). With the discovery of the presence of iron in the blood (Menghinis, 1746), the therapeutic results seemed to be easily explained on the assumption that the iron is absorbed and converted into blood, much as the nitrogen of food is converted into muscle; but when the earlier experiments failed to show absorption of the medicinal iron preparations, some writers became skeptical of the clinical results; others (especially Bunge, 1885) were inclined to attribute them to the local actions of iron in the alimentary canal. There could never be any question that iron is absorbed from food, for the hemoglobin increases with the growth of the animal. The same was conceded for certain organic irons, and Macallum (1894) and Hall (1896) studied their absorption by microchemic methods. The absorption of inorganic iron was also proved, but it was objected that the iron had produced corrosion; when this criticism was found inadequate, it was claimed that inorganic iron, while it is absorbed, cannot be converted into hemoglobin (Abderhalden, 1899), but that it is nevertheless beneficial in anemia, by stimulating the blood-producing organs to a better use of the organic irons. This objection was also found untenable and abandoned (Abderhalden, 1906).

The **absorption of iron** occurs mainly from the duodenum, but somewhat also, in decreasing order, from the succeeding portions of the intestine. A part generally escapes absorption and is eliminated by the feces. The part which is absorbed passes into the intestinal epithelium in a dissolved condition, and then directly into the capillaries, not by way of the lymph (C. V. Moore *et al.*, 1939). With anemic dogs, radioactive iron appears in the red corpuscles a few hours after oral administration (P. F. Hahn, Bale *et al.*, 1939). In the meantime, it passes presumably into the maturing cells of the bone marrow.

Radioactive iron furnishes the best means of following the absorption and further fate of administered iron. This is identical for ferrous and ferric salts. In either case, normal dogs with adequate iron store absorb little if any, 0.08 to 0.24 mg.; but dogs rendered anemic by repeated severe hemorrhages absorb 4.1 to 12.7 mg., about fifty times as much as the normal dogs. The iron absorption from the gastro-intestinal tract appears to be controlled by the level of the reserve stock of iron, or more directly, by the level of ferritin in the intestinal cells; and not by the level of hemoglobin.

The increased absorption does not occur when the hemoglobin is lowered by pernicious anemia, hemolytic neoplasms or infectious anemias (P. F. Hahn, 1945). In pregnancy the absorption is high, although the hemoglobin level may be normal; polycythemia has normal absorption (W. M. Balfour *et al.*, 1942). In acute hemorrhage, the increase sets in only when the reserve stock becomes deficient, after twenty-four hours to seven days (Hahn, Ross *et al.*, 1943).

Subcutaneous aseptic (turpentine) abscess decreases the absorption of iron from the digestive tract of anemic dogs from 41 to 4.1 per cent of the ingested dose (Hahn, Bale and Whipple, 1946).

The control of the absorption is situated within the intestinal tract, for the anemic absorption is soon inhibited by oral administration of iron, but not by intravenous injection (G. E. Sheline *et al.*, 1943).

P. F. Hahn, Bale *et al.*, 1943, believe that the intestinal mucosa becomes saturated by the iron that is fed, so as to prevent further absorption until this has been passed on to the reserve stock. They suggest that the blocking of the mucosal cells is through loose combination with iron, perhaps as the "*ferritin*" or "apoferritin" of V. Laufberger, 1937. Feeding with ferrous iron greatly increases the ferritin content of the intestinal mucosa of guinea pigs, and this disappears slowly (S. Granick, 1946).

Ferritin is described as containing up to 23 per cent of iron in protein combination. This is formed in the cells of the intestinal epithelium when their store of ferrous iron is depleted by lowering of the ferrous level of the plasma. Ferric iron is reduced in the body to ferrous, probably by SH groups, ascorbic acid, and perhaps other reducing components of the food (review, S. Garnick, 1946).

About twelve hours are required to remove a single dose of ferrous sulfate or of ferric chloride from the digestive tract, by absorption or evacuation (Austoni and Greenberg, 1940). The peak of the absorption occurs four to eight hours after feeding, when the food is largely in the small intestines; twenty-four hours after the last feeding practically all the unabsorbed isotope has passed into the colon, from which there is practically no absorption (Whipple *et al.*, 1938; P. F. Hahn *et al.*, 1938, 1939). Even under the best conditions, only about a third of the iron is absorbed. Iron absorption in healthy school children is greater than in adults, averaging about 13.5 per cent of radioactive iron (W. J. Darby, Hahn *et al.*, 1946). Diversion of the *bile* from the intestines does not lower the absorption of medicinal iron (P. W. Smith and Crandall, 1942), contrary to earlier reports.

The *quantity of iron in the feces* normally approximates that in the food (Kletzinsky, 1854), indicating either that the absorption is small or that the excretion occurs largely by the feces and balances the absorption. The latter holds true, for the feces contain this metal even in starvation; and when iron is injected subcutaneously, much more is excreted by the feces than by the urine. *Fistula experiments* have been more informative: A fistula in the lower ileum would separate the place of the principal absorption, the small intestine, from the principal excretion, the large intestine. Honigmann, 1896, found in this way that about 80 per cent of citrated iron was absorbed in the small intestine. Rabe, 1912, by using fistula dogs, found that the greatest absorption of saccharated iron occurs in the duodenum, the lower portions playing a progressively smaller role.

Experiments with radioactive iron show active absorption from gastric, duodenal and jejunal pouches (Hahn, Ross *et al.*, 1943).

Gastric absorption of iron has been confirmed by artificial stenosis of the pylorus with a rubber bag (Vahlquist *et al.*, 1945).

Microchemic evidence of the course of absorption is obtained by applying the color reactions of iron directly to the tissues. The macroscopic examination of the depth of stain gives a general idea of the quantitative distribution of the iron, the details being revealed by microscopic study. Since the iron compounds are likely to dissolve in the fixing solutions, many of the earlier experiments gave fallacious results. With improved technic, Macallum, 1894, Quincke and Hochhaus, 1896, and Abderhalden, 1906, found the reaction after the administration of iron preparations especially strong in the epithelial cells of the *duodenum.* The results below the duodenum were inconstant, depending upon the quantity administered. The *gastric epithelium* gives no reaction. The *large intestines* show diffused iron reaction of the epithelium and granules in the submucous leukocytes. It was generally assumed that this iron is in the course of excretion. However, Tartakowsky found that the large intestine shows no sulfide reaction in starvation or with iron-poor food, although the chemic examination of the intestinal contents proves the continued excretion of fixed iron. It would therefore seem that the excreted iron is too firmly combined to give the sulfide reaction, and that the sulfide reaction of the large intestine is also due to iron in the course of absorption. However, the amount absorbed here must be small. The absorption of iron must therefore take place mainly *through the cells of the duodenum.* This differs from other metals, which are absorbed *between* the cells (Hoeber, 1907).

Forms of Iron in Their Relation to Absorption.—The conceptions of these have undergone considerable modification. The "heme" iron of hemoglobin and cytochrome are the only forms of biological and medical interest which are now classed as containing "*organic iron,*" as an integral part of the molecule. Hemoglobin occurs only in blood and red meat. Cytochrome occurs in all aerobic cells (Keilin, 1928), but its quantity is relatively small. The iron of foods is therefore mostly "inorganic." "*Inorganic*" *preparations* contain ionizable iron, which either gives the ordinary iron reactions (with ammonium sulfide, ferrocyanide and hematoxylin) directly, or after treatment with dilute acid which renders it soluble (elementary iron and carbonate) or which breaks it loose from somewhat more complex ions. These complexes of "*masked iron*" are of all degrees of firmness, from the "double salts," such as iron and ammonium citrate, which are decomposed by weak acids, to the ferrocyanides, which require rather violent treatment. The *reserve iron,* which is stored in the tissues and constitutes much of the iron foods, is fairly firmly bound, and was formerly classed as "*organic.*" The iron of egg yolk, at one time considered typically "organic," is now classed as entirely "inorganic" (Tompsett, 1934), although its iron is firmly bound (M. C. Sherman *et al.*, 1934). In bakery yeast at least half of the iron is inorganic; about a third exists as heme compounds (Elvehjem, 1931).

The *iron content of foods* varies considerably. Blood, meat, yolk of eggs, and the green portions of vegetables, carrots, fruits, and so on, are especially rich in iron (17 to 40 mg. per 100 Gm. of dry substance); egg white, milk and the cereals (especially white flour) are poor in iron. Whole wheat, potatoes and the legumes are intermediate. Further data may be found in W. H. Peterson and Elvehjem, 1928. The *proportion of ionizable iron* is especially high (80 to 100 per cent) in fish, roots, tubers, cereals and legumes; high (above 50 per cent) in sweetbreads, fruits and green vegetables; intermediate in pork (15 to 47 per cent), and low in beef and mutton (10 to 25 per cent); (Shackleton and McCance, 1936; dipyridyl test). Wheat contains 3 to 5 mg. of Fe per 100 Gm., 18 per cent of this as fully available "inorganic" forms, equal in the treatment of anemic rats to the same amount of iron as ferric chloride (A. H. Free and Bing, 1940).

Simple ferrous and ferric salts differ in degree of absorbability, because ferric salts form insoluble compounds with proteins, phosphates and carbonates, even in the acid medium of the stomach and duodenum, while ferrous salts precipitate only when the reaction becomes alkaline (Starkenstein, 1928). Smaller doses of ferrous salts therefore suffice for nutrition and hemoglobin formation, but if enough ferric iron is taken, the needs are met just as completely, both in normal and in anemic subjects (F. Reimann and Fritsch, 1930; Lucas and Summerfeldt, 1939), perhaps because a sufficient amount of ferric iron is reduced to the ferrous state in the stomach and intestines (Starkenstein and Weden). The amount by which the dosage of ferric iron must be increased over that of ferrous varies according to the total iron income; from equality to as much as fifteen times clinically; with dogs there is little difference between ferrous and ferric (C. V. Moore *et al.*, 1944; Hahn, Lowe *et al.*, 1945).

Clinically, ferric salts gave much less rise of the serum iron concentration than did the ferrous, unless a reducing substance, such as ascorbic acid, was given (C. V. Moore *et al.*, 1939). In ligated loops of rabbits' intestines the absorption of ferric chloride was about a third that of ferrous chloride (O. Fürth and Scholl, 1936). Lintzel, 1933, found no absorption if the ferrous iron was rendered insoluble by the administration of alpha, alpha dipyridyl. It is conceivable, however, that ferric iron need not always be completely precipitated. In any case, in anemia the administration of adequate amounts of ferric iron results in the production of hemoglobin just as readily and completely as ferrous iron (Hahn, Bale *et al.*, 1938). Ferric ammonium citrate appears to be effective in some cases where iron-rich food is not so effective (Patek and Heath, 1936). The utilization of sodium iron phosphate by anemic rats is only half as efficient as that of ferric chloride (S. Freeman and Burrill, 1944).

Ferric ammonium citrate and analogous double salts have a somewhat special status, as they do not precipitate proteins directly; but they do so on acidulation, so that their utilization is practically the same as that of the ordinary ferric salts, and inferior to the ferrous (P. F. Hahn, Lowe *et al.*, 1945). *When the reaction is alkaline*, ferrous salts are also precipitated. The alkaline therapy of peptic ulcer interferes seriously with the utilization of iron and the regeneration of hemoglobin (Kellogg and Mettier, 1936).

Achlorhydria leads to a negative iron balance on moderate iron income (10 to 12 mg. daily); but large doses of ferric ammonium citrate are utilized as well as by normal subjects (Barer and Fowler, 1937). In experimental achylia, produced in dogs by extirpation of the gastric body and fundus, the absorption of iron from ferrous chloride is practically normal, and is only slightly augmented by administering hydrochloric acid (J. P. Quigley *et al.*, 1936).

The truly *organic compounds* of heme and cytochrome are not absorbed directly, but gastric juice and bacteria may break them down to inorganic. As this is generally incomplete, their utilization is imperfect (Elvehjem, Hart and Sherman, 1933), but even crystallized hemin may in this way be utilized up to 90 per cent when administered by mouth (Bing *et al.*, 1936). Up to 25 per cent of the iron of a liter of blood is absorbed from the human alimentary tract (D. A. K. Black and Powell, 1942).

The excretion of iron occurs mainly in the feces. The urine of man contains normally about 0.25 to 0.3 mg. per day, about a fiftieth of the amount in the feces. The latter is in large part unabsorbed iron, but considerable fecal excretion continues in fasting (Bidder and Schmidt, 1852; F. Mueller).

Mechanism of the Fecal Excretion.—The iron of the feces parallels their dry weight rather than their fluid (Reznikoff, 1932), indicating that it is excreted otherwise than by diffusion or filtration. It was at first assumed that the excretion occurred mainly by the *bile*, which always contains iron, but actual observation showed that the quantity of iron in the bile is small (mean, about 40 mg. per liter); and that it is not materially increased by the administration of iron (E. W. Hamburger, 1880; Anselm, 1892, 1916). A human biliary fistula yielded a maximum of 0.5 mg. per day, and this was not increased by intravenous injection of iron lactate (Henriquez and Roland). The biliary excretion of iron in normal dogs is constant at about 0.2 mg. per day. The bile also excreted little intravenously injected radioactive iron gluconate, unless there was blood destruction, as by acetyl-phenylhydrazine, but even then only 3 per cent of its iron is excreted by the bile, while the pigmentary radical is excreted in toto by this channel (W. B. Hawkins and Hahn, 1944). The main part of the iron must therefore be excreted directly into the intestines. This is confirmed by fistula experiments in which the access of food to the isolated parts of the intestines is prevented. Contrary to the older observers (Gottlieb, 1891; Honigmann, 1896), the small intestines appear to furnish the larger part of the excretion; the colon only about a fiftieth in dogs (Nicolaysen, 1935); very little in man (C. S. Welch *et al.*, 1936). In rabbits, after hypodermic and peritoneal injection of iron salts or hemoglobin, the main excretion is through the epithelium of the upper duodenum (Chevallier, 1914). The excreted iron is firmly bound, so that it gives the iron reactions only after incineration (Tartakowsky), in contrast to the black color of iron sulfide when inorganic iron is administered.

The *urine* always contains small quantities of iron, in man 0.003 to 0.8 mg. per day, median about 0.25 mg., with daily variations of about 50 per cent. Its concentration is perhaps a twentieth of that of the plasma (Hanzal and Bing, 1934; Tompsett, 1934; Henriquez and Roland, 1928; Dominici, 1929). The nature of the compounds has not been determined, but a part is loosely and a part firmly bound, and a part is removed by filtration through asbestos, indicating that it is in the formed elements (Hanzal and Bing). There is practically no increase if iron is administered by mouth (Marlow and Taylor, 1934), even for weeks (Gottlieb, 1890). Some increase occurs on intravenous injection of iron lactate in dogs (Henriquez and Roland); or iron and ammonium citrate in man (Lanyar *et al.*, 1933). Older investigators reported it somewhat increased in fever, nephritis, hepatic disease, leukemia and especially in diabetes (Tartakowsky, 1904), but Lanyar *et al.* found no increase in these and the other diseases studied, including polycythemia vera, pernicious anemia and hemolytic icterus. Iron is seen microscopically in the kidneys only if absorbable iron is administered or injected; not with a normal diet, nor with blood destruction.

Iron injected hypodermically or intravenously is largely *retained* over long periods, as reserve iron or as hemoglobin, so that there may appear to be no added excretion by the feces, and little by the urine (Nicolaysen, 1935; McCance and Widdowson, 1938). With parenteral administration of neutral radioactive ferric citrate to normal rats, less than 2 per cent was excreted in the urine and feces in the first four days (D. H. Copp and Greenberg, 1945). By the end of several weeks, however, most of the iron has been excreted by the feces (Gottlieb, 1891). With intravenous injection of *radioactive ferrous gluconate* into dogs, there is an initial extra output of 2 to 8 per cent of the injected iron, by urine and feces; then the excretion drops promptly to traces (P. F. Hahn *et al.*, 1939). If large quantities of iron and ammonium citrate or other iron salts are injected by vein, the excretion of iron by the bile and urine is promptly increased, in both cases as colloidal compounds. The *biliary excretion* is associated chiefly with the stellate cells and is decreased by blocking the reticulo-endothelial cells with India ink and by other forms of liver injury which have no effect on the biliary excretion of normal iron (Iwai, 1930). In the *kidneys*, the iron can be demonstrated by the ferrocyanide reaction to be excreted by the convoluted tubules, and none by the glomeruli, the colloidal state precluding filtration. If the injections are frequently repeated, the epithelium is injured (E. J. Stieglitz, 1921).

Normal Iron Retention, Distribution and Storage.—A positive iron balance is needed in growth, including pregnancy, and after loss of blood, for the formation of hemoglobin and cytochrome. If the income (deducting excretion) exceeds these needs, the retained iron is distributed among the organs and tissues, about as are other metals; but it is taken up more actively by the bone marrow, blood and muscle, especially with anemic patients (Austoni and Greenberg, 1940). Its microchemical reactions make it relatively easy to trace; and a considerable part is found in rather loosely bound form ("ferratin") as granules in the cells of the hematopoietic organs, in the liver and red marrow, and particularly in the spleen, to a less extent in the kidneys. In this form it remains until it is used or excreted. This constitutes an important *reserve stock* of iron which is drawn upon in hemorrhage, but which is conserved even when there is already a marked excess. It is regulated by the amount absorbed, rather than by excretion (P. F. Hahn *et al.*, 1939). The amount in the human liver and kidneys shows a characteristic life curve (Brückmann and Zondek, 1939).

The *iron content of the entire blood* averages 50.1 mg. per 100 cc. for men; 43.4 mg. for women; 44 mg. for children (A. Sachs *et al.*, 1935; Sobel and Drekter, 1933); but nearly all of this is hemoglobin. However, 5 to 10 per cent of the iron of the erythrocytes is in easily detachable ionized and dialyzable form (Lintzel, 1925), intermediate in the transformation of hemoglobin into bile pigment. The *plasma iron*, in man, ranges between 0.06 and 0.7 mg. per 100 cc. (Fourweather, 1934; Tompsett, 1934, Marlow and Taylor, 1934). The variations are due at least in part to the absorption of ingested iron: In dogs, Bing, Hanzal and Myers, 1935, found the serum level 0.1 to 0.2 mg. per 100 cc. in fasting (entirely inorganic). After oral administration of iron chloride or reduced iron, it rose to a peak of 0.3 to 0.55 mg. in three or four hours, returning slowly to the fasting level in twelve to twenty-four hours. Patients with pernicious anemia and acutely ill patients do not show the rise of plasma iron on oral administration regardless of the state of their iron reserve (C. V. Moore *et al.*, 1939). Radioactive iron, administered by mouth to anemic dogs, is transported in the *nonprotein portion* of the plasma (Hahn *et al.*, 1939).

Variations of Reserve Stock.—This disappears ("*asiderosis*" of Quincke) gradually when a diet poor in iron is given, or when there is an extraordinary use of iron, as after hemorrhages or during pregnancy (when considerable iron is transferred to the fetus). In acute hemolytic anemia of rabbits, the reserve iron largely disappears, especially from the liver cells, when the blood is regenerated. Small amounts are still present in the endothelium of the hepatic capillaries, in the spleen and in the renal cortex (Muir and Dunn, 1915). The deposits increase, on the other hand, when the iron of the food is increased or when blood is destroyed, as in toxic and pernicious anemia. The chemical nature of the tissue and storage iron is not clear; 15 to 70 per cent is nonhematin, probably in a variety of forms, presumably ferric, which may be mobilized at different rates. The most anemic animals contain considerable nonhematin iron in the liver and spleen and especially in the heart and skeletal muscles. Myohemoglobin also is not diminished in anemia (review, M. O. Schultze, 1940).

Data on the *iron content of different tissues* of dogs and rabbits are given by Elvehjem and Peterson, 1927. The *liver* is normally rich in iron (this is true likewise of animals which do not form hemoglobin—molluscs, crayfish, lobster, and so forth). The liver iron decreases with iron-poor food, or when there are extra demands for iron, as in pregnancy or after hemorrhage. The iron content of the liver may thus be taken as an index of the iron stock of the body. By prolonged high iron income (for three to four years), the liver iron of rabbits may be raised to 100 or 200 times the normal (from 0.036 per cent of the dry weight to 3.4–7.7 per cent), without hemochromatosis or other evidence of damage to the liver or pancreas (Polson, 1933). *Hemochromatosis* represents a partial accumulation of iron-containing pigment granules, chiefly hemosiderin (Rous *et al.*), associated with fibrosis, in the parenchyma cells or connective tissue, especially in the liver, which may contain 38 Gm. of iron, ten times the normal iron content of the entire body, including the hemoglobin. The formation of a blue wheal on intradermal injection of faintly acidulated 0.5 per cent potassium ferrocyanide has been proposed as a clinical test of hemochromatosis (H. R. Fishback, 1938). The *spleen* is an important depot of reserve iron, as granules of loosely bound iron. The quantity varies with the iron income and blood destruction (Chevallier, 1914). Its reserve affinity surpasses that of the liver, for animals fed from birth on iron-free food, whose liver is free from reserve iron, contain some in the spleen

(Schmidt, 1912). With normal iron metabolism, the spleen is not essential, and its excision does not entail any constant or important changes in iron balance; probably not even when the iron income is inadequate (E. Lauda and Haam, 1928). With hemolytic poisons, however, excision of the spleen affects the formation of hemoglobin (G. B. Ray and Isaac, 1930). Relatively large stores of iron and copper may accumulate in the liver and spleen during chronic secondary anemia (M. Sandberg *et al.*, 1942).

In experimental anemia, induced in dogs by repeated hemorrhages, the iron store of all organs can be largely exhausted in two or three months. When iron is administered orally to such animals, it is converted into hemoglobin, at first with little storage in the liver; more prolonged administration gives slight and variable storage (P. H. Hahn and Whipple, 1936). Tracing with radioactive iron indicates that the storage under these conditions is much greater in the liver than in the spleen (Hahn *et al.*, 1938). A *sex relation* of iron storage has been demonstrated in rats, females accumulating a larger store at sex maturity than do males. During pregnancy the store is depleted, and after parturition it is again built up rapidly to its former level. This storage is destroyed by castration and restored by injection of follicular hormone. The cycle provides for the *iron supply of the fetus*, whose store at birth is in direct relation to the amount stored by the mother (Steenbock *et al.*, 1936). When a single dose of radioactive iron is fed to the mother near the end of gestation, it appears in the fetal circulation within forty minutes. It is widely disseminated in the fetal tissues, with the highest concentration in the erythrocytes and the largest quantity in the liver (W. T. Pommerenke, Hahn *et al.*, 1942). The liver store of iron in newborn infants of normal mothers averages 50 mg. Their hemoglobin concentration is high, averaging 22 per cent; their blood volume is also high, 15 per cent of body weight. The destruction of the excess hemoglobin begins almost immediately after birth, and is completed in nine to twelve weeks, at 12.5 per cent (G. Stearns, 1939).

Intravenously injected iron compounds leave the blood stream practically completely within two or three hours. At this time, only 10 per cent has passed into the excreta; about 50 per cent is deposited in the liver, and the remainder in other organs, spleen, kidney, intestines. Hahn and Whipple, 1936, found 50 to 77 per cent in the liver and spleen, the liver having a much larger share than the spleen in this temporary storage (D. H. Copp and Greenberg, 1945). In *anemia*, parenterally administered iron is transformed almost completely into hemoglobin (Hahn and Whipple, 1938). With ***intravenous injection of 10 to 25 mg. of radioactive ferrous ascorbate into normal individuals***, 70 per cent is converted into hemoglobin in ten days, 100 per cent in ten weeks. In *hypochromic anemia* the utilization is more rapid, 100 per cent by the ninth day. In *hypoplastic anemia* only 1 to 1.5 per cent is utilized. In *pernicious anemia* in relapse the conversion amounts to about 30 per cent in nine days and remains at this level until liver therapy is started, when it rises to 100 per cent. Various types of hemolytic anemia give a total utilization of 14 to 16 per cent, reached in six to nine days (R. Dubach *et al.*, 1946). In experimental *tuberculosis* of rabbits, the tubercles accumulate iron from intravenous injection of ferric chloride (Menkin, 1934). *Intravenously injected colloidal iron* ("dialyzed iron") is at once precipitated in the blood, forming emboli in the lungs, and considerable accumulations in the liver and spleen, chiefly in the endothelial cells. In time, the iron passes from the lung to the spleen and thence to the liver, where it is retained for long periods (fourteen months). From the liver it goes gradually into the lymph gland, where there is further prolonged retention. Eventually a part is excreted by the kidneys and cecum (Polson, 1929; Cappell, 1930).

Fate of Hemoglobin.—If free hemoglobin occurs in the plasma, in concentrations above 0.12 per cent as a result of its injection or of extensive hemolysis, the excess is mainly filtered through the kidneys, producing hemoglobinuria (Pearce, Austin and Eisenbrey, 1912). On standing, the urinary hemoglobin changes fairly rapidly to methemoglobin (Drabkin *et al.*, 1935). With intravenous injection of dissolved hemoglobin into normal man, it does not appear in the urine until its plasma level exceeds about 100 mg. per 100 cc. With injections up to 16.4 Gm., less than 15 per cent goes into the urine. In patients with preexisting albuminuria, traces of hemoglobin may pass into the urine when the plasma level is 40 mg. per cent. The plasma bilirubin increases parallel to the injected hemoglobin (D. R. Gilligan *et al.*, 1941). A part of the free hemoglobin of the plasma is decomposed into bile pigment, or all if the concentration is lower, and therefore with the normal destruction of the corpuscles. In this decomposition, the iron is split off and deposited as storage iron, so that injection of hemoglobin increases markedly the iron content of the liver, spleen and bone marrow. With hemolysis so severe as to destroy nearly half of the blood in three days, almost all the iron of the destroyed corpuscles was found deposited in the liver, spleen and kidneys; a third of the total iron of the blood may be thus deposited in twenty-four hours (Muir and Dunn, 1915). The iron liberated by the normal destruction of the corpuscles may be utilized again for forming new corpuscles, so that it is practically impossible to produce severe anemia in adult animals by limiting the iron of their food. However, a part of the liberated iron is lost by the feces and urine.

Re-Use of Hemoglobin.—The lifespan of an erythrocyte, as judged by blood groupings of transfused blood-averages 129 days (S. T. Callender *et al.*, 1945); 0.75 per cent of the hemoglobin would therefore need to be regenerated daily, corresponding to nearly 20 mg. of iron. As the daily income may be only a third of this, at least two-thirds of the hemoglobin iron must be used again for this purpose. The labeled iron of hemoglobin liberated by age, trauma, or toxic hydrolysis is almost immediately and quantitatively utilized for new erythrocytes, even when there is abundant store of reserve iron (P. F. Hahn, Bale and Balfour, 1942).

Products of Hemoglobin Destruction.—In the decomposition of the liberated hemoglobin, the hematin is split into hemosiderin, which carries the iron, and into an iron-free fraction, presumably hematoporphyrin, which in turn is converted into bilirubin, and this into the fecal and urinary pigments, stercobilin and urobilin. In trauma, a transitional degeneration product with "masked" iron is taken up promptly by the mesenchymal and epithelial cells (N. W. Popoff and Popoff, 1943). With injection of hemoglobin or extensive hemolysis, the bilirubin formation may exceed the excretory capacity of the liver and lead to icterus (Pearce *et al.*, 1912).

Urobilinogen is also increased in pernicious anemia, and when polycythemia is treated with phenylhydrazine. With feeding of blood, the absorption is so limited that it does not modify the bile flow or the secretion of bile pigments (Whipple and Hooper, 1917). The destruction of the hemoglobin and the formation of bile pigment is *accomplished by the reticulo-endothelial cells*, in all organs where these are found, in the spleen, liver, bone marrow, lymph nodes, and so forth. The share of the liver in the bile pigment formation is probably smaller than that of the spleen (Whipple and Hooper, 1913; F. C. Mann). The decomposition of hemoglobin and formation of bile pigments is effected even by tissue cultures of histiocytes (Rich, 1924). Analogous changes are observed when blood is extravasated into the tissues. The scavenger function of the reticulo-endothelial system begins with the phagocytosis of the fragmenting erythrocytes, which break down throughout the vascular system when their life span is run, averaging four months in dogs (Hawkins and Whipple, 1938) and estimated at one-half to two months for man. The spleen is especially prominent in the disposal of the aged corpuscles, probably retaining them in the sluggish current through its network, and perhaps mashing them in its rhythmical contractions; but if it is excised, other reticula, especially the bone marrow, fulfill its hemoclastic functions, without any marked disturbance. In normal animals, splenectomy, with or without hemoglobin injection, does not modify bile pigment excretion (Hooper and Whipple, 1917).

Spleen as a Colloid Trap.—The colander function of the spleen is exerted not only against the blood corpuscles, but also against other particles in the blood, including suspension colloids. In this process the reticulo-endothelial system is concerned, probably partly by adhesiveness and partly by engulfing the particles.

Chemical Structure of Hemoglobin.—Hemoglobin makes up about a third of the mass of the erythrocytes. It consists of a protein, *globin*, probably allied to histone, which differs in different animals, combined with about 4 per cent of hematin (hemochromogen), which in turn contains 8.5 per cent of iron, so that hemoglobin contains 0.37 per cent of iron, as four ferrous atoms to the molecule. The chromogen or heme is probably identical in different animals. It is a compound of ferrous iron with a porphyrin molecule. *Porphyrin* is a complicated ring formed by the linkage of four methyl pyrrhole rings. In forming the heme, the four nitrogens of the porphyrin unite with the six places of iron, analogous to ferro- and ferricyanide, $K_4Fe(CN)_6$ and $K_3Fe(CN)_6$. This leaves two places in the Fe free which may be filled on the one hand with globin, nicotine, pyridine, and so on, and on the other hand with oxygen, carbon monoxide, cyanide, and so forth. Many iron porphyrin compounds are found in all cells and tissues and constitute a family of *hemin compounds*, viz., the various forms of *cytochrome* found by Keilin; and Warburg's respiration ferment (L. Michaelis, 1931).

Muscle hemoglobin, which occurs in certain muscles, represents about a fourth of the total hemoglobin of the body. It differs from blood hemoglobin in that its molecule contains only one iron atom, and by a high affinity for oxygen and relatively low affinity for carbon monoxide. It furnishes muscle with a limited local oxygen store. Its quantity is greater in the muscles that require sustained repetitive activity of considerable force, such as the heart muscles of larger animals and the pectoral muscles of birds. Its concentration increases with age and activity (G. A. Millikan, review, 1939).

Oxygenation and Oxidation.—Hemoglobin can be oxidized in two divergent ways: (1) It combines reversibly with molecular oxygen without the iron being oxidized from ferrous to ferric. This is *oxygenation.* (2) Ferrous may be oxidized to ferric iron, by *true oxidation;* the oxidized hemoglobin is methemoglobin. True oxidation to ferric does not occur perceptibly with molecular oxygen, but only by an oxidant, *i. e.*, hemoglobin is not auto-oxidizable. This is essential to its function as an oxygen carrier. Most *other heme compounds* in the ferrous state are auto-oxidizable to ferric and therefore act as oxygen catalysts or as oxidants of organic foodstuffs, *i. e.*, as respiratory ferments. The majority of organisms require some iron, even those which do not form hemoglobin. (The blood of some *invertebrate animals* contains copper or manganese in place of iron.) The *effects of iron and copper on yeast growth* are similar to their effects on hemoglobin formation, suggesting the analogy of the hemes and the cytochromes (Elvehjem, 1931).

Ferric Salts as Catalysts.—The oxidation of glucose by hydrogen peroxide occurs slowly *per se;* by the addition of 0.001 per cent of ferric sulfate the oxidation occurs much more rapidly, so that the mixture may boil (quoted from J. Stieglitz, 1924). The catalytic effect is produced only by ferric ions.

The *activity of vegetable peroxidases* appears to increase with the iron content up to a certain point; but by further purification the activity increased as the iron content fell; so that iron is not a constituent part of the enzyme, but only an accelerator (Willstaetter, 1927).

Hematoporphyrin occurs in small amount in normal blood and urine and may be greatly increased in a variety of diseases, and especially in poisoning by sulfonal and barbital, so as to give a burgundy color to the urine. Smaller amounts appear in lead poisoning. Its occurrence in these conditions is capricious (review, V. R. Mason *et al.*, 1933). It causes marked hypersensitiveness of the skin to light. After hypodermic injection and exposure to light, mice die in a few minutes to several days according to the dose (Hausmann, 1910; Hutschenreuter, 1933; review, K. Dobriner and Rhoads, 1940).

Since the animals show increased motor activity, hematoporphyrin hydrochloride was introduced clinically as "Photodyn," against *psychotic depression* (Huhnerfeldt, 1931) with apparent improvement in about half the cases (Angus, 1936); but multiple neuritis has been reported (Thornes, 1937). Its injection into animals causes marked degeneration in the nerve cells, myelin sheath and axis cylinders of the spinal cord, in peripheral nerves and in sympathetic ganglia. In the presence of oxygen and light, visible and ultraviolet, hematoporphyrin develops proteolytic properties, hydrolyzing fibrinogen and other proteins, including serum albumin (Howell, 1921; M. J. Boyd, 1933). Injected into rabbits, it produces significant changes in the quantity and composition of the urine, indicating increased breakdown of nitrogenous and non-nitrogenous metabolites and increased Cl excretion (Hinsberg and Merten, 1938). It also seems to have some relation to the growth of the bone (Borst, 1930).

Fate.—Intravenously injected hematoporphyrin leaves the blood stream rapidly, and is scarcely measurable after twenty-four hours. It is largely taken up by the liver and eliminated by the bile, sometimes partly by the urine. After hypodermic or intraperitoneal injection, it appears promptly in the blood, increasing slowly to a maximum in twelve to twenty-four hours (Smetana, 1938). It is apparently not absorbed from the oral administration (Hutschenreuter, 1933).

Chlorophyl, the characteristic green pigment of plants, essential to their peculiar metabolism and synthetic functions, is formed on the same four pyrrhole ring pattern as hemochromogen, but united to magnesium instead of iron. Two closely related chlorophyls, a and b, have been isolated pure by Willstaetter, and there are doubtless others. They constitute 0.1 to 0.2 per cent of the fresh green leaves. The structural similarity suggested that the ingestion of chlorophyl would promote the formation of hemoglobin in anemia, but this is not so (Whipple and Robscheit-Robbins, 1925; Patek, 1936). The greater part of the ingested chlorophyl is eliminated as pheophytin in the feces (F. T. Edwards and Holley, 1932). The special value of green vegetables is due to their carotene and other vitamins.

Parenteral injection of chlorophyl may produce fatal hemolytic anemia in mice and rabbits if these are exposed to light, red and yellow being especially effective for this photodynamic action (Guerrini, 1933). Direct stimulant effects of chlorophyl on *excised heart, intestine and uterus* have been reported (Gordonoff, 1927; other pharmacologic effects, Rentz, 1929).

Local application of a *water-soluble chlorophyl* derivative is claimed to hasten the healing of wounds (L. W. Smith and Livingston, 1943) and ulcers (E. Gahan *et al.*, 1943), but requires further confirmation. It is reported to be bacteriostatic by interfering with oxidation-reduction. Intravenous injection is not toxic (L. W. Smith, 1944).

The formation of hemoglobin appears to occur by the transformation of the iron-containing nuclear chromatin of the hematoblasts (A. B. Macallum, 1920). Protoporphyrin is probably a step in its synthesis. The hemoglobin then passes from the nucleus into the cytoplasm (Villa, 1930), and in the mammalian corpuscles the nucleus disappears into the cytoplastic reticulum (Macallum, 1931). The erythrocytes themselves are derived from the reticulo-endothelial cells that line the blood sinuses; in early embryonal life quite diffusely, later largely in the spleen and liver, and at birth almost exclusively in the red bone marrow, although the spleen and liver remain potential dormant centers throughout life (review, H. E. Jordan, 1942). Red bone marrow replaces fatty marrow during hematopoietic stimulation. It is a stagnant area in which erythrocytes are formed and matured through long periods. The small endothelial cells develop successively through megaloblasts (colorless, nucleated basophilic cells), erythroblasts (progressively less basophilic), normoblasts (acquiring hemoglobin) and reticulocytes (disappearance of nuclei which mature rapidly into the erythrocyte when it enters the circulation) (review, M. O. Schultze, 1940; Middleton and Meyer, 1935). Notwithstanding this elaborate course, radioactive iron appears in the erythrocytes of anemic dogs in a few hours after its oral administration (Hahn *et al.*, 1939).

The *regulation of hemoglobin and red cell production* to maintain the normal level is ordinarily very efficient. The hemoglobin concentration of normal human blood is practically independent of race and habitat, except for altitude and nutritional state. It averages 15.8 Gm. (14.5 to 18.5) per 100 cc. in men, 13.8 (12.5 to 15) in women, 12.0 in children (V. C. Myers and Eddy, 1939). The mechanism of the regulation is not known, but it extends back as far as the absorption of iron, which is much greater when there is need for additional blood formation. The most potent measure for increasing hemoglobin and erythrocyte production is the need for them, as after hemorrhage, and the rate of hemoglobin production increases with the degree of the deficiency, being one and a half times as high when the hemoglobin level is 6 per cent than when it is 11 per cent (F. S. Robscheit-Robbins and Whipple, 1941). Oxygen deficiency as in mountain sickness sets them to a higher level. Injection of hemolyzed blood is also a potent stimulus (review, S. Isaac, 1920). The administration of iron, copper and other metals facilitates restoration of the normal level, and cobalt produces polycythemia. Hematopoiesis is also stimulated by parenteral injection of extracts of spleen (Krumbhaar and Musser, 1914), of bone marrow, and more potently by both together (Leake, 1923). All these agencies cause hyperplasia of the bone marrow. The production of red cells is decreased, with resulting anemia, when the red marrow is injured, as by toxic doses of the metals, or by benzene and some of its derivatives. Temporary increase of the red corpuscle count, by as much as 250,000, may result from contraction of the spleen.

In blood donors, with the removal of 555 cc. of blood the hemoglobin dropped acutely from an average of 12.8 to 10.3 Gm., per 100 cc., a loss of 2.3 Gm. per 100 cc. or 18 per cent. It required about fifty days to replace the loss, the hemoglobin being reformed at the average daily rate of 0.05 Gm. per 100 cc. for men; 0.04 for women. Oral administration of iron ammonium citrate, 1 Gm. per day, increased the daily hemoglobin regeneration by half, shortening the average restoration period to thirty-two days. Repeated donations slow the recovery and diminish the response to iron administration (W. M. Fowler and Barer, 1942).

Auxiliary Action of Copper and Other Metals in Blood Formation.—The utilization of suboptimal amounts of iron for the formation of hemoglobin is promoted by the oral injection of minute quantities of copper (0.16 mg. per day for rats), which stimulate the bone marrow (E. B. Hart *et al.*, 1927; C. A. Elvehjem, Hart and Kemmerer, 1929; D. W. Frost *et al.*, 1940). The absorption and retention of iron does not appear to be promoted by the copper (Josephs, 1932), but only the formation of erythrocytes and hemoglobin, and when this is efficient as in hemorrhage (Whipple *et al.*), or with a liberal iron income, the copper seems to be superfluous. This may account for the discrepant conclusions of different workers as to the need of copper, even when similar conditions were sought (Bing, Sauerwein and Myers, 1934). The effects of copper may also be produced by a large number of other metals (Ni, Ge, Mn, As, Ti, Zn, Ru, Cr, Va, Se, Hg). All these, as well as iron itself, hasten the mobilization of reticulocytes from the bone marrow. They may produce polycythemia in normal animals, but excessive dosage, at least of some of the metals, may injure the bone marrow and may therefore fail to improve anemia, or they may even exaggerate it (review, M. O. Schultze, 1940). This may account for some of the discordant experimental results. Clinically, this has been known especially for lead, and also for arsenic and mercury.

Therapeutic Insignificance of Copper in Anemia.—The optimal dosage of copper is so small that extreme precautions must be taken to exclude it from the food and iron, in order to demonstrate its effects. The artificial addition of copper to ordinary foods or iron preparations is therefore generally superfluous. However, it is reported that hemoglobin regeneration in anemic infants is improved by adding copper to the iron therapy in the ratio of Cu 1: Fe 25. The iron, copper and manganese content of common foods is reviewed by M. A. Hodges and Peterson, 1931, in J. Am. Diet. Assoc., *7:* 6. The *average daily intake* for man would approximate: iron, 15.44 mg.; manganese, 2.39 mg.; copper, 2.26 mg. The occurrence of these metals, and also of aluminum and zinc in foods, and their role in nutrition are also reviewed by M. S. Rose, 1929, in J. Nutrit., *1:* 541.

The addition of a mixture of arsenic, manganese and iron increases the hemoglobin synthesis of rats on a restricted diet, more than does a mixture of iron with either arsenic or manganese alone (J. T. Skinner and McHargue, 1946).

Iron Therapy in Anemias.—Interest in iron therapy was revived by the chemical demonstration of iron in the blood by Menghinis, 1746, and his claim that this could be increased by a diet rich in iron. Foedisch, 1832, demonstrated that the blood of chlorotic patients is low in iron; and Andral, Gavaret and Delafond, 1842, claimed that the administration of iron to chlorotic patients increases the number of red cells. It was assumed that it was essentially an inorganic food element, and that it would be useful in all conditions characterized by low hemoglobin. This generalization was not borne out by practical trial. It proved notably ineffective in anemias in which there is no iron deficiency; especially in pernicious anemia and many acute anemias, *f. i.*, that of hemorrhage, where recovery is probably as rapid without iron medication, owing to drawing on the iron stores of the body.

The *reticulocyte response as index of iron therapy* has the advantage of giving definite, prompt and quantitative data. It is not so regular or so extensive as the response of pernicious anemia to liver. A positive reticulocyte response of varying degree to iron therapy has been observed in the anemias of chronic blood loss, dietary defects, gastro-intestinal disorders, pregnancy, ill defined anemias and chronic microcytic anemias with achlorhydria, although the response is not so regular nor so extensive as that of pernicious anemia to liver. The degree of response increases with the degree of anemia, as with liver therapy in pernicious anemia; but the relation is not constant, following the hemoglobin more closely than the blood count. Infections and other complications hinder the response. Patients with achlorhydria respond less to iron than those with normal acidity. In all cases, large doses of iron are much more effective than small doses (Minot and Castle, 1931; Minot and Heath, 1931).

Nutritional Anemia in Growing Individuals.—Rapid growth requires relatively large quantities of iron for the increase of tissue and especially of blood, and anemia readily results if the iron income is inadequate. This is likely to be so in infants since milk, the chief food, is poor in iron. *Cows' milk* contains 0.4 to 0.7 mg., average 0.5 mg., per liter. It is not influenced by administering iron to the cow (Elvehjem, Herrin and Hart, 1927). The content of human milk ranges about five times higher, *i. e.*, average 2.5 mg. per liter (Dorlencourt and Calugareanu-Nandris, 1926). The newborn are protected for a time by the large iron reserve which they have stored in fetal life. This suffices normally until the time when the young are naturally weaned; but the stock is exhausted in a few months, and if the infant is kept too long on a milk diet, infantile anemia sets in, especially with premature infants.

owing to their smaller iron storage and less developed bone marrow.

The *nutritional anemia of young rats* has been extensively studied as evidence of the utilization of inorganic iron and for demonstrating the effect of auxiliary metals. Young animals on a milk or milk and rice diet develop a progressive fall of hemoglobin percentage and become emaciated, with stunted growth. As soon as iron, in any form, is added to the diet, the animals recover rapidly and resume growth (Hoesslin, 1890; Cloetta; Tartakowsky; Abderhalden). It has been used as a test of the relative effectiveness of iron preparations; the differences among these appear quite unimportant (H. S. Mitchell, 1927).

Bunge found that the proportion of iron in newborn animals is high (increasing rapidly in the last three months of fetal life; Hugounencq, 1899), and that it decreases steadily during the period of lactation (because milk is poor in iron) until it has reached a practically constant quantity—about the seventeenth day in guinea pigs or rabbits, and the twenty-third or twenty-fourth day in dogs. Animals of the same litter can therefore be used for controls, some being fed, at the end of the lactation period, with iron-poor food, others with the same food to which the iron preparation is added. Rice and milk, which contain a small proportion of iron, are commonly employed. The animals which do not receive the iron remain small and emaciated. Those which receive iron, in any form, show an unmistakable increase in the total iron content of the body, especially of the liver, spleen and bone marrow (Hall, 1894; Kunkel, 1895; Oerum, 1906). The response to iron administration may be followed in living animals by the *reticulocyte count.* In the circulating blood of normal young rats, reticulocytes form about 3 per cent of the total red corpuscles. As milk anemia develops, the reticulocyte percentage increases in six days to 15 or 20 per cent. If iron is now added, there is a further increase to 30 or 40 per cent in six days, then a decrease to normal in three days or longer. The addition of copper or other metals hastens both phases of the process, so that a normal level is reached in six to eight days (H. H. Beard, Myers *et al.*, 1931). *Female rats* improve under iron and copper more rapidly than males (M. C. Smith and Otis, 1937); this is probably due to the larger intake of the restricted diet by the males (H. H. Mitchell and Hamilton, 1937).

Nutritional anemia in adults may result from long-continued injudicious diets. It is probably an element of hypochromic anemias, including chlorosis, although there are other factors. Bethell *et al.*, 1939, found that half of the pregnant women examined by them were anemic from inadequate iron income. In most cases this can be controlled or prevented by 0.3 Gm. of ferrous sulfate, three times daily, with a good diet (C. C. Sturgis, 1946).

The *anemia of pregnancy* disappears spontaneously within a week after parturition, if the diet during gestation was adequate in iron; otherwise it is more persistent. It responds to full doses of iron and ammonium citrate (6 m. per day), but not to small doses (0.5 Gm. per day) or to liver extract. The hemoglobin level of the fetus is not lowered by anemia of the mother (Strauss, 1932).

The oxygen affinity of the hemoglobin is lower in fetal than in maternal blood; but this is reversed if the corpuscles are suspended in saline solution (E. F. McCarthy, 1943).

Because of the iron reserve, nutritional anemia is not readily produced in relatively short-time experiments on adult animals, except by *complete fasting.* In this the body weight decreases and the blood volume diminishes in a fairly corresponding degree. The blood count also falls, however, especially in birds (Barlow, 1926), and to a less degree in rats (Whitehead). This is due in part to hydremia, but also to excess destruction of the corpuscles, perhaps by the bacteria which invade the blood from the intestinal tract. This anemia is not prevented by the administration of iron (Barlow, 1926). The anemia of rice disease is similar to that of starvation; it is counteracted by laxatives which diminish the bacteremia (Barlow; Whitehead).

Anemia of Acute Hemorrhage.—Every loss of blood necessarily results in temporary anemia; but after a single severe hemorrhage, healthy adult individuals recover their blood count and hemoglobin completely, after some weeks, even on an iron-free diet. The reserve iron therefore suffices for the restoration of all the hemoglobin lost in a single nonfatal hemorrhage (Kunkel, 1895; Tartakowsky, 1903; Williamson, 1924).

Even if the hemorrhage is rendered more severe, by repeating the hemorrhage of a fourth of the blood volume on two successive days, complete restoration of hemoglobin and corpuscles occurs in four to twenty weeks with dogs. It may be hastened by a mixed diet (four to seven weeks), and still more by a meat diet (two to four weeks), but not by the administration of medicinal iron. The accelerating effect of the diet is therefore not due to the iron, but to some other factor (Whipple, Hooper *et al.*, 1918). Liver is especially effective (Williamson, 1927).

Hemolysis Products on Blood Regeneration.—Blood regeneration is much more rapid after hemolytic poisoning than after simple hemorrhage. This has been attributed to stimulation of the bone marrow by substances liberated in the destruction of the corpuscles, presumably from their lipoid envelopes (Kepinow, 1910); and the injection of hemolyzed blood into bled animals leads to much more rapid recuperation than would correspond to its iron content (Itarri, 1911). The intramuscular injection of 10 to 20 cc. of human defibrinated blood was used in severe anemia (Weber, 1909), but its advisability is doubtful.

Chronic hemorrhage is a frequent cause of clinical secondary anemia, for it tends to exhaust the reserve iron faster than it can be replenished from the ordinary diet, which furnishes iron for not more than 30 cc. of blood daily, and probably less. It can be effectively corrected by the administration of iron, but more promptly if the diet also includes other hematogenous factors; meat, kidney and particularly liver (Whipple, 1938). *Chronic hemorrhage anemia induced experimentally in dogs* is an important means of testing the utilization of iron preparations and the efficiency of other measures. It was introduced for this purpose by Kunkel, 1895, and Tartakowsky, 1903, and developed and improved by Whipple and his associates, 1918 to date.

The reserve iron of dogs can be exhausted by this means in two or three months, and the hemoglobin may then be maintained for years at about half the normal level. The parenchyma (reserve) iron of such standardized depleted dogs is 1 to 2 mg. per 100 Gm. of fresh liver, kidney and pancreas, 5 to 6 mg. for spleen, 10 mg. for red marrow (Hahn and Whipple, 1936). If iron is injected *intravenously* into such dogs, it is converted quantitatively into additional hemoglobin, the full theoretical quantity of 3 Gm. of hemoglobin for 10 mg. of iron, practically regardless of dosage. The formation of additional hemoglobin is therefore a measure of the absorption of iron when given by mouth. This varies with the dose, 40 mg. per day being most efficient. With this optimum dosage, the absorption averages about 35 per cent of the ingested inorganic iron, the same for ferric, ferrous or reduced; 10 per cent for ingested hemoglobin iron (whole blood); 44 per cent for liver (Whipple and Robscheit-Robbins, 1936). The absorption of liver and other organ iron does not parallel the dipyridyl (ferrous) fraction (Hahn and Whipple, 1938). When radio-active iron is fed to anemic dogs, either as ferrous sulfate or as ferric chloride, it can be demonstrated in the erythrocytes within four hours, and within two or three days it is converted almost completely into hemoglobin; up to three-fourths of the total amount (4.1 to 12.7 mg.) absorbed is in the erythrocytes within eighty-four hours, presumably as hemoglobin. The percentile absorption is greater with small than with large doses. Dogs that were not anemic had absorbed little (0.08 to 0.24 mg.), but again a quarter to a half of this was in the erythrocytes (Hahn *et al.*, 1938, 1940).

The plasma proteins can also be kept at low levels, 4 to 5 Gm. per cent, by chronic hemorrhage with adequate iron but low protein intake; such animals are suitable for testing the restoration of plasma protein by various proteins and amino acids (F. S. Robscheit-Robbins, Miller and Whipple, 1943).

Toxic anemias may be caused by injury to the corpuscles, as with hemolytic poisons (saponin, cobra venom, hemolytic sera, hookworm infection, AsH_3, toluylene diamine), or by injury of the bone marrow (radium, benzene, aniline, nitrobenzene, trinitrotoluene, CCl_4, Pb, As, P, ricin); *chronic infections* (endometritis; nephritis) inhibit the absorption of iron and injure the bone marrow (Robscheit-Robbins and Whipple, 1936), so that the absorbed iron is not utilized (W. M. Balfour, Hahn *et al.*, 1942). Blood destruction stimulates the bone marrow at first, but this is injured if the stimulation is too great or too prolonged. Although part of the liberated iron is stored in the spleen and liver, considerable is lost by the feces (Fukui, 1926), and the hemolyzed hemoglobin by the urine, so that iron administration hastens recovery (hookworm, Rhoads and Castle, 1932; toluylenediamine, Petow *et al.*, 1930; infections, Minot and Heath, 1931), but they are useless unless the cause is removed. In *pernicious anemia*, iron therapy is a rather minor adjuvant of the liver treatment, since the destruction of the corpuscles (probably through an unknown hemolytic agent) is accompanied by a considerable increase of the reserve iron of the liver and spleen (Rumpf, 1901) and of the dissolved iron of the spleen (Erben, 1900). The urinary excretion of iron remains normal (Queckenstedt, 1913).

Iron in Chlorosis.—The "green sickness" is confined to girls in puberty, and disappears spontaneously at maturity. It is distinguished by hypochromemia, *i. e.*, marked decrease of hemoglobin, with little or no decrease of the corpuscle count. It appears to be an exaggeration of the normal tendency of adolescent girls toward anemia, created by their increased need for iron on account of growth, menstrual losses and perhaps other features of sexual development, with inadequate dietary income of iron. It is promptly and completely corrected by the medicinal administration of iron. The absorption of iron is normal. The maximum rate of hemoglobin regeneration under iron occurs usually between the second and fourth weeks of treatment (W. P. Murphy, 1933). It is indicated by the height of the reticulocyte response and by the rate of hemoglobin increase.

The disease appears to be less common than formerly, presumably because the regimen of girls has become more hygienic. However, 26 per cent of "healthy" student nurses have hemoglobin readings of 70 to 79 per cent (Patek and Heath, 1936). The tendency is exaggerated by the low iron income generally characteristic of most chlorotic subjects, as first pointed out by Stockman, 1895, who found that the diet of chlorotic girls in Scotland contained only 2.8 to 3.2 mg. of iron per day. Four chlorotic patients studied by Patek and Heath, 1936, in America averaged 5.4 mg., which is adequate for adults, but in the lower range. Twenty days of diet rich in iron raised their hemoglobin only from 30 per cent to 36 per cent; but it rose to 73 per cent in sixteen days of treatment with medicinal doses of iron and ammonium citrate.

The **therapeutic dosage** of iron in anemias should supply rather large quantities, so that the restoration may be accomplished promptly. The increase of hemoglobin should be no less than 1 per cent per day, if the original level was below 50 per cent. This amount of hemoglobin contains about 24 mg. of iron, and this quantity of iron suffices if it is administered parenterally (Heath, Strauss and Castle, 1932), *f. i.*, as iron and ammonium citrate; but since absorption is incomplete and varies for different individuals and different preparations, considerably larger quantities must be given by mouth, from 50 mg. to more than 1000 mg. of iron per day, usually about 200 mg. per day when administered as ferrous iron.

The *utilization of clinical iron medication*, with the modern full oral dosage, in hypochromatic anemias has been compared by Fullerton, 1934, on the basis that a rise of 1 per cent of the hemoglobin level contains about 24 mg. of iron. The results as shown in the table demonstrate that the four preparations studied gave practically the same improvement if effective doses were used. The difference of dosage corresponds to the difference in utilization, which was highest for the soluble ionized salts, less for the carbonate, and lowest for the citrate. On the basis of this table, the *effective daily dosage* (to utilize 30 mg. of iron) would be about 1500 mg. of reduced iron, assuming the absorption as 2.5 per cent. Tincture of ferric chloride, containing 4.5 per cent of iron, and assuming 20 per cent absorption, would require 3 cc. per day. The daily parenteral dose of the citrate, with 100 per cent utilization, would be 0.2 Gm.

Modern Dosage of Iron Compounds

Compound	Daily dose in Gm.	Fe content of daily dose in mg.	Utilization of daily Fe per cent	mg.
Iron and Ammonium Citrate	6.0	1215	2.5	30.4
Ferrous Sulfate, Exsiccated	0.6	180	15.7	27.2
Ferrous Carbonate Mass*	2.0 (U.S.P.) 3.0 (B.P.)	330	7.5	25.0
Ferrous Chloride, as pills	0.4	180	18.0	32.4

*Equivalent to ten Blaud's pills.

Until recent years, these preparations were generally used in an eighth to half of the above daily doses: six Blaud's pills; 2 cc. of tincture of ferric chloride; 0.2 Gm. of reduced iron; and 0.75 Gm. of the citrate by mouth, 0.1 Gm. hypodermically. This may account for the discredit into which iron therapy had fallen until it was reinstated in more effective form by better controlled observations.

In nutritional anemia of *infants*, 10 mg. of Fe per day suffices if administered as ferrous chloride, but 750 mg. are required as ferric ammonium citrate. Older children require 50 to 200 mg. as ferrous chloride (Lucas and Summerfeldt, 1939).

Choice of Iron Preparations; Administration.—The demonstration of the therapeutic effects of iron was first made with inorganic forms. Sydenham, 1661, in the treatment of chlorosis, used a wine of iron, but chiefly the chalybeate mineral waters, as "more congenial to nature"; Blaud in 1831 introduced his famed pills of ferrous carbonate; many other iron salts had demonstrated their clinical usefulness in the treatment of chlorosis before the "food-iron" theory came into vogue (about 1885). Notwithstanding the polemics of Bunge, clinical experience continued to confirm that the inorganic preparations are more effective than the organic. Even the insoluble carbonate (Blaud's pill) or reduced iron are readily dissolved by the gastric hydrochloric acid. The choice may therefore be determined chiefly by the differences in local action, by expense and by convenience. Solutions of ionized iron salts are astringent in the mouth, and attack and discolor the teeth, somewhat even when taken much diluted and through a glass tube. Their stains on silver spoons may be removed by ammonium hydroxide. The citrate in solution also blackens the teeth. These effects may be avoided by using the solid drugs in pills or capsules. They may also cause gastro-intestinal irritation, constipation and diarrhea, these being less with the citrate and least with the carbonate and reduced iron. The water-insoluble preparations require gastric acidity for their solution, and would therefore be less effective in hypochlorhydria. They should be taken just before meals, to secure maximal contact with the gastric acid, while the soluble iron salts are taken just after meals to minimize their local action. The citrate combines assured efficiency with a minimum of local action, but it is rather expensive. The ferrous sulfate and chloride are more economical, and can generally be taken as pills without serious inconvenience. They should be made into a mass with glucose, to protect them against oxidation, which renders them less effective (Reimann and Fritsch, 1930). A syrup of ferrous sulfate, containing 32 mg. of Fe per 4 cc., is described and recommended by Lucas and Summerfeldt, 1939.

There is no justification for using "organic" iron preparations. Hypodermic administration of iron and ammonium citrate (1 cc. of 10 per cent) should only be considered if oral administration is not feasible, for it is rather painful and sometimes produces severe local and systemic reaction, gastritis, and the like. These accidents have not been observed in animals even with much larger doses (L. W. Rowe, 1917).

IRON PREPARATIONS.—Only the most important preparations need be described. It may be remembered that ferric salts have a reddish, the ferrous a greenish, color. The most important *incompatibilities* are: alkalis, salicylates, phenol.

INSOLUBLE IRON PREPARATIONS.—***Reduced Iron,** U.S.P. (Ferrum Reductum), is iron reduced to the metallic state by the action of hydrogen upon ferric oxide. Very fine, grayish-black, lusterless powder, without odor or taste. Dose, 0.5 Gm., 8 grains, as powders or capsules. ***Ferrous Carbonate Pills,** U.S.P. (Blaud's, Chalybeate or Ferruginous Pills), contain 65 mg., 1 grain, of $FeCO_3$, made from ferrous sulfate and potassium carbonate. Contrary to the prevailing impression, the U.S.P. Blaud's pills are quite stable, and preferable to the proprietary substitutes (Warren, 1915). Dose, five pills. *Mass of Ferrous Carbonate,* U.S.P., *Vallet's Mass,* a pilular mass containing about 40 per cent of ferrous carbonate. Dose, 0.6 Gm. *Magma of Ferric Hydroxide,* U.S.P. (Arsenic Antidote; Ferric Hydrate with Magnesia); 40 cc. of Solution of Ferric Sulfate are diluted with 125 cc. of water. This is added, when needed, to 10 Gm. of Magnesium Oxide, or 300 cc. of Magma Magnesia diluted with water to about 750 cc. The dilute solution of ferric sulfate and magnesia mixture should be kept on hand in separate bottles, ready for immediate use, so that this antidote to arsenical poisoning may be quickly prepared. Dose, 120 cc., 4 ounces.

"SCALE SALTS" OF IRON.—***Ferric Ammonium Citrate,** U.S.P., a mixture of ferric citrate and ammonium citrate containing about 17.5 per cent Fe (20 per cent, B.P.), occurs as thin, transparent, garnet-red scales or granules without odor and having a saline, mildly ferruginous taste; deliquescent in moist air. Readily and completely sol. in water; reaction nearly neutral; insoluble in alcohol. Average dose, 1 Gm., 15 grains. *Ferric Ammonium Capsules,* U.S.P.; usual size, 0.5 Gm., 7½ grains. *Green Iron and Ammonium Citrates,* U.S.P. (Ferri et Ammonii Citrates Virides), 15 per cent Fe, occurs as green scales or granules having similar properties; very soluble in water, with acid reaction. Dose, by parenteral injection, 60 mg., 1 grain.

SOLUBLE FERROUS SALTS.—***Ferrous Sulfate,** U.S.P. (Green Vitriol); $FeSO_4 \cdot 7H_2O$, corresponding to about 56 per cent of anhydrous ferrous sulfate; large, pale green crystals; odorless, saline styptic taste; effloresces in dry air. Freely sol. in water (1:1.4) with acid reaction; practically insol. in alc. Dose, 0.3 Gm., 5 grains. The crude salt is employed as a deodorizer for fecal matter, but is not germicidal. *Exsiccated Ferrous Sulfate,* U.S.P., not less than 80 per cent of the anhydrous salt. *Dose,* 0.2 Gm., 3 grains. *Ferrous Sulfate Tablets,* U.S.P.; usual size, 0.3 Gm., 5 grains. *Ferrous Iodide Syrup,* U.S.P., 5 per cent of ferrous iodide, FeI_2, is a pale green acid liquid of strong iron taste. Very susceptible to oxidation, turning brownish. It combines the therapeutic properties of iron and iodides, and is often prescribed in goiter (2 drops, twice daily, gradually increased to 15 drops three times daily; Marine and Lenhart, 1911) and as a general tonic in "scrofulous" conditions. Average dose, 1 cc., 15 minims, contains about 52 mg., 0.85 grain, of iodine.

SOLUBLE FERRIC SALTS.—**Ferric Chloride Tincture,** N.F., about 13 per cent of $FeCl_3$ or 4.5 per cent of Fe, is prepared by mixing the liquor (solution) with alcohol. The U.S.P. IX directed it to stand three months before using, to permit the formation of esters. A bright, amber, acid liquid of slightly ethereal odor and astringent taste. Miscible with water or alcohol. Dose, 0.6 cc., 10 minims, diluted. Often used as local astringent in tonsillitis (equal parts of the tincture, glycerin and water). *Ferric Chloride Solution,* N.F., contains 30 per cent of the $FeCl_3$, or 10 per cent of Fe. Dose, 0.1 cc., 1½ minims. *Iron Subsulfate Solution* (Monsel's Solution, Sol. of Basic Ferric Sulfate) contains 21 per cent of Fe. Dose, 0.2 cc., 3 minims. Used mainly locally, as styptic. *Iron Tersulfate Solution,* N.F., contains 10 per cent of Fe as ferric sulfate. *Iron (Chalybeate) Mineral Waters* contain the iron most often as ferric bicarbonate; sometimes as sulfate, oxide and rarely as chloride.

ANTIANEMIC LIVER AND STOMACH PREPARATIONS

Liver contains a substance or complex necessary for the formation of blood in the bone marrow. The agent is formed in the stomach by the digestion of certain proteins, the "extrinsic factor," by some ferment, the "intrinsic factor." The product is absorbed and stored in the liver as the "active substance" of the liver. Its deficiency is "idiopathic," pernicious ("primary") anemia and in sprue impedes the orderly maturation of the megalocytes into reticulocytes, with secondary increased destruction of erythrocytes and hyperchromic anemia. This in turn results in degenerative anatomical changes in the central nervous system, perhaps as a result of the anoxia. The deficiency can be relieved completely by the administration of raw liver, liver extract, dried stomach and in most cases by folic acid, except for the anatomical nervous changes which have already taken place. The administration has no effect on normal individuals, but in these anemias it causes prompt resumption of the progressive development of the megalocytes, increased output of reticulocytes and steady rise of the red cell count and hemoglobin to the normal level, which is maintained as long as the administration is continued, but relapses when it is discontinued; except that a limited amount may be stored if large doses have been given, especially by a parenteral injection, when it may last some weeks. Oral administration is quite effective, but there are limits to the absorption, so that considerably larger doses are necessary. Interference of diarrhea with absorption may be a factor in the causation of sprue, while the hypochlorhydria of pernicious anemia may be a factor in diminishing the formation of the active complex. These antianemic preparations are also useful in some obscure anemias. In secondary anemias generally they have no effect unless iron is administered, when they hasten its transformation into hemoglobin and thereby increase its absorption. They are generally superfluous, but are valuable adjuncts when iron alone does not prove sufficiently effective. The active principle has not been definitely isolated. The potency of the preparations must be ascertained by actual trial on anemia patients by a standardized technic, established, reviewed and supervised by a special Advisory Board of the U.S.P.

Historical.—The treatment of pernicious anemia was unsuccessful and the course invariably fatal as the name implies, until the discovery of the specific antianemic action of liver. This started with the demonstration of Whipple and Robscheit-Robbins, 1920 and 1925, that dogs subjected to severe anemia by repeated hemorrhage assimilated iron more efficiently and recovered more rapidly on diets rich in liver, heart or skeletal muscle, or some other foods. The effect of liver was especially striking, and this came to be commonly added to the diet of patients suffering from various anemias, including the pernicious. The results were rather doubtful, until much larger quantities of liver were taken by a pernicious anemia patient under the care of G. R. Minot. Minot and Murphy, 1926, 1927, reported a considerable series of patients with this disease, in whom striking, prompt and lasting improvement resulted from diets including daily 250 to 500 Gm. of mammalian liver. Cooked liver is quite effective, although raw liver pulp may be more active. Kidney is also potent. An aqueous deproteinated extract ("*No. 343*") was found to be fully effective and suitable for clinical use (E. J. Cohn, Minot and Murphy *et al.*, 1927), even for intravenous injection. The common occurrence of gastric achylia in pernicious anemia suggests the possibility of a causal relationship. Castle, 1929, found that the feeding of beefsteak, which had been digested with normal human gastric juice, produced the same response as the liver preparations; predigestion by the ordinary commercial pepsins was ineffective. C. S. Sturgis and Isaacs, 1929, 1930, showed that the desiccated stomach of the hog is highly potent (about equivalent to an equal weight of the Concentrated Liver Extract 343). It acts even without added meat (Kandel, 1931).

Special Characteristics of Pernicious Anemia.—Pernicious or primary anemia, first described in 1849 by Addison as "idiopathic anemia," differs from other so-called "secondary" anemias not only in the absence of recognized cause, but in the failure to respond to the forms of treatment to which these are amenable. Iron therapy is totally ineffective in pernicious anemia; indeed, it appears that the untreated patients have more iron available than can be used in the diminished manufacture of red blood corpuscles, for the color index is high and the granular *reserve iron* of the liver and spleen is considerably increased (Rumpf, 1901), as is also the dissolved iron of the spleen (Erben, 1900). The *iron of the serum*, which is normally between 1 and 1.4 mg., median 1 mg., per 100 cc., rises to 1.5 mg. in the attacks of pernicious anemia, returning to about 1.1 mg. during recovery. The excretion of iron is increased, even for eleven weeks after remission (H. H. Ricker and Winters, 1930). The urinary excretion was said to remain normal (Queckenstedt, 1913). It is evident, therefore, that the disease does not depend upon deficiency of iron, but on an anomaly in the blood-corpuscle regulation. There is direct evidence for defective blood formation in an actual paucity of blood-regenerating cells of the hematopoietic system, and in megaloblastic hyperplasia of the bone marrow (F. W. Peabody, 1927; F. Koller, 1939); the increase of urobilinogen indicates that blood destruction is also increased. The disease is subject to spontaneous remissions. It is associated with characteristic digestive disturbance, especially gastric achylia, anorexia, and glossitis; and eventually with anatomic degeneration of the central nervous system, especially the sensory spinal tracts, leading to paresthesias. These nerve changes may perhaps be the result of deficient oxygen supply. The gastric disturbance may be concerned directly in the causation of the disease (Johansen, 1929).

The **therapeutic response** to effective liver or stomach administration in pernicious anemia starts with prompt and extensive, but temporary, increase of immature blood cells, the reticulocytes, in the peripheral blood; this is accompanied by a slower increase of mature red cells and of hemoglobin, which progress to the normal level. The megaloblastic hypertrophy of the bone marrow recedes to normal as the blood picture improves. The reticulocytes rise from the normal of 1 per cent or less, to 15 per cent or more, within five to ten days (Porter and Irving, 1929), then decline to the original level in about sixteen days when the restoration of the mature red cells is only half completed. This is distinctly improved within ten days, and attains to nearly normal generally within three weeks. With adequate and continuous dosage the improvement is certain. The response may be checked by complications, such as infections, but failure to respond within four weeks throws doubt on the diagnosis. Relapse occurs only if the administration is intermitted.

The *stimulation of the bone marrow to maturation of th megaloblasts* is confirmed by the response of healthy grain-fed *pigeons*, which normally have a megaloblastic condition of the bone marrow and a 10 per cent reticulocyte count. In these, the liver preparations, and their analogues, by mouth or vein, produce an increase of reticulocytes and diminution of the megaloblastic tissue. In contrast to pernicious anemia, the increase of reticulocytes is maintained, and there is no increase of erythrocytes. The difference may be attributed to the fact that the megaloblastic condition is normal for pigeons, and is, therefore, not abolished, but merely modified by treatment. The effect is specific for active preparations (including beefsteak); it is not produced by iron or histamine, or by inactive extracts (J. F. Vaughan, Muller and Zetzel, 1930). The excretion of *endogenous uric acid* is increased during the liver treatment in pernicious anemia (not in normal individuals), presumably by destruction of the red cell nuclei (M. C. Riddle and Sturgis, 1929).

Infections interfere with the response to liver therapy. This holds also for *pigeons:* infection with virulent Staphylococcus aureus decreases the normal reticulocyte count to half or lower, and prevents a good reticulocyte response to the injection of liver extract (G. L. Muller).

Responses of Other Anemias.—Liver or stomach therapy is as effective in *sprue* as in idiopathic anemia. It is also effective in *pellagra,* in conjunction with vitamin therapy (T. D. Spies, 1934), and in *tapeworm* anemia as adjuvant to iron (Birkeland, 1932). Clinical *secondary anemia* improves most rapidly if the iron therapy is supported by liberal diet and liver therapy, preferably by weekly parenteral injection of liver extract (Powers and Murphy, 1931; Murphy, 1933; review, West, 1935).

Liver has generally proved ineffective in the anemia of rice diet and fasting in pigeons (G. L. Muller, 1927, 1929; Barlow, 1930); in the bartonella anemia of rats (Neumann, 1930); and in entameba anemia of dogs (Kagy and Faust, 1930). With phenylhydrazine anemia in rabbits, no response was obtained by Adlersberg and Goldsegen, 1920, but Wright and Arthur, 1930, reported benefit. Paschkis and Taylor, 1934, reported it ineffective against phenylhydrazine, but effective against saponin anemia in rabbits.

The gastric factors furnish the starting point of the hematopoietic substance. This is formed by the digestion of meat and certain other protein foods with an unidentified enzyme present in the *intrinsic factor* of normal gastric juice of man and other mammals, but not in the gastric juice of pernicious anemia patients or in acidified solutions of pepsin (Castle, 1929). Idiopathic anemia is caused by partial or complete lack of this intrinsic factor in the gastric juice. It may be exaggerated by inadequate supply of *extrinsic factor* in the diet; and by failure to absorb the active substance from the digestive tract, or by its destruction there, so that oral administration of stomach or liver preparations may be ineffective, while parenteral injection of liver extract is effective; which is not uncommon in advanced cases (review, Castle, 1935).

Gastric juice does not contain the active principle, unless it has been in contact with extrinsic factor (Castle and Ham, 1936). *Extracts of the gastric mucosa* are also ineffective (Henning and Stieger, 1930), but become effective by incubation with extrinsic factor (Conner, 1931). Acidulated extracts of all regions of the stomach contain active substance if they include the muscular coat, which furnishes the extrinsic factor. It is abundant in dried *excised stomach,* if desiccated below 70° C. (Sturgis and Isaacs, 1929), being doubtless formed by self-digestion, the gastric muscle serving as extrinsic factor. Pylorus preparations are highly active, the fundus inert, the reverse of their content of pepsin and rennin (Meulengracht, 1935); but excision of the entire gastroduodenal portion of the stomach (Bachrach and Fogelson, 1937), or indeed of the entire stomach from dogs, does not lead to pernicious anemia, even after six years.

The *intrinsic gastric factor* is inactivated at 70° C., in solution and is presumably an enzyme (Strauss and Castle, 1932), but it has not been identified with any known constituent of gastric juice. It is not pepsin, rennin, lipase or hydrochloric acid. It is absent from normal saliva and duodenal juice and from the gastric juice in pernicious anemia, even when this contains normal amounts of acid and pepsin; it is present in the gastric juice of achlorhydria, if this is not caused by pernicious anemia (review, Castle, 1935). Exposure of normal human gastric juice to *p*H 10 for thirty minutes destroys its peptic activity without markedly affecting the intrinsic factor (Flood and West, 1936). The *extrinsic or food factor* resists autoclaving and is soluble in 80 per cent alcohol. It may be furnished by muscle, eggs, autolyzed yeast, rice polishings, wheat germ, spleen pulp, liver (fraction G); not by casein, wheat gluten or nucleic acid (Castle, 1935). *Digestion of liver extract* or its "G" fraction with stomach or gastric juice increases the activity three to seven times, permitting smaller dosage (Walden and Clowes, 1932). Autolysis of liver was reported to increase its activity (Herron and McElroy, 1933), implying that it may furnish the intrinsic as well as extrinsic factor. It has therefore given rise to some controversy (1937).

Liver Extract and Active Substance.—The continuous consumption of large quantities of liver is inconvenient and generally distasteful. E. J. Cohn, Minot and Murphy, and their associates, 1927, found that the activity is retained by deproteinated aqueous extracts, which may be greatly concentrated and are not disagreeable to take. "*Liver Extract No. 343*" is a powdered concentrate of this sort; several other liquid extracts for oral and for parenteral administration are on the market.

The *active substance* is soluble in water and dialyzable, insoluble in absolute alcohol, somewhat soluble in acidified alcohol, and in fat solvents. It is destroyed by strong alkalis and acids, not by boiling. It is free from protein, iron, carbohydrates and lipoids. Its nature has not been identified, but the properties point to polypeptide structure (Dakin and West, 1935; reviews, West, 1935; Y. Subbarow, Hastings and Elkin, 1945). It contains 10.6 per cent of nitrogen, but does not give the biuret reaction. Its hydrolysis yields beta hydroxyglutamic acid and l-gamma hydroxypyroline. Later evidence (B. M. Jacobson and Subbarow, 1937, 1941) indicates that the activity is not due to a single substance, but to a complex of at least four chemical entities. The primary factor, not chemically identified, produces submaximal reticulocyte response, but does not increase the erythrocytes when administered alone. The full response requires three accessory substances which are inert when given without the first substance. They have been identified as derivatives of tyrosine, purine and peptide, respectively.

Other Liver Extracts.—Several other kinds of active extracts are prepared from liver: for instance, Heparin, which prevents the coagulation of blood; another extract, which lowers the blood pressure on intravenous injection by a shock reaction, has been suggested against hypertension and eclampsia; it would appear a dangerous agent.

Standardization and Dosage.—The activity of liver extracts and also of stomach preparations varies widely, even if prepared by the same method, so that they must be standardized. This is done clinically on patients with pernicious anemia, by the reticulocyte response and by the rise of hemoglobin, as no other reliable method is available. The U.S.P. Anti-Anemia Preparations Advisory Board "*unit*" is the smallest amount which, given daily to patients with pernicious anemia, produces a satisfactory hematopoietic response, according to the criteria prescribed by the Board. The strength of the preparation is shown by the amount which must be administered to produce this effect, which is then the minimal daily dose, whether given daily or in multiple amounts with longer intervals. Larger amounts are often administered. In general, the oral unit would be contained in 300 to 400 Gm. of fresh liver, 30 to 40 Gm. of desiccated stomach, 13 to 25 Gm. (3 to 6 level teaspoonfuls) of dry liver extract, and widely varying amounts (but not less than 1/15 cc.) of the solutions intended for parenteral injection. The latter are not interchangeable with the oral preparations, since the factor of absorption enters into the assay, for ordinarily about thirty and up to seventy times more is required by mouth than hypodermically. The unit therefore applies to the method of use. Even with oral use, the potency of the extracts does not necessarily correspond to the amount of liver from which they have been produced.

Standardization on animals would be desirable and has been attempted, especially on pigeons (Wakerlin *et al.*, 1936) and on guinea pigs (B. M. Jacobson, 1934, 1936), but the results are not sufficiently consistent. Isolated bone marrow was proposed by N. Pace *et al.*, 1942.

Administration.—*Dry liver extract* occurs as a yellow water-soluble powder of not unpleasant taste. It is administered orally in water, soup, orange juice or other vehicle. *Liquid liver extracts* for oral use are also marketed. *Desiccated stomach* (ventriculin) is administered similarly. The therapeutic response is identical with that to the liver extract, quite as uniform, and perhaps even somewhat prompter (Rosenow, 1930; Wilkinson, 1930). *Parenteral administration of antianemic liver extract* is more effective than oral (Strauss, Taylor and Castle, 1931; W. P. Murphy, 1932) and is preferred in patients who are critically ill, especially to arrest spinal degeneration; where oral administration is not sufficiently effective; or when distaste is invincible. The smaller dosage renders it more economical. The solutions especially prepared for this purpose may be injected intramuscularly or intravenously, but the latter sometimes causes serious shock reactions, especially if the extracts are not sufficiently pure (Castle and Taylor, 1931). *Intramuscular injection* can be used without hospitalization and with relatively little discomfort. There may be pain, extending along the leg; sometimes fever of 99° to 102° F.; but no allergic reactions or erythema (Murphy, 1932). (Intradermal injection may produce severe reactions; J. G. McSorley and Davidson, 1944.) The parenteral injections are usually given in sufficient amount so that they need be repeated at intervals of one to three weeks, for maintenance. With massive doses, intramuscularly, the effect may last two to eight months (F. H. Miller, 1937), so that there is evidently effective storage. The substance passes across the placenta, for it is plentiful in fetal calves' liver (Wigodsky *et al.*, 1938).

PREPARATIONS.—***Liver Extract,** U.S.P. (Extractum Hepatis; Dry Liver Extract); "contains that soluble thermostabile fraction of mammalian livers which increases the number of red blood corpuscles in the blood of persons suffering from pernicious anemia." The average dose, corresponding to one U.S.P. unit, is to be stated upon the label of the container. *Liver Solution,* U.S.P., contains 12 to 25 per cent alc.; not more than 40 per cent of glycerin. Conforms to the U.S.P. specifications. Dose, to be stated upon the label of the container. ***Liver Injection,** U.S.P., **Purified Liver Solution,** is a sterile watery solution prepared for parenteral use. Conforms to the U.S.P. specifications. May contain not in excess of 0.5 per cent of cresol or of phenol; ampuls of 2, 5, 10 and 15 units in one cubic centimeter. *Liver with Stomach,* U.S.P., a dry mixture of liver extract and minced hog stomach. Its potency is higher than that of its separate components; the average dose, however, corresponds to one U.S.P. unit. ***Powdered Stomach,** U.S.P. (Stomachus; Ventriculin), is the dried and powdered defatted wall of the stomach of the hog. It contains that antianemic factor which causes an increase in the number of red blood corpuscles in the blood of persons suffering from pernicious anemia. Conforms to specifications as outlined by the U.S.P. The activity is readily destroyed when the preparation is suspended in hot liquids.

◆

FOLIC ACID (PTEROYL-GLUTAMIC ACID)

Folic acid, M vitamin, Lactobacillus casei factor (also named $B_{10, 11}$, c and factors U, R and S), is a constituent of the B vitamin complex, which has been crystallized and synthesized (R. B. Angier *et al.*, 1945; R. B. Angier, Boothe *et al.*, 1946; J. H. Mowat, 1946). The therapeutically active form of synthetic pteroyl-glutamic acid is pteridyl-p-aminobenzoyl glutamic acid, abbreviated as *pteroylglutamic* acid. This is the form marketed as *synthetic folic acid.* Several clinically inactive modifications contain additional molecules of glutamic acid.

Folic acid has antianemic actions closely resembling those of liver, but not quite identical. Striking clinical effects against macrocytic anemia, pernicious anemia and sprue have been reported by T. D. Spies, 1946; C. V. Moore *et al.*, 1946; R. W. Heinle and Welch, 1947; G. A. Goldsmith, 1947; and others. It is not effective in any condition in which liver is ineffective; the restoration of the blood picture is often not complete. In some patients it does not prevent neurologic relapse even when the blood picture is restored; indeed, it appears as if the folic acid actually precipitated the neurologic manifestations in some cases. It should therefore be used only as adjuvant to liver therapy in pernicious anemia. It is employed especially in sprue. Oral administration is equally effective as parenteral, or more so. Folic acid appears essential to all types of bone marrow cells. It stimulates hematopoiesis and growth in rats, chicks and guinea pigs.

Historical.—P. L. Day *et al.*, 1935, observed that Rhesus monkeys on restricted diet developed a deficiency disease which was cured by some special factor in yeast and liver extract which they called *M vitamin.* P. L. Day *et al.*, 1945, also found this essential for the growth of *Lactobacillus casei*, and necessary for normal growth and hemoglobin formation in chicks.

Occurrence.—The name folic acid was derived from spinach leaves, one of the earlier sources. It occurs in liver, but highly purified potent liver extracts contain only ineffective traces. Folic acid is also present in many other foods, chiefly in the conjugated forms, which appear inactive in anemia, although they seem to suffice for normal protection (A. D. Welch, Heinle *et al.*, 1946).

Toxicology.—Folic acid is almost devoid of side actions even when doses far above the clinical equivalent are continued for long periods. It is not irritant hypodermically, has no effect on the blood sugar level, and has a feeble action on isolated intestines. The acutely lethal dose exceeds 200 mg. per Kg. (Harned *et al.*, 1946).

Deficiency Phenomena.—Folic acid has been shown to be a dietary essential for chickens and turkeys, rats, mice, guinea pigs, dogs, monkeys and man. Its deficiency produces stunted growth, anemia, leukopenia, granulocytopenia, digestive disturbances, spastic cervical paralysis, dermatoses, achromotrichia, perosis. The defect probably enters into some phase of nitrogen metabolism, perhaps in the synthesis of thymine (review, F. S. Daft, 1946). T. D. Spies, Vilter *et al.*, 1946, report that *thymine* appears as successful as folic acid in pernicious anemia.

Deficiency of folic acid can be induced in rats by adding 1 per cent of succinyl sulfathiazole to the food, presumably inhibiting the normal synthesis of folic acid by intestinal bacteria. The effects can be prevented or corrected by adding folic acid to the diet (K. M. Endicott and Ott, 1945). Deficiency in monkeys produces the effects of deficiency of the antianemic liver factor (J. M. Cooperman, Elvehjem *et al.*, 1946). Acetylcholine hyperchromic anemia in dogs is cured by folic acid, as by liver extract. Both increase the cholinesterase activity of the blood (J. E. Davis, 1946).

Clinical Results.—T. D. Spies, 1946, reports prompt hematopoietic response, increase of reticulocytes, erythrocytes, and decrease of the megaloblasts of the bone marrow, on parenteral or oral administration of synthetic folic acid in the macrocytic anemias of pellagra, pernicious anemia, sprue and pregnancy. It is ineffective against aplastic anemia, leukemic anemia, and iron deficiency anemia. It improves nutritional neutropenia, but not that of infectious diseases or idiopathic conditions. It is supposed to accelerate the development of immature erythrocytes in the bone marrow (C. C. Sturgis, 1946); but it does not mature the primitive red cells *in vitro*, as does antianemic liver extract (E. E. Hays, 1946). Folic acid would be especially useful for patients who do not tolerate liver. The maximal response may often be procured by 10 or 20 mg. daily by mouth, and can generally be maintained with 2.5 to 10 mg. daily. No untoward symptoms were produced by 400 mg. daily. W. J. Darby and Jones, 1946, obtained complete hematologic response in nontropic sprue from daily intramuscular injections of 15 mg. C. V. Moore *et al.*, 1946, find that the potency is quantitatively less than some of the liver extract fractions. At least 5 mg. parenterally are required for maximal response, sometimes 100 mg. The potency is not increased by incubation with gastric juice.

◆

GERMANIUM

The injection into rabbits of the dioxide of this rare element causes some increase of the blood cells, attributed to stimulation of the bone marrow (Hammett *et al.*, 1922; J. H. Muller and Izsard, 1922; Beard, Myers *et al.*, 1931). This does not occur in rabbits (Minot and Sampson, 1922), and no significant effects have been observed in any type of clinical anemia (Garvin, 1922; Alexander, 1923).

Plants absorb germanium if it is added to the soil. Small amounts stimulate their growth, large amounts are toxic. The mould Aspergillus niger can take up and store large quantities without being poisoned (Geilmann and Brünger, 1935).

◆

MANGANESE

This metal resembles iron chemically and occurs widely distributed in nature. Small amounts are present in all animal and plant tissues, and appear essential for growth and reproduction, probably as oxidative catalyst. The absorption is limited, so that it does not produce acute effects other than local, the latter especially as the oxidative, antiseptic and astringent effects of potassium permanganate, the form in which it is principally employed in medicine. Continued administration of manganese assists in the assimilation of iron into hemoglobin. Prolonged exposure to excessive quantities of manganese, especially in the form of dust, leads to an industrial manganese toxicosis, with prominent cerebral symptoms, mental and ataxic (review, Fairhall and Neal, 1943).

Potassium permanganate, $KMnO_4$, in the presence of organic matter splits readily into MnO_2 (forming a brown precipitate) and active oxygen. It is therefore an effective oxidizing agent and disinfectant, but its efficiency is limited by any excess of organic matter. Its action is only superficial, and it is markedly irritant. It is used as an antiseptic for *mucous membranes and the skin*, in dilutions of 1:10,000 to 1:100; especially in the urethra (1:4000 to 1:1000). Hot irrigation with this solution is followed by catarrhal secretion which is supposed to clear the gonococci. A 1:5000 solution is said to be a satisfactory anesthetic for introducing urethral sounds (Barton, 1913). Beck, 1913, recommended it against *burns* (1:4000 to 1:3000 on gauze and as lotion). As a *mouth wash*, one or two crystals may be added to a tumbler of water, enough to give a rose or claret color. *Tablets* of 0.03 Gm. are convenient for these uses. *Ringworm and bromidrosis of the foot may be treated by soaking* half an hour daily in a basin of hot water with permanganate, a tablet per pint. The *brown discoloration* of the skin, due to reduction products, may be removed by vinegar or lemon juice. A saturated solution may be employed for disinfecting the hands, followed by 1 per cent oxalic acid solution to remove the stain. It is effective against *snake bite*, but only if used within five minutes (1 per cent, applied to free incisions after double ligature, if possible; Weidenmann, 1915; A. M. Reese, 1934). Permanganate has been widely used as a general *antidote to organic poisons* before they leave the stomach, but its usefulness is limited by the presence of food in the stomach and by its own toxicity. Concentrated solutions are caustic, and even fairly dilute solutions are quite irritant. Large doses may produce fatal gastro-enteritis. The concentration should not exceed 1:2000 if a tumblerful is administered; 1:10,000 may be used for lavage; none should be left in the stomach. It should not be relied upon to destroy all the poison, but the stomach should be evacuated. It may be quite *effective* against a number of alkaloids, including aconitine, morphine and strychnine; also against picrotoxin, amidopyrine and antipyrine. It is useless against atropine, cocaine, phosphorus, and most hypnotics and of little use against cyanides. Phenol would require larger doses than can be used (Hatcher, 1935).

Intravenous injection of permanganate causes immediate intense hemolysis and capillary injury. It is reduced, first to colloidal manganous oxide, MnO, and finally to the dioxide, MnO_2 (Sabbatani, 1928).

Smooth muscle is stimulated by direct contact with permanganate, 0.02 to 1 per cent; perfused blood vessels of guinea pigs are constricted as with epinephrine; excised *intestine* of rats and rabbits responds with increased tonus, which may be inhibited by atropine. Excised *uterus* of guinea pigs also gives prolonged increase of tonus, which is relaxed by epinephrine, but not by atropine (de Jongh, 1933). Oral administration to rabbits, 1 to 2 cc. of 1 per cent, also increased uterine activity; daily administration caused death of the embryos in pregnant guinea pigs, and abortion in pregnant mice (de Jongh, 1933), presumably secondary to gastroenteritis.

Intravenous injections of manganese chloride, $MnCl_2$, were introduced in schizophrenia (1 to 8 cc. of 1:400 solution, twice weekly for ten weeks). They cause some flocculation reaction, which probably accounts for whatever therapeutic effects may have resulted. English, 1929, claimed marked improvement in the mental and physical condition of over half of the patients, but later observers do not seem to have obtained these favorable results. Oral administration and intramuscular injection of colloidal manganese are ineffective (R. G. Hoskins, 1934). Bargero, 1906, found manganese toxic by vein, and observed fatty degeneration of the liver. A variety of *skin diseases*, especially acne, furunculosis and sycosis, have been reported benefited by injection of manganese preparations (E. L. Oliver and Crawford, 1936), but further trials proved quite unsatisfactory (M. Sullivan, 1940).

Occurrence of Manganese.—Traces occur naturally in all organs, in man and various animals, and much more in plants, its presence being fairly constant in the same species (Bertrand and Medigreceanu, 1912). The daily income for man is about 10 mg. The amount in *wheat* is about equal to the iron (Headdon, 1915). Dried wheat grain contains 2.7 to 4.7 mg. per 100 Gm., depending on the soil; the greater part is in the bran (Javilliers and Imas, 1927). Whole wheat flour averages 3.5 to 4 mg. per 100 Gm.; patent flour, only 0.4 mg.; white bread, 1.1 mg. per pound; whole white bread, 11 mg. (C. Hoffman *et al.*, 1943). The *manganese of animals* is derived partly from vegetable, but mainly from animal, food; it does not disappear from the body even on manganese-free food. Mammals contain only one-tenth to one-fifth as much as other classes of animals. The content of the human liver and kidneys is practically constant throughout life (Brückmann and Zondek, 1939).

The manganese content of normal human blood averages 0.014 mg. per cent; of urine, 0.01 mg. per liter (W. C. Dreesen and Sievers, 1946).

Fate.—Manganese is *absorbed* to a slight degree from the alimentary canal, being *deposited mainly* in the liver and kidneys, and passing also to the fetus *in utero*. Its *retention* in preschool children is proportional to the amount ingested (Everson and Daniels, 1934). After intravenous injection of radioactive manganese the highest concentration by far is in the liver and kidneys; that in the brain is only a seventieth of the liver (H. J. Born *et al.*, 1943). Bone retains very little (M. S. Mohamed and Greenberg, 1943). Its *excretion* appears to take about the same course as iron (Harnak and Schreiber, 1901). After oral ingestion it appears as black sulfide in the feces. The absorption is slight (Bargero, 1906). Benedetti, 1906, and Piccinini, 1910, 1912, claimed that it increases the reserve iron. Benedetti also investigated the fate after subcutaneous injection of the citrate. *The excretion after intravenous or peritoneal injection* of radioactive manganese is almost entirely fecal; almost half of this is through the bile (D. M. Greenberg *et al.*, 1943). The excretion of bile is diminished by blocking the reticulo-endothelial cells with India ink, as is also the case with Fe, Ni and Co (Iwai, 1930).

Manganese deficiency phenomena in mammals consist in interference with growth and reproduction. They have been studied especially on *rats*, with synthetic diets practically freed from Mn. Impaired growth and slight progressive anemia develop when the daily income is reduced to 0.005 mg. (L. W. Wachtel *et al.*, 1943). The addition of 0.03 mg. of MnO_2 daily increased growth by a third over the controls; 0.9 mg. gave less growth than the controls, although the animals ate as much (McCarrison, 1927). Manganese deficiency diminishes the arginase concentration of the liver. The estrous cycle may be irregular or suppressed. Testicular degeneration and lack of spermatozoa production result in sterility. No histologic abnormalities are observable in the adrenals, kidneys, pituitary or thyroid; the ascorbic acid content of the tissues is normal (P. D. Boyer, Shaw and Phillips, 1942). *Mice* show little effect on growth, but the males become sterile, the young nonviable. All the changes in rats and mice can be reversed by administering manganese (M. E. Shils and McCollum, 1943). *Mn deficiency phenomena in chicks* are much more marked, resulting in "perosis" or "slipped tendons," shortness of legs, wings, spinal column and beak. This is said to occur also in chicks hatched from the eggs laid by Mn-deficient hens (C. D. Caskey *et al.*, 1944). It is not due to general growth retardation, nor to rachitis. The ash content of the bone is significantly lower than normal. It is remedied by adding Mn to the food, more effectively if the Ca and P income is relatively high. Hypodermic injection is more completely effective, with smaller doses (Schaible *et al.*, 1938; Insko *et al.*, 1938; Caskey *et al.*, 1939). If the diet remains deficient in Mn, the addition of Ca and P increases the perosis, probably by making the Mn less soluble (Wilgus and Patton, 1939). Sunlight decreases the deficiency phenomena (Christiansen *et al.*, 1939). When radioactive manganese is administered to deficient chicks it is excreted as in the controls (M. S. Mohamed and Greenberg, 1943). Small amounts of manganese and other elements, especially zinc and boron, increase materially the *growth of plants*. This is easily measured on cultures of the mould Aspergillus niger. It has been suggested that they act by killing competing or infective bacteria, but they appear to act directly (Bertrand, 1912).

Enzymes.—Manganous chloride accelerates autolysis when added to excised liver (Bradley and Morse, 1915). Manganese is essential for the oxidase concerned in plant color changes. It has been suggested that it is necessary for the utilization of thiamine.

Manganese Toxicosis.—Chronic poisoning results from exposure to the dust or fumes of any of its compounds in the industries, in zinc mines, grinding, and so forth (review, L. T. Fairhall and Neal, 1943). R. Kawamura *et al.*, 1940, reported a group intoxication from water of a well near which a large number of dry cells had been buried. The susceptibility varies considerably. The phenomena are due to severe atrophic changes in the basal ganglia, with symptoms closely resembling those of Parkinson's disease. They generally start insidiously in one to three years, sometimes three months after the beginning of the exposure, with languor, sleepiness, weakness of the legs; then fine tremors or gross rhythmical movements, marked emotional disturbances, uncontrollable laughter or crying, impulsive acts with a background of euphoria; then slowly progressive motor ataxia, usually without sensory disturbance; a peculiar stiffness of the muscles, with jerky walk; difficulty in speech, deglutition and facial expression, cramped handwriting; other muscle groups may become involved. The workers are reported to be more susceptible to pneumonia. Industrial workers exposed to inhalation of manganese oxides have a high incidence of respiratory inflammations, nasopharyngitis, bronchitis and pneumonia (T. A. L. Davis, 1946). Destruction of ganglion cells of the basal ganglia involving the thalamus and caudate and lenticular nucelus is responsible for most of the symptoms. The spinal cord and the peripheral nerves may also be affected (H. Voss, 1942). The prognosis is good as to life. Early cases recover spontaneously, more or less, when removed from exposure; the psychoses generally disappear slowly but completely; the neurologic symptoms persist in almost every case, and advanced symptoms cripple permanently, especially the legs. There is no effective treatment except prevention. The maximal permissible concentration in air has been tentatively placed at 6 mg. per cubic meter (review, L. T. Fairhall and Neal, 1943). The condition is not observed in the uses of manganese that do not involve dust; nor is it produced in animals by oral administration (von Oettingen and Sollmann, 1926), but this results in hepatic cirrhosis, preceded by excessive rise of blood sugar after administration of levulose or galactose. Manganese administration to rats decreases the time required by p-*dimethylaminoazobenzene* to produce liver tumor. This effect is not produced by Cu, Zn, Co or iodine (G. R. Sharpless, 1945). *Permanganate poisoning* may cause nephroses.

Preparations—*Potassium Permanganate, U.S.P.; $KMnO_4$; occurs as slender, dark purple prisms; odorless; astringent taste. Sol. in water (1:15); decomposed by alc. and all organic matter, and explosive. Dose, 0.06 Gm., 1 grain, U.S.P.; 0.06 to 0.2 Gm., 1 to 3 grains, B.P.; diluted.

Mangani Dioxidum Praecipitatum (Mangan. Diox. Praec.) consists chiefly of manganese dioxide (MnO_2). Prepared by precipitating manganese sulfate by ammonia in the presence of hydrogen dioxide. Heavy, fine, black powder, without taste or odor; insol. in water or alc. Dose, 0.25 Gm., 4 grains.

RHENIUM

Physiological effects have been studied by P. P. Cohen, 1940.

◆

CHROMIUM

Uses.—Chromium trioxide (chromic acid), CrO_3, is used externally as caustic. It and the chromates have some toxicologic importance, the *dichromate*, $K_2Cr_2O_7$, being used in dyeing and in "battery fluids." They produce a characteristic *nephritis* and glycosuria.

Chromic acid ulcers are an important industrial hazard in chromium plating.

The hydrogen evolved in the chromic acid bath carries up a fine spray of the liquid. This causes rhinitis, terminating in perforating ulcers of the nasal septum. Continued daily exposure to 1:10,000 of air suffices for this. The skin of the exposed hands and forearms may also be involved, with diffuse dermatitis, progressing to simple or multiple ulceration ("chrome holes"), but generally only if there has been previous abrasion. The ulcers develop slowly, but are deep and painful, with sloughing of the entire thickness of the skin and slow separation of the slough, with scarring. If they are not treated, they last indefinitely and may spread; but when the base is cleared, healing is fairly rapid and complete. *Prophylaxis* consists in transverse artificial ventilation to carry the spray away from the operator; rubber gloves and care as to any fissures and abrasions; protection of the inside of the nostrils and exposed skin by an ointment applied several times daily (petrolatum, preferably with 25 per cent of hydrous wool fat); washing with 5 per cent sodium thiosulfate ("hypo") (L. Schwartz, 1939).

Zinc chromate used as primer for paint, often produces gradual sensitization, persisting or increasing with continued exposure. A. F. Hall, 1944, reports that it was responsible for two-thirds of the dermatites among aircraft workers. The average time of exposure was seven months.

Acute peroral chromate poisoning exhibits corrosive effect and nephritis, with death in one to forty-eight hours. The symptoms begin with sore throat, vomiting, diarrhea, albuminuria and hematuria. Nervous symptoms develop. The blood pressure is low. Hemorrhages occur into the gastro-intestinal or respiratory tract. Less than 0.5 Gm. of potassium dichromate may cause serious poisoning, and the fatal dose is below 8 Gm.; of chromic acid, 6 Gm. The *treatment* is by evacuation and demulcents (review and bibliography, Rabbeno, 1933).

Fate.—When bichromates are given by mouth, they are reduced to chromous oxide and partly deposited as such in the organs, the rest being excreted by the urine (Kappeler, 1896). Bichromate transforms *hemoglobin* into methemoglobin *in vitro* (Mattucci, 1933).

Chromate nephritis is produced experimentally by hypodermic injection of the chromates. It is mainly tubular, but the glomeruli are involved first. All the phenomena are similar to those of uranium (including retention, glycosuria, chronic nephritis, and so forth), except that edema is not common (Gergens, 1876; Hellin and Spiro, 1897; Schlayer and Hedinger, 1907; Ophüls, 1908; Austin and Eisenbrey, 1911; R. M. Smith, 1911; Folin, Karsner and Denis, 1912; MacNider, 1912; Eisenbrey, 1913; E. Franck, 1913; glycosuria, Mosenthal and Schlayer, 1913; diuretics, and so on).

Internal Therapy.—Kolipinski, 1902 and 1908, reported favorable results from chromium sulfate (8 grains, three to four times daily) in neurasthenia, tabes and other nervous conditions. They have not been adequately confirmed.

PREPARATIONS.—*Chromium Trioxide*, U.S.P. (Chromic Acid; Chromic Anhydride); CrO_3; occurs as dark red, needle-shaped crystals, deliquescent and very sol. in water (1:0.6). *Explosive* with all organic matters. Used as a caustic, solid or in solution (1:1; as astringent (2 to 3 per cent); for urethral injections (1:2000 to 4000); and against sweating feet (5 per cent).

ALUMINUM

The soluble salts are strongly precipitant to proteins, and therefore astringent, styptic and antiseptic, but not corrosive to intact skin or mucosae. They are used externally and sometimes against diarrhea, the hydroxide also as antacid and protective in gastric ulcer. Very little is absorbed from the alimentary canal. Even large doses cause only vomiting and diarrhea, or local exudative inflammation and no direct systemic effects. The quantities which may be dissolved from aluminum cooking vessels, even by dilute acids, are too small to be of any importance. Alum baking powders also appear to be harmless.

Precipitant and Astringent Action.—A 1 per cent solution of alum precipitates proteins, and most colloidal suspensions. This is employed for clarifying turbid water. The protein precipitation is also used in the purification of toxins and antitoxins. The protein precipitates tend to redissolve in excess of protein. The precipitation or gelation of serum proteins is maximal with 8 per cent of aluminum acetate; this also produces maximal contraction of excised rat tendon (W. Straub, 1926). The astringent action was studied by Barinetti, 1914.

Local Use on Skin.—Solution of Aluminum Acetate, N.F. (Burow's Solution), containing about 5 per cent of neutral aluminum acetate, $Al(C_2H_3O_2)_3$, and the somewhat less astringent and less irritant *Solution of Aluminum Subacetate,* N.F., containing nearly 8 per cent of basic aluminum acetate, $Al(C_2H_3O_2)_2OH$, are used in dermatitis and burns. Both require dilution with 5 to 10 parts of water. A 1 per cent dilution of the acetate solution was reported to be antiseptic, and 5 per cent germicidal (Kuehl, 1913). *Alum* (potassium or ammonium and aluminum sulfate), as 1 per cent solution, is somewhat more irritant. A 2 per cent solution is used against excessive sweating; a saturated solution in 50 per cent alcohol is employed for the prevention of bed sores. *Aluminum chloride,* which is more irritant, is used as deodorant and against localized sweating of feet and axillae, as a 25 per cent solution, applied at first twice, then once, a week (Stillians, 1916). *On mucous membranes* alum is applied as astringent in dilutions of ½ to 1 per cent for the conjunctiva and urethra, 1 to 5 per cent for gargling; but it is somewhat injurious to the teeth. Aluminum chloride has no advantage. Alum crystals may be used as styptic; exsiccated or "burnt" alum is somewhat caustic when applied in powder, mainly by abstracting water. *Protection against poliomyelitis infection,* by intranasal sprays of alum and other astringents, which gave promising results on monkeys, proved unreliable clinically (C. Armstrong, 1937; see further under Zinc Sulfate).

Colloidal aluminum hydroxide as antacid and protective in peptic ulcer, administered as a creamy suspension ("*Aluminum Hydroxide Gel*") corresponding to 16–32 Gm. of $Al(OH)_3$ daily, offers advantages over soluble alkalis in that its insolubility provides against excessive alkalinization; its solution by the gastric acid renders it astringent and antiseptic. The undissolved hydroxide also adsorbs intestinal bacteria, but is somewhat constipating.

Its administration decreases the secretion of total and free acid, especially in marked hyperacidity, without diminishing the response to histamine, even after the administration has been continued for several months. Symptomatic relief starts in a few days. No bad effects of any kind were observed. The absorption is insignificant, the urinary excretion amounting to less than 1 mg. per day (W. L. Adams, Einsel and Myers, 1936). It is also used by continuous intragastric drip (E. E. Woldman and Rowland, 1936). Ivy *et al.*, 1937, found prompt reduction of free acidity in response to the alcohol test. Havens, 1939, reported a case of fatal intestinal obstruction following intragastric drip of 2000 cc. of 5 per cent suspension daily for five days. In normal dogs, massive doses (120 cc.) produced no significant effects on the motility or tone of the stomach or pyloric antrum, or on the gastric evacuation time (J. P. Quigley *et al.*, 1939). It does not depress the gastric pouch secretion (W. L. Adams and Clark, 1944). The action is therefore chiefly that of buffering against the hyperchlorhydria of the ulcer patients. It interferes materially with the absorption of PO_4 by rats (S. Freeman, 1942). The administration of aluminum hydroxide with kaolin is reported to suppress coli growth in fecal cultures much more successfully than the kaolin alone (W. Smith, 1937).

Dried aluminum hydroxide can be prepared with different degrees of solubility, the truly amorphous being more soluble. The acid-soluble form is more effective for neutralizing gastric acidity; the acid-resistant form is more suited as adsorbent in the intestines (N. Mutch, 1946).

Fate.—Practically no absorption of aluminum occurs if its compounds are administered by mouth, either as soluble salts or as the hydroxide or carbonate, or as baking powder residues, which are largely dissolved by the acidity of the stomach. Virtually the entire amount is recovered from the feces, almost none from the urine, although parenterally injected aluminum is excreted by both channels; nor is the small normal aluminum content of the organs increased significantly even when the administration is continued over long periods, in man or dogs or rats.

The highest content, in the liver of rats, amounted to 0.161 mg. per 100 Gm., against the normal of 0.130 mg. (V. C. Myers and pupils, 1928). Older investigations led to contradictory results, due largely to inadequate analytical methods. These are discussed by Evelyth and Myers, 1932.

The *feces*, after oral administration, contain the aluminum largely as the insoluble *phosphate* (Schmidt and Hoagland, 1919). This prevents the absorption and utilization of the phosphate, and if the dosage is large and the phosphate income is small, in guinea pigs and rabbits, the blood phosphate may be lowered to 15 per cent of the normal, and urinary phosphate excretion may almost cease (G. L. Cox *et al.*, 1931). A form of rickets may be produced by this means, but it is practically unimportant unless the phosphate income is deficient. *With intravenous injection* of aluminum chloride, aluminum appears promptly in the urine, bile and feces; but a considerable proportion is retained (Evelyth and Myers, 1936).

Occurrence of Aluminum in the Tissues Normally and after Administration.—Although aluminum is but slightly absorbed, its wide distribution insures its continuous ingestion and universal presence in animal tissues, in concentrations of 0.06 to 0.22 mg. per 100 Gm. of fresh tissues, human, dog, rat and others. The addition of considerable quantities of various aluminum salts does not materially increase the concentration in the tissues, generally to less than 0.25 mg. per 100 Gm. Parenteral (intraperitoneal) administration of small amounts of aluminum chloride over three to six months causes more marked increase, especially in the liver and spleen, but concentration still does not exceed 1 mg. per 100 Gm. (V. C. Myers and pupils, 1928; Evelyth and Myers, 1936).

The concentration in the tissues of dogs, after oral administration, averages (mg. per 100 Gm. of fresh tissue): bile, 0.35; liver, 0.27; kidneys, 0.07; heart muscle, 0.12; brains, lungs, pancreas, urine, 0.10; spleen, 0.08; blood and bone, below 0.04. The liver of rats averages 0.08 mg. on Al-free diet; 0.14 on normal diet; 0.18 on Al-enriched diet; and 8.2 on intraperitoneal injection. E. W. Schwartze *et al.*, 1933, found the normal Al of guinea pigs to average less than 0.04 mg. per 100 Gm. Feeding large amounts of aluminum salts increased it to less than 0.1 mg. Wührer, 1934, also confirmed that feeding aluminum salts does not increase the aluminum of the organs.

The harmlessness of aluminum compounds on oral administration, even when prolonged (aside from local actions if concentrated solutions are swallowed, and the phosphate disturbance if large doses are given) is clearly established both by animal experiments and by clinical experience.

Rats fed for four generations with 2 mg. of alum daily did not show diminished growth or fertility or any other damage (Mull and Myers, 1928). McCollum *et al.*, 1929, similarly found that the addition of 0.06 per cent of aluminum compounds to the food caused no harmful effects on growth, reproduction or otherwise. Other investigators have arrived at the same conclusion, with few exceptions; and it is well to remember that many accidents may happen in prolonged experiments, so that absence of harm is more convincing than inconstant harm. Conversely, aluminum does not appear to be essential to growth; at least, no deficiency phenomena appear if the income in rats is reduced to 0.001 mg. per day (Hove *et al.*, 1938). *Clinically,* no deleterious effects were noted in patients who received 16 Gm. of the aluminum hydroxide daily for six months or longer (Einsel *et al.*, 1930).

In view of the harmlessness of aluminum, the question of the *ingestion of aluminum from cooking vessels* loses practical significance.

This has been the conclusion of various government boards after prolonged and exhaustive experiments on men and animals (J.A.M.A., *95:* 1849). Monies-Williams, 1935 (The British Ministry of Health, 1935; Report 78), concludes that distilled water takes up practically none of the metal; hard water and organic acids attack it slightly; alkalis markedly.

The question of *alum baking powder* has become similarly insignificant. The other types of baking powder, tartrate, phosphate and ammonia, are equally harmless under the conditions of their practical use (see below).

Rats fed for two generations with alum, tartrate and phosphate baking powders in double the proportion usually employed in baking showed no effects on growth or reproduction (W. C. Rose and Catherwood, 1929).

Powdered aluminum is nontoxic (Tocco and Mulas, 1935). Rabbits and guinea pigs exposed for many weeks to aluminum ("bronze") dust for six hours daily showed no pathologic conditions except respiratory catarrh when large quantities were inhaled (Ehrismann, 1939).

Powdered aluminum is being tried as a *prophylactic against silicosis.* It appears to be effective in animals (E. J. King *et al.*, 1945), but requires clinical confirmation (Report of Councils, J.A.M.A., *130:* 1223, 1946).

Intravenous injections of aluminum chloride, into rabbits, 2 or 3 mg. of Al per Kg., repeated daily, caused severe anemia, and changes in the white cells, kidneys and spleen (Seibert and Wells, 1929). Myers *et al.* did not find these effects in dogs, or with intraperitoneal injections in rats. Siem, 1886, described symptoms resembling those of subacute arsenic poisoning, appearing several days after subcutaneous injection. Apparently these have not been confirmed.

Baking powders are chemicals which serve as substitutes for yeast fermentation, aerating bread and pastry dough by evolving carbonic acid. They are, of course, altered in this process. The decomposition products are partly expelled by the heat of baking. The fixed residue is the part which could conceivably produce pharmacologic action.

The baking powders belong to four chemic types (Crampton, 1889):

1. **Cream of Tartar Powders.**—Mixture of acid potassium tartrate and sodium bicarbonate. Reaction: $KHC_4H_4O_6 + NaHCO_3 = KNaC_4H_4O_6 + CO_2 + H_2O$. Residuum: 11 Gm. of Rochelle Salts per loaf of bread.

2. **Phosphate Powders.**—Calcium superphosphate and sodium bicarbonate. Reaction: $CaH_4(PO)_4)_2 + 2NaHCO_3 = CaHPO_4 + Na_2HPO_4 + 2CO_2 + H_2O$. Soluble residuum: 3.5 Gm. of sodium phosphate per loaf of bread.

3. **Alum Powders.**—Alum (usually ammonic) and sodium bicarbonate. Reaction: $(NH_4)_2Al_2(SO_4)_4 + 6NaHCO_3 = Al_2(OH)_6 + 3Na_2SO_4 + (NH_4)_2SO_4 + 6CO_2$. Residuum, per loaf of bread: 1.3 Gm. of aluminum hydrate; 3.65 Gm. of sodium sulfate; 1.1 Gm. of ammonium sulfate. The aluminum hydrate is insoluble in water, but 10 to 22 per cent dissolves in the gastric juice and 10 per cent in the intestinal juice, regardless of acidity. Biscuits baked with various alum baking powders contained 15 to 92 mg. of Al per 100 Gm.; 0.4 to 14.6 mg. (2 to 20 per cent) of this was found in solution in the gastric contents of human subjects an hour after consuming the biscuits (V. C. Myers and Kilian, 1928). The addition of alum whitens pastry baked from inferior flour. This fraudulent use is prohibited in several countries.

4. **Ammonium Carbonate.**—Decomposed and volatilized as $NH_3 + CO_2$. Expelled so completely that it is inactive.

Some baking powders are mixtures of several of the above. They are often diluted with indifferent substances (starch, and so forth).

PREPARATIONS.—***Alum,** U.S.P.; Alumen; Potassium Alum; Aluminum Potassium Sulfate; $AlK(SO_4)_2 . 12 H_2O$; or Ammonium Alum, $AlNH_4(SO_4)_2 . 12 H_2O$; large colorless crystals, of strongly astringent taste, and without odor. Freely sol. in water (pot. alum, 1:7 ammonium alum, 1:5.2); practically insol. in alc.; freely sol. in glyc. *Incompatible* with alkalis, carbonates and lead salts. Dose, 0.3 to 0.6 Gm., 5 to 10 grains.—*Exsiccated Alum*, U.S.P. (*Burnt Alum*), is alum with 45 per cent of water (of crystallization) expelled.—*Aluminum Acetate Solution* (Burow's Solution), a clear colorless solution, contains about 5 per cent of aluminum acetate. Used as a mild astringent and antiseptic. A 1 per cent dilution is said to be antiseptic and a 5 per cent germicidal (Kuehl, 1913). For application to the skin it should be diluted five to fifteen times.

***Aluminum Hydroxide Gel,** U.S.P. (*Colloidal Aluminum Hydrate*); a white viscous, aqueous suspension equivalent to about 4 per cent of Al_2O_3, chiefly as hydrous oxide of aluminum. It may be flavored, and preserved by addition of sodium benzoate. *Dosage*, 4 to 8 cc. in water or milk every two to four hours, or by continuous drip through stomach tube. *Dried Aluminum Hydroxide Gel*, U.S.P., a white powder equivalent to not less than 50 per cent of Al_2O_3. Average dose, 0.6 Gm., 10 grains. *Aluminum Phosphate Gel*, N.N.R., an aqueous suspension of about 4 per cent of $AlPO_4$, has the same actions but does not interfere with phosphate absorption. Its dosage should be twice that of the Hydroxide Gel.

◆

RARE EARTH METALS

These resemble aluminum closely in pharmacological as in chemical properties. Their chlorides precipitate proteins and are therefore astringent and antiseptic. Their insoluble salts, such as the oxalates, are practically nontoxic by mouth, even in the enormous dose of 50 Gm. per dog (Dreyfuss and Wolf, 1905; Bachem; Hobert, 1907; Hoeber and Spaeth, 1914).

The *protein precipitation* depends on the salt concentration and on the *p*H. Properly buffered solutions of the chlorides of lanthanum, cerium and didymium do not precipitate (Oelkers, 1940).

Blood Coagulability and Liver Injury.—Intravenous injection of the chlorides (50 mg. per Kg.) lowers blood pressure and markedly lengthens the coagulation time of the blood for many hours, depending on the dose. The effect has been attributed to liver injury (central lobular necrosis, regeneration on withdrawal), but this is denied by Oelkers. The blood sugar level is lowered at the height of the action, and amino acids and urobilin appear in the urine. *In vitro*, coagulation is prevented by ¼ to ½ per cent of the salts. Hypodermic and oral administration are ineffective (Dyckerhoff *et al.*, 1936; Vincke and Oelkers, 1937; Fischler, 1938; Oelkers, 1940).

Cerium resembles aluminum. The insoluble Cerium Oxalate is employed against vomiting, especially in pregnancy (Simpson, 1854; Mills, 1876), but it is probably useless. It is nontoxic even in large doses.

Since cerium oxalate is not absorbed (Bachem, 1907), its action must be local and analogous to that of bismuth. Accordingly, Baehr and Wessler, 1909, found that it has no effect on central vomiting (apomorphine), but that large doses delay vomiting from local gastric irritation (ipecac). They also showed that central vomiting is not affected even by the soluble and absorbable cerium nitrate. The systemic effects correspond to those of thorium, but the metal is excreted exclusively by the feces. Cerium has been claimed to be beneficial in tuberculosis, but the evidence appears quite inconclusive (see Editorial, J.A.M.A., 1920, *75:* 247). Injection of neutral solution of cerium tartrate injures the heart, lowers the blood pressure and arrests respiration. Death occurs by pulmonary edema. Repeated sublethal doses do not seem to produce nephritis (Ozaki, 1919).

Cerium Oxalate is a mixture of the oxalates of cerium (about 40 per cent; Coblentz, 1910), didymium, lanthanum and other associated elements. Fine white or slightly pink powder, without odor or taste. Insol. in water. Dose, 0.05 to 0.5 Gm. as powder. *Cerium Nitrate* (soluble) has been substituted, in doses of 0.05 Gm. or less, but is irrational.

Beryllium is not used in therapy, but *industrial poisoning* has become important because of the increasing production and use, involving exposure to dust and fumes. It is extracted chiefly from a beryllium-aluminum silicate. In some processes this is fused with sodium silico-fluoride, and it is contended that systemic poisoning is due to fluoride, and that beryllium itself is not very toxic (F. Hyslop *et al.*, 1943).

Beryllium sulfate and especially the oxyfluoride (not the oxide) produce contact irritation with papulovesicular *dermatitis*. Inhalation of beryllium dusts or fumes causes irritation of the *respiratory tract*, the "berylliosis" of Fabroni, 1935, which may progress to fatal diffuse pneumonia or regress to complete recovery after removal from exposure. This is attributed to fluoride. Guinea pigs and rats do not show lung changes after exposure to industrial fumes (F. Hyslop *et al.*, 1943; H. S. Van Ordstrand *et al.*, 1945; review, L. T. Fairhall, 1945).

Oral administration to animals is practically nontoxic, and very little is absorbed. By peritoneal injection, the toxicity is less than that of zinc or magnesium. Hypodermically, it causes local edema and necrosis. Intravenous injections are toxic, with increased diuresis, bloody diarrhea and vomiting and disturbances of circulation, respiration and temperature. Beryllium salts inhibit the action of digestive ferments. Peculiar effects result in rabbits from intravenous injections of suspensions of beryllium silicate and oxide, twenty doses in six weeks: splenic atrophy; progressive hepatic cirrhosis; characteristic bone changes, cortical sclerosis, obliteration of marrow cavity, followed in seven months by *malignant osteosarcoma.* Beryllium is not demonstrable in the bones. These changes are not seen in other species or in man; nor do other chemicals induce them in rabbits (L. U. Gardner and Heslington, 1946). In amphibians, beryllium injections inhibit regeneration and cause perversions of *embryologic development* (A. E. Needham, 1941). Beryllium may take the place of magnesium in the growth of plants (Sestini, 1888).

Beryllium Rickets.—The feeding of beryllium carbonate or sulfate to rats results in disturbance of calcium deposition in bones, analogous to rickets, by lowering the plasma phosphate. This is attributable to the formation of the insoluble beryllium phosphate in the intestines. The mineral content of the bones is low and they do not contain detectable amounts of beryllium. This form of rickets is not prevented by cod liver oil or viosterol or ultraviolet irradiation (A. E. Sobel *et al.*, 1935).

Indium salts are slightly astringent, and hypodermic injections are somewhat irritant. Buffered with citrate and injected by the peritoneum, 2 mg. per Kg. in rabbits, 10 mg. per Kg. in rats, produce paralyses, localized convulsion and death with hemorrhages and degenerative changes in the liver, kidneys, ureter and lungs (C. P. McCord, Meek *et al.*, 1942). They have little or no effect on experimental syphilis in rabbits (von Oettingen; Steidle, 1933).

Gallium.—L. Schwarz and Sicke, 1928, reported irritation of the blood-forming organs. Levaditi *et al.* studied its distribution in the tissues of rabbits after intravenous and intramuscular injection of the tartrate. The kidneys generally had the highest concentration.

Yttrium was studied pharmacologically by Steidle and Ding, 1929. It is closely allied to cerium and aluminum.

Zirconium and Hafnium.—The effects of the oxychlorides on isolated organs were investigated by van Niekirk, 1937.

Lanthanum was studied as to local and general effects by Mancini, 1926; on smooth muscle by Bernardi, 1929.

Thorium.—The effects resemble those of aluminum. Nitrate of thorium is markedly astringent, precipitating proteins and coagulating blood. Injected hypodermically, it causes ulceration. The toxicity is slight. Very large doses are required to produce vomiting. It is not absorbed from the alimentary canal. The addition of sodium citrate prevents the coagulant action. When this solution is injected intravenously, it does not affect the circulation, or any other function, even with 0.25 Gm. per Kg. of dog. The thorium is excreted by the kidneys. It has no effect on the excised muscle or heart of frogs (Chace and Gies; Brown and Sollmann, 1907). The nitrate was tried for stimulating ulcers, but did not prove superior to alum. The oxalate and oxide are practically insoluble. Thorium salts cause swelling of frog erythrocytes and of sea urchin ova, even in hypertonic solutions of electrolytes or nonelectrolytes (Dorfman, 1932). The thorium-sodium citrate solution is opaque to x-rays, and was used for radiography (Burns, 1915). It has been displaced by other agents (sodium iodide or bromide, colloidal silver, iodized oil).

Radioactive Thorium Compounds.—Ordinary thorium gives off alpha rays and changes into mesothorium, whose chemical properties resemble those of radium and barium. It gives off beta rays and changes into radiothorium, and this, by giving off alpha rays, passes successively into thorium X and emanation. *Thorium X* is therefore the principal radioactive product. The distribution, excretion and effects are described by Plesch *et al.*, 1912. The actions and therapeutic uses are in all respects similar to those of radium. It is less efficient (Falta and Zehner, 1912; Gudzent, 1912).

Colloidal thorium dioxide as diagnostic roentgenographic agent (*Thorotrast*) was introduced for intravenous injection to outline the vascular system, locally, and especially to outline the liver and spleen because it is picked up from its intravascular injection by the reticulo-endothelium of these organs (E. Randerath and Schlesinger, 1931). It was also used for ventriculograms of the brain and for mammograms of the lacteal duct system. It gives good pictures, and most patients have shown no ill effects for months or years. The thorium oxide that remains behind is a grave potential hazard, however, for it acts not only as a foreign body, but the clinical intravenous dose of 75 cc. emits gamma radiation equivalent to 1.37 microgram of radium; 2 micrograms of the latter have produced symptoms of radium poisoning (Taft, 1937). In addition, it gives off alpha rays which are considered 10,000 times more dangerous than gamma radiation. The absence of reaction, even after some years, does not preclude later trouble, as ten to fifteen years may elapse before gross changes can be demonstrated in radium poisoning. Microscopic changes have already been reported. Intravascular injection leads to extensive destruction of the arterial elastic tissue. The thorotrast from *intraperitoneal injection* is slowly absorbed, remaining practically unchanged in six months. Local degenerative changes are at first similar to those of other mild irritants, but after eight to twelve weeks they correspond to roentgen irradiation of the peritoneum (L. Efskin, 1941).

Fate.—Soon after the intravenous injection, the thorium oxide particles are taken up phagocytically by monocytes, neutrophils and especially by the reticulo-endothelial cells. Here it persists for years, new cells taking up the thorium from the dying cells (R. Pomeranz, 1934). Traces are also found in the parenchymal cells of the liver, suprarenal cortex and ovaries (Irwin, 1932; Wen and Jung, 1934). It is excreted slowly, chiefly as thorium X, and can be demonstrated in the liver, spleen, bone marrow and reticulo-endothelial cells generally for over a month after relatively small doses (Barkan, 1940). In a patient who died after several days, half of the injected thorium was found in the liver, large amounts also in the spleen, and traces in the long bones (Taft, 1937).

Considerable remained in the tissues of two patients who had received 75 cc. of thorotrast six or seven years previously. When 2 cc. were injected by vein into rabbits, the blood contained a negligible amount after five hours. After four months, the radioactivity of the organs of the sacrificed animals was twenty times higher in the spleen, and four times higher in the bone marrow, than in the liver, per Gram of tissue; bone shafts contained relatively little (W. Stenstrom, 1941). In a dog killed five years after the injection, practically none had been eliminated (Naegeli and Lauche, 1936).

Histologic Changes.—Intense degeneration was observed, especially in the liver and spleen of animals, but they practically recovered in two or three months (Shute and Davis, 1933). Two human autopsies showed proliferative reactions in the connective tissue and radioactivity of the liver, five months after the injections (Fleming and Chase, 1936). On the other hand, Rigler *et al.*, 1935, with three and a half years of experience on 175 patients, report little or no hepatic damage demonstrable during life or post mortem (the latter on thirty-five cases). C. W. McClure *et al.*, 1944, insist that no harmful effects have been reported from its clinical use for the fourteen years since its introduction. No carcinogenic activity has been reported clinically or experimentally after intravenous injection; but larger subcutaneous or intraperitoneal injections into rats and mice were followed by subcutaneous or peritoneal sarcoma (Roussy *et al.*, 1935; Selbie, 1936). This has not been demonstrated clinically (W. M. Yater and Whitmore, 1938).

Injections into the cerebrospinal fluid spread widely, so that it is found in the meninges of the cerebral cortex after lumbar injection (Freeman and Schoenfeldt, 1936). Severe Nissl changes in the cerebral cortex were reported after spinal injections in animals (Koshimizu, 1935).

Injections into the lacteal duct system have repeatedly given rise to severe foreign body reactions, granulomatous changes and necrosis, necessitating amputation of the breast (Reis and Mesirow, 1938; Romano and McFetridge, 1938).

RADIUM

Thorium, radium and uranium undergo atomic decay into a series of new elements (emanation, and so on). This decay is accompanied by the generation of rays which produce irritant or destructive effects which are utilized in the radiation treatment of localized malignant tumors. Their internal use was tried against various conditions, especially rheumatic and arteriosclerotic, without much success. It is no longer justified, in view of the serious chronic progressive osteosarcomatous changes of radium poisoning, due to the continued radiation from the retained radium, which is deposited similarly to lead, particularly in the bones. The chemical properties of radium, and probably also its direct pharmacological actions, resemble those of barium.

Because of its chemic reactivity, radium cannot be kept in the metallic state. It is marketed in the form of its salts, especially the soluble bromide or chloride, and the insoluble sulfate and carbonate. It is generally mixed with more or less of the corresponding barium salts and is sold on the basis of its radium content.

Disintegration of Radium.—This proceeds at such a rate that half of the element will be transformed (*i. e.*, a "half period") in about seventeen hundred years. It goes through a number of successive products. The first is formed by giving off alpha rays and consists in a gas niton, or radium "emanation" or "radon," with a half period of not quite four days; this emits weak alpha rays, changing to radium A (induced radioactivity), and this, with successive losses, of alpha, beta and gamma rays, in proportions characteristic for each compound, goes through radium B, C (three varieties), D, E and F.

Disintegration of Other Radioactive Metals.—Radium itself is formed by the disintegration of uranium, through the stages of: Uranium = Uranium X = Ionium = Radium. *Thorium* takes the course: *Thorium* $-\ \alpha =$ Mesothorium; $-\ \beta =$ Radiothorium; $-\ \alpha =$ Thorium X; $-\ \alpha =$ Emanation; $-\ \alpha =$ Thor. A; $-\ \beta =$ Thor. B; $-\ \alpha =$ Thor. C; $-\ \alpha =$?

Radium emanation or "*radon*" consists of the element "niton," a heavy, inert gas of the argon group. It is liberated continuously from slightly acidulated solutions of radium salts, and may be collected, purified, liquefied and dispensed in capillary tubes applied to, or implanted in, the tissues, in place of radium. It produces the same effects, but because of its rapid decomposition its action diminishes quickly and stops automatically in a few days; the action of radium endures indefinitely and practically undiminished. The emanation may also be dissolved in water, for internal use. *Thorium emanation* loses its activity within a few minutes.

Radium Deposit.—Substances exposed to radium become coated with active deposits, consisting of all the degradation products. The "half period" of this "induced radioactivity" is an hour. Such deposits on lead foil may be used for superficial application; or exposed sodium chloride may be used for making solutions for intravenous injection.

Varieties of Rays.—The rays emitted by the disintegration of the metals are of three kinds, differing in their nature, their velocity, penetration and ionizing power: Alpha rays are positively charged helium atoms; the beta rays are negatively charged electrons, identical with the cathode rays; the gamma rays are electromagnetic vibrations in the ether, a variety of the roentgen rays, but of shorter wave length and deeper penetration. The three varieties of rays produce qualitatively similar *effects*, differing mainly in degree and in the power of penetration. These two properties vary inversely: *i. e.*, the actions of the alpha rays are superficial and most intense; those of the hard gamma rays are the deepest and most moderate. The effects on living tissues progress, according to the duration of the exposure, from stimulation to inflammatory reaction and destruction. The susceptibility of the tissues varies in degree, being in general proportional to the growth rate, and being additive to already exciting irritation, inflammation or necrotic degeneration. Tumors are therefore more susceptible than normal tissue; rapidly growing tumors more than benign; sarcoma, especially lymphosarcoma, more than carcinoma. Lymphoid tissue, the sexual glands and capillary endothelium are also very susceptible. The *bones* store relatively large quantities of radium, thorium and polonium, and become thin and brittle, due to osteitis and rarefaction, with increased liability to infection. The deposits are mobilized by parathyroid hormone, but not by viosterol.

Topical Application.—One of the most important fields in radiotherapy is the treatment of tumors. Specialized training and experience are required to decide the advisability of the treatment, and to select and apply the rays so as to secure the desired degree of action on the tumor tissue, with the minimum of harm to the normal tissues. Ovaries and testicles are especially susceptible to permanent injury.

Fate of Radium.—Soluble radium salts, injected or taken by mouth, are excreted rather slowly, mainly by the large and small intestines, somewhat by the urine, none by the liver or skin (E. Smith and Bellingham, 1912; Brill and Zehner, 1912). The storage is mainly in the liver and spleen. The insoluble radium sulfate is very little absorbed, but its emanations are carried through the tissues. With hypodermic injection of radium chloride into rats, half to two-thirds is excreted in a week, the remainder much more slowly. In chronic administration about 25 per cent is retained, 99 per cent of this in the bones (H. E. Thomas and Bruner, 1933). The *emanation* has a high lipoid coefficient and is distributed in the organs in proportion to its solubility (Knaffl-Lenz, 1912). When injected intravenously into rabbits, 95 per cent was exhaled within five minutes (R. R. D. Milligan and Rogers, 1928). With *inhalation*, the amount in the blood increased with the time of exposure. The excretion is rapid, especially by the expired air, and partly by the urine. It is completed in about four hours.

Systemic effects are important chiefly from the standpoint of chronic poisoning. *Acute and subacute effects* have been imperfectly studied.

Inhalation of large amounts of emanation leads to dyspnea and depression (but not true narcosis), terminating in death. The autopsy shows widespread hyperemia, with histologic changes in the brain cells, and to a less degree in other central nerve cells (Knaffl-Lenz, 1912; Poulsson, 1908).

Excised Heart.—Zwaardemaker, 1916, reported that the potassium of Ringer's fluid may be replaced by equiradioactive quantities of any of the radioactive metals, and that therefore the action of potassium in aiding automatic contractions is due to its radioactivity. Further work is needed to confirm this theory.

Chronic Industrial Radium Poisoning.—Martland, in 1925, reported the development of necrosis of the jaw and progressive anemia in girls who had been engaged a year or longer in painting luminous watch dials and had conveyed small quantities of radium-containing paint to the mouth with the brush. The patients either died of general sepsis or developed rapidly growing osteogenic sarcoma in various bones (Martland, 1931), perhaps in response to the irritation of bacterial invasion of the necrotic tissue. Considerable quantities of active radium were isolated from the bones of those who died (Gettler). Miners of radioactive ores are said to show high incidence of primary lung carcinoma. Martland called attention to the danger of therapeutic ingestion of radioactive waters; those containing only emanation are probably excreted and harmless (J. P. Leake, 1932, review). Neutrophile leukopenia is an early and constant feature of overexposure. Different individuals vary in sensitivity. The more sensitive develop early lymphocytosis. Eosinophilia is also a frequent early occurrence. Restoration of the leukocyte count requires variations of more than four weeks (Goodfellow, 1935). The risk of dial painting has since been practically abolished by mechanical processes. Removal of the absorbed radium from the bones has been attempted by viosterol and decalcification regimen (F. B. Flinn); but Cravert and Schlundt, 1935, failed to mobilize a significant amount from four radioactive girls during three months of the treatment with viosterol and parathyroid extract.

Experimental chronic radium poisoning has resulted in osteogenic sarcoma and the other changes characteristic of clinical chronic poisoning, in rabbits (M. Rosenthal and Grace, 1936; also with mesothorium; F. R. Sabin *et al.*, 1932) and in rats (H. E. Thomas and Bruner, 1933; R. D. Evans *et al.*, 1944). Direct introduction of radium into the liver produced sarcomas and carcinomas in rats, mice and guinea pigs (Biltris, 1933). Intravenous injection into dogs caused chronic renal insufficiency, without hypertension and without changes in other organs (L. J. Adams *et al.*, 1933). *Dental changes* on oral administration of radium sulfate were studied on rabbits by M. Rosenthal, 1937. He found the radium stored in the teeth as well as in the alveolar bone, producing profound changes in the entire morphologic picture of the tooth, enamel organ and periodontal structures.

Radioactive isotopes of various elements are being used to localize radiation in the tissues for which they have special affinity. They avoid the radiation sickness, which is attributed to massive tissue destruction (P. F. Hahn and Sheppard, 1946). *Radioactive sodium acid phosphate* is reported to produce marked improvement in chronic lymphatic and myelogenous leukemia, polycythemia vera and lymphosarcoma. The results in Hodgkin's disease are doubtful. *Radioactive strontium* is being investigated for neoplasms of bone, *radioactive iodine* against hyperthyroidism (R. V. A. Low-Beer *et al.*, 1942).

◆

SILVER

The inorganic silver salts, especially the nitrate, are used to produce astringent, caustic and antiseptic effects. They form resistant precipitates with proteins, so that their local action is easily controlled. The toxicity for higher animals is low, and the antiseptic efficiency is high. In the tissues, silver surpasses mercury, since the protein compounds of silver as well as the colloidal oxides and metallic silver liberate a small quantity of silver ions. These may be used directly when antiseptic action without irritation is desired. Silver is not absorbable in sufficient quantity from the alimentary canal to produce systemic actions. Because of its precipitation by proteins and chloride, even large doses of silver nitrate rarely cause serious poisoning. Long-continued use of any silver preparation results in blackish discoloration of the skin (argyrism) by the deposition of silver particles, probably organic. Traces must therefore be absorbed.

Local Astringent and Caustic Action.—Silver nitrate acts as astringent, irritant or caustic, according to the strength and duration of its application. The surface turns white, then gradually gray and black by the reduction to metallic silver and oxide. The precipitation permits easy control of its action. The nitrate, fused into pencils ("lunar caustic"), sometimes "mitigated" with potassium nitrate, is applied in substance for the removal of warts and the stimulation of ulcers and granulations. The pencils should be moistened before use. Painting with 10 or 20 per cent solution is used for the same purpose. The concentrated solutions are said to be less painful than the more dilute. A 1 per cent solution is instilled in the conjunctival sac for the prevention of ophthalmia neonatorum. Dilute solutions of 1/100 to ½ per cent (see tabulation) are employed as astringent and antiseptic in acute and chronic catarrhal inflammations of mucous membranes, especially against gonorrhea and congestion of the deep urethra. The mucous membrane should be cleansed before the silver is applied. The solutions must be made with distilled water. The caustic and astringent action may be stopped with sodium chloride. The antiseptic action of silver nitrate extends deeply, since it forms easily soluble double salts of silver albuminates and sodium chloride in the tissues (Lubinsku, 1914).

In ophthalmia neonatorum, silver nitrate must be used with caution, or cauterization of the cornea and blindness may result, especially if the applications are repeated. For prophylaxis a single drop of 1 per cent silver nitrate which is marketed in wax capsules should be placed in the conjunctival sac, at birth, after cleansing the eyelids. This should be followed in a few minutes by normal saline, to arrest the irritant action. In treatment, where the applications are repeated, the strength should never be above 1 per cent, and generally not over 0.5 per cent. Indeed, 0.5 per cent applied every four hours is more effective also for prophylaxis, and does not produce inflammation (A. B. Bruner).

The efficiency of the silver nitrate prophylaxis is not so well established as is commonly assumed. When it was introduced by Credé, he reported that it had reduced the ophthalmia incidence in his clinic from 10.8 to 0.2 per cent. Later statistics, however, show about 2 per cent. Crede's method originally included vaginal douching with 2 per cent phenol, which may have had the larger share in his results. Lehrfeld, 1935, recommends superficial sterilization of the birth canal and thorough flushing of the eyes with boric solution, followed by 0.5 per cent silver nitrate, repeated on three successive days, and continuing the boric flushing for two weeks.

Smoking.—Painting the posterior pharynx with 10 per cent silver nitrate, or rinsing the mouth with 0.5 per cent after meals, gives rise to a disagreeable irritating taste when smoking is attempted.

Pills of silver nitrate, 10 to 20 mg., ⅙ to ⅓ grain (made with kaolin and petrolatum), were used in gastric ulcer, and the like. There is probably a slight local action before the silver is precipitated, and after it is dissolved by protein. The oxide, 0.03 to 0.1 Gm., was similarly employed. The gastric use of silver compounds is not advisable, since their efficiency is slight and they carry considerable risk of argyrism.

Amomniacal silver nitrate is applied locally to arrest the progress of *dental caries* (Howe); the precipitated silver sterilizes the dentin. It penetrates slowly, but in the course of a month the precipitate is carried into the pulp (J. A. Zander and Burrill, 1943).

Silver Stains.—The stains produced locally by the direct application of silver salts are quite distinct from argyrism and wear off spontaneously. Recent and superficial stains are easily removed by rubbing with a crystal of potassium iodide, or painting with a 10 per cent solution, which is allowed to remain for several hours. One application usually suffices (Wilkinson, 1932). Full strength "chlorox," followed by scrubbing with soap, is also effective. Effective but less safe are 10 per cent potassium cyanide and 10 per cent mercuric chloride in 10 per cent ammonium chloride (Mankiewicz, 1916).

Colloidal Silver Preparations.—The antiseptic action of silver nitrate is complicated by irritation, astringency and corrosion. These may be desirable for the destruction of tissue or the stimulation of indolent wounds, but when they are not necessary they are undesirable. Colloidal silver preparations avoid these effects, as most of their silver is not ionized and does not precipitate chloride or proteins. Their antiseptic action is also due to the small amount of silver ions, which may be present in free form, or adsorbed by the colloids (Pilcher and Sollmann, 1924; Dreser, 1917; Neergaard, 1923). Their concentration is low and their precipitant and corrosive actions are mitigated by the presence of proteins, which serve as protective colloids and as demulcents (Kolthoff and Tomicek, 1925). The major part of the silver which is in colloidal form appears to be inactive, and does not increase the antiseptic action, even on prolonged contact (Pilcher and Sollmann, 1924). The activity of these preparations is therefore independent of their silver content, but is determined by the ion concentration which varies for the different compounds.

A striking correspondence exists between the ionization (as judged by the inhibition of the growth of yeast) and the concentrations that have been selected, for instance, for conjunctivitis, by the empirical experience of the clinics. The "oligodynamic" action of metallic silver is also due to the liberation of silver ions (D. Abel, 1920).

The *mechanism* of these effects is analogous to the late action of silver nitrate. This probably acts in two stages: (1) the immediate, irritant and germicidal effects produced by the direct application of the free silver ions; and (2) the later, milder antiseptic effects produced by the re-solution and ionization of the silver-protein compounds formed in the first stage. If this second stage alone is desired (*i. e.*, antisepsis without irritation), the direct application of the colloid compounds may have advantages over their indirect production from silver nitrate, aside from the avoidance of irritation. The absence of coagulation membrane would facilitate their access to the cells; they form more concentrated solutions than are likely to be formed from the re-solution of the silver precipitates in situ; the colloidal aggregates are likely to be smaller and therefore more reactive; and because of the absence of irritation, they are likely to be more frequently applied and would therefore secure a more continuous action.

Composition and Classification.—Metallic silver and insoluble compounds of silver such as the oxide, the halogen salts (iodide, chloride, and so on) and silver protein precipitates may be brought into "colloidal solution"; *i. e.*, if they are sufficiently finely divided, they become miscible with water, so that they apparently go into solution, actually as permanent suspensions of the insoluble substance in a state of ultramicroscopic particles. The commercial preparations are for the most part produced by dissolving reduced silver or silver oxide, or some protein-silver precipitate in an excess of denatured protein, and drying in vacuum. This results in substances that dissolve freely although somewhat slowly in water, yielding brown-colored "colloid solutions," which consist of probably indefinite mixtures of metallic silver, silver oxide, and various silver-protein compounds, all in colloidal form. The proportions of these and the properties of the mixture vary according to the conditions under which they are produced. Although there are gradations, the products on the market fall into a small number of fairly definite groups: the members of each group are practically equivalent therapeutically, although they possess minor peculiarities, due mainly to the nature of the proteins used as protective colloids. The adjectives "strong" and "mild" refer to the therapeutic action, *i. e.*, to the silver ions, and not to the total silver content, which happens generally to be in the inverse order.

Strong protein silver (*protargol type*) contains a lower percentage of silver (7 to 8.5 per cent), but in solutions this becomes largely ionized; so that they have the strongest germicidal action, but are also distinctly irritant. The irritant action of protargol is estimated as about 1/10 that of silver nitrate (Neisser), confirming that practically all the silver is ionized. The strong silver proteins are therapeutically between silver nitrate and mild silver protein.

Protargol is said to be prepared by precipitating a "peptone" (albumose) solution with silver nitrate, or with moist silver oxide; dissolving the silver peptonate in an excess of protalbumose; and drying in vacuo (Fraenkel). Another preparation (Protargentum) is said to be prepared by the action of silver nitrate on gelatin, in the presence of an alkali, precipitation by alcohol and drying.

Mild protein silver (*argyrol type*) contains 19 to 30 per cent of silver, of which only a small fraction is ionized, together with alkali proteins which confer demulcent properties. They are therefore not irritant, but rather soothing. To this type belong argyrol, cargentos, silvol, solargentum, and the like. They are prepared by the action of alkali protein on moist silver oxide, and drying in vacuum.

Collargol appears to be a variety of the mild silver-protein type, containing a larger proportion of colloidal silver (78 per cent), said to be prepared by reducing silver nitrate with ferric citrate (Bechhold, p. 366), and also stabilized by alkali albumin. It was intended mainly for intravenous injection, to provoke the "colloidal reaction" which is sometimes useful in infections. It has been suggested that the proteins play the major part in this reaction (Bottner, 1921; W. Lutz, 1921).

Electrically Dispersed Silver.—Metallic silver may be brought into colloidal solution by forming an arc between silver electrodes under water. These solutions, however, are dilute and unstable, and gradually form silver oxide and ionic silver.

Colloidal Silver Haloid Salts.—Silver iodide and chloride may also be obtained as colloidal suspensions. These do not differ in principle from the other colloidal preparations; some are more, some less, ionized.

Interference of Chlorides and Proteins.—Silver chloride is insoluble and therefore ionizable only to a limited extent, so that in the presence of chlorides the silver ion concentration does not reach the irritant and astringent level, but the concentration may suffice for a limited degree of antiseptic action. Proteins increase the dispersion and therefore the solubility of the silver chloride (Stas; Glovczynski, 1914).

Changes on Standing.—Watery solutions of the colloidal silver compounds tend to alter on standing, the direction of the changes being the reverse in the strong and mild silver protein: with the *protargol type*, the silver ions decrease slowly, by about one-fifth in a month, by one-half in a year. Their therapeutic activity would be correspondingly decreased, but this would have little therapeutic importance. With the *argyrol type*, the silver ions increase, by slow ionization of the colloidal silver, and the solutions therefore become more efficient but also more irritant. Tish process is sufficient to be clinically important; the silver ions increase by one-third to one-half in a week, and by one-half to three times in a month and onward (Sollmann and Pilcher, 1924).

Therapeutic Uses.—The colloidal silver compounds are used as antiseptics on mucous membranes. The strong silver protein group is the most effective, but is distinctly irritant and stimulant. The compounds of the mild silver protein group act largely as mucilaginous demulcents and protectives, and as detergents, by dislodging pus.

Dosage and Administration.—The concentrations for mucous membranes range from 0.1 to 10 per cent for strong silver protein; from 5 to 50 per cent for mild silver protein, and from 0.02 to 1 per cent for collargol. These are applied every two to four hours. The details are shown in the tabulation. Solutions should be recently prepared, and should be protected against light. Stains on linen are removed by 1:1000 solution of mercuric chloride. The usual concentrations for special purposes are shown in the tabulation.

	Strong Protein Silver Per Cent	Mild Protein Silver Per Cent	Silver Nitrate Per Cent
Eye:			
Conjunctivitis, simple, purulent or gonorrheal	2 to 10	Solution, 25 Ointment, 10	0.2 to 2 (see text)
Prophylaxis against ophthalmia neonatorum	2 to 10	25	0.5 to 2 (see text)
Corneal ulcers		50	
Nose and throat	0.5 to 10	Spray, 10 to 20 Swab, 25 to 50	2 to 10
Ulcers			0.1 to 10

Suppositories	5	Suppositories, 20 (0.3 Gm. or 5 grains)	
Rectal:			
Irrigation	0.1	0.1 to 1	
Injection	2	10	
Suppositories	5 to 10	20 (0.13 Gm. or 2 grains)	

Pyelography started with colloidal silver solutions (Völcker and Lichtenberg, 1906). They have been displaced by the iodized compounds.

Intravenous injection of colloidal silver (collargol) was used to produce "nonspecific reactions" for the treatment of septicemic conditions. This form of therapy is now rarely employed, and other agents are safer than silver. The injected silver is taken up by the reticulo-endothelial cells, which are thereby "neutralized," so that they cannot take up other particulate matter. The blood cholesterol is markedly decreased (Goebel and Gnoinski, 1927). Repeated injections of nonlethal doses into dogs produce hyperplasia of the bone marrow, never aplasia. Large single doses cause pulmonary congestion and edema, with death in twelve hours (Shouse and Whipple, 1931).

Toxicology.—Silver nitrate to 0.01 or 0.1 Gm. by mouth produces no symptoms. Swallowing pieces of the pencils up to 2½ Gm. is also often harmless. Larger quantities cause acute gastritis. The actions are purely local. Death has occurred in a few hours to a few days from 2 to 30 Gm.; 10 Gm. are generally fatal, but 30 Gm. have been survived. The *treatment* would be by sodium chloride and demulcents.

Symptoms start with burning in the throat and epigastrium, followed by violent abdominal pain; black vomitus; severe salivation; diarrhea may or may not be present; the patient goes into severe shock. Death occurs by convulsions (which may set in early with large doses), or in coma. The lungs appear normal (Hill and Pillsbury, 1939).

Subacute silver poisoning has been reported apparently in only one case resulting from silver nitrate applications over two months to an extensive burn. The patient developed argyrism of the mucosa, severe diarrhea and convulsions, and died (Olshausen, quoted by Gerschun, 1894).

Systemic actions are not seen in man, but may be produced in animals by the injection of nonprecipitant silver solutions (AgCl in sodium thiosulfate, Gaehtgens, 1890; colloid AgCl or AgI, Gros, 1912). The actions are mainly on the central nervous system, with paralyses and spasms, beginning in the lower extremities; disturbances of respiration; and fall of blood pressure; sometimes diarrhea. The secretion of bronchial mucus is greatly increased, probably by injury to the epithelium, and may lead to asphyxia. Death usually occurs promptly, by paralysis of respiration; the diaphragm is paralyzed before the other respiratory muscles. The heart is but little affected and may beat after death. In frogs, the paralysis is preceded by convulsions (Ball, 1865; Jacobj, 1877; Gaehtgens). *Chronic systemic poisoning* shows changes in the blood corpuscles; disturbances of metabolism; cloudy swelling of the heart and skeletal muscle; and fatty degeneration of the liver and kidney (Bogoslovski).

The *therapeutic use of silver in nervous diseases* (insanity, epilepsy, and so forth) was a survival of medieval concepts based on its dedication to the moon, and the supposed connection of the latter with lunacy. Although silver cannot be absorbed in amounts sufficient to have any action, it has been tried again and again against all forms of nervous disease with uniformly negative results.

Argyrism (argyria, argyrosis) consists in a permanent bluish black discoloration of the skin, ashen gray in lighter cases, involving also the mucosae (conjunctiva) and internal organs. It is due to the deposition of a silver compound and develops gradually when silver in any form enters the tissues, by direct injection, or by continued application to mucous surfaces or open wounds or by prolonged oral ingestion. It is permanent and incurable and should be prevented by judicious use. The blueness is first recognizable in the areas exposed to light; in most cases in the face, often on the conjunctiva, sometimes in the distal margin of the lunule of the finger nails; its appearance here should lead to the immediate discontinuance of the use of silver (I. S. Wright, 1933). The buccal mucosa often shows discoloration, sometimes other mucosae; a "gum line" is present in about 10 per cent. About half the reported cases were due to silver nitrate, but many cases have been reported from the routine use of colloidal silver preparations, especially by the laity as prophylaxis against colds, generally in children and young people (Gaul and Staud, 1935; Olson, 1917). It has also followed the injection of silver arsphenamine. The oral administration of silver was formerly a frequent cause (Blumberg and Carey, 1934). It has been produced by the application of silver-containing hair dyes. The intensity of the discoloration depends on the quantity of silver and of exposure to solar and especially to ultraviolet radiation (Zacks, 1933).

Historical.—Argyrism is said to have been first reported by Angelus Sala in 1647. It was extensively studied by Frommann, 1859; Riemer, 1876; and Gerschun, 1894; industrial argyria by J. M. Harker and Hunter, 1935. A comprehensive monograph "Argyria" was published by Hill and Pillsbury, 1939 (Williams and Wilkins Co.). The term "argyrosis" is sometimes restricted to the eye.

The *pigment* consists of opaque granules, easily soluble in potassium cyanide, but difficultly in concentrated nitric acid, so that they are not metallic silver or silver oxide, as was formerly believed (B. Riemer, 1876). In the skin, they are located in the collagen and especially in the elastic fibers of the corium, immediately under the epithelium, and about the sweat and sebaceous glands. The dark-field method of Hoffmann and Berek shows that its distribution in the skin is much more extensive than it appeared to be (Habermann, 1924).

The first appearance of argyria is usually in the eye, in the conjunctiva and eyelids, especially the lower, and also in the cornea, chiefly in Descemet's membrane. It can also be produced there from long-continued local application (Bruchker and Knapova, 1929; W. Dieter, 1929). Argyria can be induced in experimental animals by oral as well as by parenteral administration, but rarely appears to involve the skin, perhaps because the fur protects against light. It is seen especially in the mucosae and internal organs. Silver may be deposited in practically all structures, excepting perhaps nerve, muscle and epithelial cells, but the quantitative differences between organs are marked. Connective tissue and blood vessels are universally involved; relatively rich are the skin, renal glomeruli, choroid plexus, mesenteric glands, thyroid (Hill and Pillsbury, 1939). The silver may be outside or inside. The pigment appears first in the reticulo-endothelial cells and in the leukocytes, and is distributed by these through the body, where it occurs as intra- and extracellular granules (Gerschun), apparently in the cement substance and membrana propria, probably most abundantly in the kidneys at the junction of the cortex and pyramids, and in the liver. Silver determinations in argyrosis patients always show the highest percentage in the kidneys; Frommann, 1860, for instance, found 61 mg. per 100 Gm. of kidney, 40 mg. per cent for liver. In persons not exposed to silver the concentration does not exceed 1 mg. per 100 Gm. of dry tissue (Sheldon *et al.*, 1933). The deposited silver causes no symptoms. *Other metals* that may cause somewhat similar discoloration are bismuth, arsenic and gold. Kobert, 1893, emphasized analogies with siderosis; but Gerschun, 1896, pointed out significant differences.

Absorption of silver occurs from all mucous and serous membranes more rapidly with silver chloride and nitrate than with the colloidal compounds. Unbroken skin does not absorb enough to produce argyria; nor is this likely to result from the brief use of silver as caustic. Absorption may occur from the respiratory tract, but chiefly from the upper small intestines. The form in which it is absorbed and transported is presumably chloride or proteinate. In the blood it exists chiefly in the plasma, some in the phagocytes, none in the red cells (H. Blumberg and Carey, 1934; B. Minz, 1930). A patient with generalized argyria *excreted* less than 2 mg. of silver per week in the feces, none in the urine (N. L. Kent and McCance, 1941). The *time of treatment* before argyria appears is usually two or three years; rarely less than six weeks. *The total amount of silver* administered orally is probably never less than 6 Gm. With argyria after intravenous injection of silver arsphenamine, the average amount was 16 Gm., containing 2.3 Gm. of silver; it occurred rarely with half of this dosage.

Argyrism *persists* indefinitely or disappears slowly. Crispin, 1914, and Olson, 1916, believed that recovery is hastened by methenamine. Stillians and Lawless, 1928, reported some success with multiple endermic injections of a solutionc ontaining 1 per cent of potassium ferricyanide and 6 per cent sodium thiosulfate. Mercuric chloride decolorizes the granules *in vitro*, but not *in situ*.

PREPARATIONS.—***Silver Nitrate,** U.S.P. (Argenti Nitras; Lunar Caustic); $AgNO_3$. Colorless crystalline tablets, becoming gray to black on exposure to light in the presence of organic matter. Odorless; metallic taste. Freely sol. in water (1:0.4), sol. in alc. (1:30). *Incompatible* with chlorides, bromides, iodides; carbonates and hydroxides; organic drugs and reducing agents. *Toughened Silver Nitrate,* U.S.P. (Silver Nitrate Pencils; Stick Caustic), contains about 5 per cent of silver chloride to toughen the mass. *Silver Picrate,* N.N.R., is used against vaginal infections by Trichomonas, Monilia and gonococci, as watery solution, powder (1 per cent in Kaolin), suppositories or jelly (Corbit *et al.*, 1941). ***Strong Silver Protein** (Protargol) contains not less than 7.5 per cent and not more than 8.5 per cent of silver. A brown, odorless powder, usually somewhat hygroscopic; freely sol. in water. Slightly but distinctly irritant; not precipitated by chlorides, which, however, interfere with the action. Applied as a 0.1 to 10 per cent solution. Solutions are best made by sprinkling the powder on cold water, without stirring. Solutions of strong protein silver should be freshly prepared and dispensed in amber-colored bottles. Products of this type are: Proganol-Heyden, Protargentum-Squibb, and Protargol-Winthrop. ***Mild Silver Protein,** U.S.P. (Argyrol), contains not less than 19 per cent and not more than 23 per cent of silver Dark brown or almost black scales or granules; frequently hygroscopic; freely sol. in water. Not precipitated by or incompatible with chlorides. Applied as 10 to 40 per cent solution in water. Solutions of mild silver protein should be freshly prepared and dispensed in amber-colored bottles. Products of this type are: Argyn-Abbott, Argyrol-Barnes, Cargentos-Mulford, Silvol-Parke Davis, Solargentum-Squibb, Vargol-Heyden. *Silver Iodide,* freshly precipitated, was recommended by Siter and Uhle, 1905. Colloid silver iodide has been used intravenously, similarly to collargol, producing leukocytosis, and so forth (Voigt and Corinth, 1919). A colloidal silver odide preparation is marketed as "*Neo-Silvol*"; a coloidal silver chloride as "*Lunosol.*"

◆

GOLD

Gold salts are readily reduced to metal, which is poorly absorbed. Intravenous injections, especially of gold and sodium thiosulfate, and sometimes intramuscular injection of oil suspensions of soluble salts, produce rather striking reactions, perhaps by flocculation of the reduced gold. They are used with marked success in lupus erythematosus and certain other skin diseases; with more variable success in rheumatoid arthritis; with rather disappointing results in pulmonary tuberculosis and in asthma; and without success in leprosy. They are fairly effective against syphilis, but inferior to arsphenamine, bismuth and mercury. The oral administration (sometimes only pretended) as a "tonic" and "alterative," and for the cure of dipsomania, is a mystification, like the "potable gold" of the alchemists which was to be the elixir of life and youth—to the charlatan. The parenteral administration, and especially the intravenous, is a rather dangerous procedure.

The *mechanism of the therapeutic action and of the toxic reaction* is not known, but may be connected with the flocculation of the reduced gold. This would be analogous to the "nonspecific protein reactions," involving the reticulo-endothelial system.

Therapeutic Efficiency in Lupus Erythematosus.—The good results reported by Schamberg and Wright, 1927, have been confirmed by many others. Marked improvement or entire healing of the lesion occurs in about two-thirds of the patients, but sometimes with recurrence.

Rheumatoid Arthritis.—Long-continued intramuscular or intravenous injections of soluble gold salts produce gradual improvement in about ⅓ to ½ of patients, especially in early cases, apparently arresting the inflammatory process. Other joint diseases are not improved. The mode of action is not known. Many patients relapse. Familiarity with the treatment and extreme care in its application are essential. Serious toxic effects may develop at any time during the administration (see below). This should therefore be used only if the diagnosis is clear, and the disease has lasted more than three months, so that it is not likely to improve spontaneously (B. I. Comroe, 1945; E. F. Hartung, 1943). Many physicians have abandoned its use (Hench, 1946).

The improvement usually does not begin until the injections have been continued for one to three months. It starts with relief of the pain in the joints, then the joint swellings soften and subside and the general health improves. In about a third of the patients the arrest of the disease persists over a year.

Several workers have found that gold preparations benefit experimental proliferative arthritis in *mice*. The effect is not bacteriostatic, nor does it correlate with the toxicity (A. B. Sabin and Warren, 1940).

Pulmonary Tuberculosis.—Gold cyanide had been recommended against tuberculosis and scrofula by Chrestien, 1811. It fell into disuse, but the observation of Robert Koch, 1890, that gold salts inhibit the growth of tuberculosis bacilli in cultures, prompted further trials. Bruck and Glueck, 1913, claimed successful results from intravenous injection of gold-potassium cyanide (especially when combined with tuberculin!) in lupus and in syphilis, but DeWitt, 1918, found gold salts unsuccessful in experimental tuberculosis of guinea pigs. Indeed, they tended to shorten life, through hemorrhage and hyperemia. Nevertheless, Mollgaard, 1924, claimed beneficial results from the intravenous injection of gold and sodium thiosulfate, under the name of "Sanocrysin." The results in pulmonary tuberculosis again proved disappointing (Editorial J.A.M.A., 1926, *86:* 487; Miyagawa, Jap. Res. Com., 1927).

Syphilis.—Gold treatment was tried early, and Legrand of Amiens in 1836 wrote a book upon the subject, in which he ranked gold with mercury; but since it was administered orally, it must have been quite ineffective. Positive results by the intravenous injection of gold and sodium thiosulfate were obtained in rabbit syphilis by Levaditi, and confirmed clinically by Fournier and Mollaret, and by Jeanselme and Burnier. Judged by the effect on the Wassermann test, it is generally less effective than arsphenamine or bismuth, but may succeed when these have failed.

Clinical Toxicity.—Erythema, pruritus, urticaria and rashes occur frequently, generally some hours after injection. Serious reactions are infrequent with care and restricted dosage, but they may be fatal. They include renal irritation, exfoliative dermatitis, ulcerative enteritis, leukopenia, thrombopenia, agranulocytosis, aplastic anemia. G. S. Mirick, 1940, reviews the eighteen cases of agranulocytosis reported to that time as following gold therapy. Basophilic granulations, probably regenerative, were observed in 94 per cent of rheumatic patients treated with gold (Hulst, 1937). The literature is reviewed by Driver and Weller, 1931; the fatal cases by Fatzer, 1935.

The *toxic effects in animals* resemble those of arsenic (Schultz, 1892). Oral administration of gold chloride to dogs produces emesis. With hypodermic or intravenous injection, the acute toxicity of the thiosulfate is rather low; indeed, there may be no immediate symptoms with doses that prove fatal after two weeks with characteristic changes in the erythrocytes, violent diarrhea, and especially degeneration and necrosis of the renal epithelium which is the cause of death. Therapeutic doses produce some renal congestion and slight degeneration (Orestano, 1933; Kallo, 1934). Repeated injection of nearly fatal amounts produces tolerance up to twice the ordinary lethal dose by greater resistance of the regenerated renal epithelium (R. Cortell and Richards, 1942). Theobromine decreases the acute toxicity of sodium gold thiomalate; theophylline has no significant effect (K. I. Melville, 1944).

Dimercaptopropanol (BAL) is proving successful in various gold toxicities: acute (A. Cohen *et al.*, 1947); dermatitis (C. Ragan and Boots, 1947); and granulocytopenia (L. M. Lockie *et al.*, 1947). It hastens the urinary elimination of the gold (Ragan and Boots).

Fate.—Gold administered as the thiosulfate is fairly rapidly but incompletely *absorbed* after oral administration to rabbits (Orestano, 1933). The colloidal preparations are absorbed more slowly than the crystalline from intramuscular injections (W. D. Block *et al.*, 1941). With *clinical administration* of the thiosulfate or thiomalate, 75 to 80 per cent of each injection is retained indefinitely; the remainder is excreted chiefly by the urine, four times more than by the feces. Gold can be demonstrated in the blood plasma for long periods, up to ten months, after discontinuing the injections, the time increasing with the dosage (R. H. Freyberg *et al.*, 1943; B. I. Comroe, 1945). The highest concentration of the *retained gold* is in the kidney, then usually the liver, the other organs being more variable. In the blood, it is practically all in the serum, and only traces are in the corpuscles. Deposition in the skin leads to "chrysiasis." A patient who died of ulcerative enteritis two weeks after the last of a series of intravenous injections of gold and sodium thiosulfate yielded the following quantities of gold, mg. per 100 Gm. of moist tissue: spleen, 3.4; kidneys, 2.5; liver, 0.6; colon, 0.2; lung, 0.1 (N. L. Anderson and Palmer, 1940). *Colloidal gold*, injected intravenously, is retained practically entirely in the liver (95 per cent), somewhat in the spleen, and very little in the kidneys and lungs (Lomholt, 1926; Heubner, 1929; Henius and Weiler, 1929; Kurosu, 1927). With intramuscular injections of colloidal gold or gold sulfide into rats, the liver contained almost ten times more gold, the kidneys only a sixth, than when gold and sodium thiosulfate was injected. Almost half of the administered thiosulfate gold was excreted by the urine, only a thirtieth of the colloidal (W. D. Block and Buchanan, 1941).

Normal Presence of Gold.—This is said to be in amounts almost comparable to the common metals, 0.03 to 1 mg. per cent in most food materials, with normal daily excretion in man amounting to 0.1 mg. in the urine and 1 mg. in the feces (R. Berg, 1928.)

"Chrysiasis," permanent skin discoloration by deposited gold, analogous to argyria, may result from repeated injections of small doses (Hansborg, 1928), but generally only after large doses; indeed, generalized pigmentation is rare. It is normally preceded by erythema, in contrast to argyria (Cascos, 1936). Blonde women are reported more susceptible (Curtis and Conte, 1936). *Injection* of gold compounds outside the vein produces a local greenish-blue discoloration (Schamberg, 1928).

Gold appears to be eliminated into the *skin and hair*, as is arsenic. None is found there normally, in human or rabbits, but it appears in the skin after eight to sixty days of oral administration of the thiosulfate, and in the hair after forty-five days (Casazza, 1934; Glingani, 1934).

Administration and Dosage.—*Gold Sodium Thiosulfate* ("Sanocrysin"), $Na_3Au(S_2O_3)_2.2H_2O$, contains approximately 37.4 per cent of gold. It occurs as white crystals freely soluble in water. It is marketed in ampuls of 10, 25, 50 and 100 mg. The solution is colorless and neutral or faintly alkaline. It should not be administered unless liver, kidney and other serious organic disease has been excluded. The dosage should be started with 5 mg., intravenously, in 2 to 5 cc. of sterile distilled water. Injections are repeated at weekly intervals, increasing by 5 mg. at each injection, provided no untoward reactions occur, to the maximum of 50 mg. for women, 75 mg. for men, to a total of 500 to 1000 mg. for the course, and six to eight weeks should intervene before a second course is undertaken. The patients should be closely watched, and a differential white count taken weekly. In mild reactions the dosage is reduced; with severe reactions it must be discontinued. Extreme hypersensitivity is likely to exist in patients with the disseminated type of lupus erythematosus, and if gold is used at all in them it must be with extreme caution and probably with not more than half of the usual dosage. *Gold Sodium Thiomalate* (*Myoschrysin*) is used in rheumatoid arthritis with somewhat lower dosage (B. I. Comroe, 1945).

Gold and Sodium Chloride (Auri et Sodii Chloridum) is the salt usually employed orally. Dose, 5 mg., $\frac{1}{12}$ grain. It is a mixture of equal parts of anhydrous gold chloride ($AuCl_3$) and anhydrous sodium chloride. Orange-yellow powder, odorless, saline and metallic taste; deliquescent. Very sol. in water.

PLATINUM

The actions on animals are similar to those of gold (Kebler, 1878; Cohnstein, 1892).

RHODIUM

Sodium and rhodium chloride hypodermically or, better, intravenously is effective against experimental syphilis and frambesia of rabbits, with a therapeutic index of 1:25 to 30. It causes considerable local irritation. Rhodium chloride, $RhCl_3$, is more toxic (Jahnel, 1937).

COPPER

Cupric sulfate irritates the nerve endings in the stomach which gives rise to the vomiting reflex, and thus has a rather specific emetic action. It is also used on mucous membranes as an astringent and caustic. Copper ions catalyze a number of reactions, and minute quantities of copper are essential in the metabolism of plants and animals; but a little more is toxic. It has a relatively high toxicity for fungi, protozoa and algae, and has been employed for the purification of water, but it is not a reliable bactericide. Its absorption is limited and its toxicity to animals is therefore low, but large doses may be fatal. The ingestion of the small quantities normally present in food promotes the conversion of iron into hemoglobin in nutritional anemia. It is itself a constituent of the blood pigment of mollusks and crustaceans.

Astringent and Caustic Action.—Solid copper sulfate is used as a mild escharotic against granulations and trachoma. The everted lid is lightly touched with the copper crystal or pencil, and then rinsed with water. The pencils are made by fusing 1 part of potassium alum with 2 parts of copper sulfate. Solutions of 0.1 to 3 per cent may be employed as stimulant astringents in conjunctivitis, urethritis and vaginitis, but have no particular advantage over silver.

Antiseptic Action and Use in Water Purification.—Copper may be used to purify water from contamination with algae. The traces of copper remaining in the water are probably harmless. It is fairly effective against bacteria of the coli group. Its use against typhoid contamination seems to be unreliable (Clarke and Gage, 1906). Thomas, 1915, describes its use for the disinfection of swimming pools.

Copper sulfate is effective as *anthelmintic* against various gastro-intestinal parasites of the sheep, a drench of 1.5 per cent solution being administered every three weeks. No ill effects were noted (Reitz, 1935).

Emetic Action.—Copper sulfate is effective and prompt, with short nausea. It is irritating, however; and should it not be effective there is some danger of poisoning, and it must be removed by lavage. It is therefore not to be recommended, except in phosphorus poisoning, in which it oxidizes the phosphorus and coats the globules with a layer of metallic copper. The emetic dosage is 0.5 Gm., in a single dose; or three doses (if necessary) of 0.25 Gm. each, fifteen minutes apart. It should be dissolved in a glass of water.

Acute Toxic Actions.—Large doses (20 Gm.) of soluble copper salts produce hemorrhagic gastro-enteritis, nephritis, collapse and coma.

Copper Metabolism.—Small quantities of copper are probably indispensable. The *copper content* of a human adult is 100 to 150 mg.; the *daily turnover* is 2 to 2.5 mg. This is the copper content of the ordinary diet, and the amount of the total *excretion* (Tompsett, 1934; T. P. Chou and Adolph, 1935).

In *American children of preschool age*, the daily intake was found to range from 0.07 to 0.11 mg. per Kg. of body weight. This gave a retention of 0.012 to 0.048 mg. per Kg. of body weight, so that 0.1 mg. per Kg.

appears to furnish an adequate supply for growth (A. L. Daniels and Wright, 1934). In young women on self-chosen diets, the daily intake averaged 2.65 mg. with average retention of 0.85 mg. A larger proportion was retained when the intake was increased (R. M. Leverton and Binkley, 1944).

Normal Copper in Food.—Traces of copper, as of other metals such as manganese and zinc, occur universally in plants and animals (Flinn and Inouye, 1929), and therefore in food. Larger quantities are found in organic combination in the liver, fat and other organs of *cephalopods* (octopus) crustaceans, snails, mussels and insects, but only small amounts in vertebrates (K. Okamoto *et al.*, 1938).

The *copper content of food* ranges from 0.1 mg. per Kg. for fresh celery to 44 mg. in fresh calves' liver (Lindow, Elvehjem and Peterson, 1929). Cow's *milk* normally contains 0.12 to 0.18 mg., average 0.15 mg., per liter, with rather small differences between herds. It is not increased by feeding copper to five times the normal income (Elvehjem, Steenbock and Hart, 1929), but it may be considerably increased by contact with copper vessels. The copper of human milk runs somewhat higher, 0.21 to 0.28 mg. per liter.

The **absorption** of copper from the alimentary tract is limited, so that its administration does not increase the urinary excretion above the normal, which is less than 1 mg. daily. The *skin* can absorb some copper from the oleate (C. L. Vogt and Buckhardt). The *urinary excretion of copper* is about 0.25 mg. daily in adults, ranging between 0.08 and 0.7 mg. (Rabinowitch, 1933; Tompsett, 1934), and is approximately the same in dogs (A. Ross and Rabinowitch, 1935). It is not affected by the income. The *fecal excretion* is ten or twenty times greater, varying with the food income.

Retention.—The *increase with growth and with copper administration* is illustrated by the rat data of Lindow, Peterson and Steenbock, 1929: the total copper content increased to forty times, from 0.011 mg. at birth to 0.44 mg. at seven to eight months. The content at birth was not raised by increasing the copper intake of the mother. Addition of copper to the food increased the copper content of the body by two or three times. The increase was greatest in the liver, to twenty times; only to 1.6 times in the bones; the copper of the blood increased only to 1.6 times, from 0.055 mg. to 0.082 mg. per cent. Of the copper added to the food, about 98 per cent was eliminated by the feces, but the content of the urine was increased by five times. The copper content returned to the normal level in four or five weeks after the administration was discontinued.

The *copper content of organs* is highest in the liver, which shows the largest increase when copper is administered. Human liver averages 0.75 mg. per 100 Gm. Its content follows a characteristic curve during life, the kidney content does not (Brückmann and Zondek, 1939). The spleen, kidneys and lungs average about 0.25 mg. per 100 Gm. (Gerlach, 1935; Tompsett, 1935). Fetal liver is especially rich in copper (H. Ramage, 1934). Gerlach did not find the liver concentration significantly changed in hepatic cirrhosis, diabetes, tuberculosis or blood diseases, but K. Okamoto *et al.*, 1938, describe its occurrence in the cells of nonpigmented and atrophic cirrhosed liver. Copper is always present in human *bile* (Judd and Dry, 1935). Human *blood serum* contains normally 0.062 to 0.124 mg. per 100 cc. (Kraft, 1928). Human *whole blood* contains 0.185 to 0.229 mg. per 100 cc., so that the copper is fairly evenly distributed between the corpuscles and plasma (Tompsett, 1934; Sachs, Levine and Fabian, 1935; children, Currado, 1933). *Fetal blood* contains 0.195 to 0.235 mg. per 100 cc. at five to six weeks of gestation, 0.073 to 0.082 at term, 0.100 to 0.176 in older infants. The content is generally higher in anemias (whole blood, 0.70 to 1.33 mg., average 0.98, Bence *et al.*, 1936; serum, Sachs *et al.*, 1935). The normal blood and tissue copper appears to be in loose nondialyzable combination with proteins, in the serum with the albumin. It is dissociated by acid (R. Boyden and Potter, 1938).

Hemocyanin, the blue blood pigment of mollusks and crustaceans, is a copper compound, probably molecular, differing somewhat in the different classes of animals. That of limulus contains 0.173 per cent of copper and 17.3 per cent of nitrogen (Redfield *et al.*, 1928).

Hematinic Action.—The traces of copper normally present in the food, or their addition to artificial diets, aid greatly as supplements to iron in the formation of hemoglobin in young animals (E. B. Hart and Steenbock, 1928) and in nutritional anemia, in all species studied, including birds and man (J. Waddell, Steenbock and Hart, 1929; dogs, A. R. Maase *et al.*, 1944). V. C. Myers *et al.*, 1931, reported that most other metals produce similar effects, although they generally require larger doses. It is doubtful whether this action of copper is of therapeutic importance, for extreme precautions are necessary to produce experimental copper deficiency, so that a spontaneous deficiency appears improbable (A. H. Smith, 1933). The subject is discussed under Iron (see Index; review, M. O. Schultze, 1940).

Copper Deficiency.—The rigorous exclusion of copper from the diet of rats is fatal in a few weeks (McHargue). A regional disease of cattle and goats, characterized by diarrhea, loss of weight and loss of black color, was found by Sjollema, 1938, to be associated with low copper content of the blood, liver, spleen and hair, and improved when copper was administered.

Fur and Skin Color.—The fur and underlying skin of black or hooded rats changes gradually to a silvery gray when they are fed an exclusive milk diet poor in copper, and returns promptly to the darker color when copper is added (H. S. Keil and Nelson, 1931); but not on the addition of iron and other inorganic elements, or of vitamins. Similar changes occur in black cats and rabbits (Gorter, 1935): The black fur and the skin under it have a somewhat higher copper content (about one-fourth) than the unpigmented areas (Cunningham, 1931; Sarata, 1935), and it is plausible that copper acts as a local catalyst in the formation of the pigment in the skin. The *feather pigment* of certain birds contains copper, probably as part of the pigment molecule.

Catalytic functions of copper are especially important for the oxidation of *sulfhydry compounds* such as cysteine (S. M. Rosenthal and Voegthir, 1933). In *plants* it is the prosthetic group of ascorbic acid oxidase (J. F. McCarthy *et al.*, 1938) and of phenol oxidase (F. Kubowitz, 1938).

Adventitious copper in foods and drink is probably harmless in the quantities in which it is likely to be present.

Copper may be introduced into foods by *insecticide sprays*, such as Paris Green or Bordeaux Mixture, but these owe their toxicity to the arsenic, not the copper. However, the U.S. Food Administration has set 30 mg. per Kg. of food as the permissible limit of extraneous copper. Copper may enter the *water supply* in the copper sulfate treatment for algae. The U. S. Treasury Department has set a limit of 0.2 mg. per liter for potable waters, which is surely on the safe side. *Copper cooking vessels or piping* does not impart significant quantities to water or food. Copper is sometimes used to give a bright green color to canned *vegetables*, especially peas and beans. These contain 25 to 120 mg. per Kg. The copper enters into a firm compound with the chlorophyl. Older vegetables, not so rich in chlorophyl, contain it in much looser combinations with proteins. The chlorophyl compound produces no effects of any kind, even when continued for long periods in quantities corresponding to 12 to 15 mg. of Cu per day, the maximum amount which would be taken in food. The use of copper with young green vegetables would therefore be harmless (J. H. Long, 1912), and it is doubtful whether harm could result even from the looser compound in old vegetables. *Prolonged* administration of copper sulfate up to 0.5 Gm. per day has been shown to be devoid of bad effects (Du Moulin). It is true that these were not continued indefinitely.

Inhalation of copper dust may cause changes in the gums of exposed workers, probably by local action. Rabbits subjected to copper dust half an hour daily for two to eight weeks showed no toxic effects or pathological changes, although the copper concentration of the liver rose to thirteen times the normal average (Remy and Zimmermann, 1931).

Hepatic cirrhosis and hemochromatosis ("gin-drinker's liver") was attributed by Mallory, 1926, to the long-continued consumption of copper, as contamination of alcohol, the latter potentiating the metal. The causal connection is not proved, and is improbable. Experimental evidence has been contradictory, and the clinical occurrence of increased copper concentration in the liver is not constant and need not be significant (Gerlach, 1935).

Addition of copper sulfate to the diet of rats receiving *p-dimethylaminobenzene* delays the production of liver tumors by 25 to 50 per cent, although it does not prevent them (G. R. Sharpless, 1946).

Intravenous injection of copper salts lowers blood pressure, doubtless largely by flocculation. In rabbits, intravenous injection of 10 to 20 mg. of copper acetate or cadmium salts (but not other metals) *induces ovulation* (so also do metrazol and picrotoxin). This effect probably consists in stimulation of the hypophysis, for it is prevented by transsection of the hypophyseal stalk (C. M. Brooks *et al.*, 1940; C. W. Emmens, 1940). Intravenous injection of 0.1 cc. of 1 per cent copper acetate induces pseudopregnancy in adult estrous rats, as does also pituitary extract. The copper probably acts through the posterior pituitary (A. Drury and Bradbury, 1942). The copper ovulation in rabbits is inhibited by progesterone (M. H. Friedman, 1941). *Excised* skeletal and cardiac muscle are depressed by copper salts. Autonomic responses are altered as by other precipitants. Epinephrine, for instance, is rendered stimulant to the intestines and uterus (Hazama, 1925).

Colloidal copper has been injected intravenously for tumors, without real success. Its distribution in the organs is similar to that of copper salts (Corper, 1914). It has repeatedly caused serious inflammation, necrosis and gangrene at the site of injection. *Colloidal copper sulfide* was studied by Lo Cascio, 1930, with oral, hypodermic and intravenous administration.

Ethylenethiocarbonate derivatives of copper were tried by Dixon and Hoyle, 1929, against experimental tuberculosis in guinea pigs and rabbits, but the results were not promising.

PREPARATIONS.—***Cupric Sulfate, U.S.P.** (Blue Vitriol, Bluestone); $CuSO_4.5H_2O$; large, deep blue crystals; odorless; metallic taste. Freely sol. in water (1:3); slightly sol. in alc. (1:500); freely sol. in glyc. (1:2.8). *Incompatible* with fixed alkalis and carbonates. Dose, emetic, 0.3 Gm., 5 grains. *Cupric Citrate*, U.S.P.; slightly soluble in water. *Cupric Citrate Ointment*, U.S.P., 8 per cent.

ZINC

The local actions of the *soluble zinc salts* resemble those of copper, but are less potent. Zinc sulfate is employed as emetic, and locally as astringent and antiseptic. Other soluble zinc salts are also used locally. The acetate is milder; the chloride is escharotic. The insoluble zinc oxide and stearate are used externally as protectives, similarly to bismuth. There are no systemic effects under therapeutic conditions, but traces of zinc are indispensable in nutrition. Inhalation of fumes of zinc oxide causes "metal fume fever."

Insoluble zinc compounds, the oxide, carbonate and "*calamine*" (a native zinc carbonate), are employed extensively in dermatology as mildly antiseptic and astringent, protective and sedative applications in inflammatory skin diseases and on superficial wounds. They may be applied dry or as ointment, alone or mixed with boric acid, bismuth subnitrate, starch or phenol. The calamine is often used as a 5 to 10 per cent aqueous suspension, or as the *Calamine Lotion* or *Calamine Liniment*. *Zinc stearate* forms a light fluffy dusting powder which is not adhesive and does not cake; but it has the serious disadvantage that fatal pneumonia results if a considerable quantity of the light dust is inhaled. Such accidents are not infrequent when infants play with the containers. The latter should be devised so that they cannot spill considerable quantities of the powder.

Zinc undecylenate is among the most effective preventive agents against fungus skin infections, such as athletes' foot. It may be applied as powder, 20 per cent in talcum, with 2 per cent of undecenylic acid; or as ointment of 5 per cent of the acid and 18 per cent of the zinc salt (H. C. Shaw *et al.*, 1945).

Zinc sulfate as emetic acts like copper sulfate, and is generally preferred, being nearly as efficient and less irritating. The short nausea, slight depression and absence of harmful irritation make it particularly suitable in gastric disturbance from overeating. One to 2 Gm., 15 to 30 grains, may be given in a glass of water.

Astringent and Antiseptic Action.—Zinc sulfate or acetate is used in conjunctivitis, particularly that caused by the Morax-Axenfeld bacillus, which it arrests promptly by inhibiting the bacterial proteolytic enzyme. It is also employed in chronic gonorrheal urethritis and other catarrhal conditions. The strength of solution for collyria is 0.1 to 1 per cent; for urethral injections, 0.5 to 4 per cent. The phenolsulfonate has no advantage.

Poliomyelitic Prophylaxis.—Spraying the nasal mucosa of monkeys with 1 per cent zinc sulfate solution, as with other astringents, affords considerable protection against experimental inoculation with poliomyelitis virus (Armstrong and Harrison, 1935). It appears to be totally ineffective in man (Armstrong, 1937), perhaps because of the difficulty of effective application (E. W. Schultz and Gebhardt, 1937); but it is doubtful whether the virus naturally enters by the nasal mucosa.

Zinc chloride as escharotic is used as the Liquor Zinci Chloridi on granulations, ulcers, and the like. It has been extensively exploited as *disinfectant* and overestimated in proprietary preparations. MacClintic, 1905, found 1:200 to 1:500 a poor germicide and feeble antiseptic, though a fair deodorant. Injection of 5 per cent zinc chloride solution into the testis of fowl produces *teratomas* of rapid growth, exceeding 200 Gm. in two or three months, which continue to grow after transplantation (Anissimova, 1939).

Zinc in Food.—Birckner, 1919, showed that traces of zinc are common in many foods (review, D. M. Hegsted *et al.*, 1945). Milk contains about 4 mg. per liter, hen eggs about 1 mg. per egg. However, spectographic data indicate that the zinc content of food is almost 40 per cent lower than the published data (Scoular, 1939). Zinc is almost invariably present in oysters from the Atlantic Ocean. It is probably always associated with copper, but the two metals do not occur in uniform ratio (Hiltner and Wichmann, 1919).

The excretion of zinc varies with the income, as little is retained. In dogs it amounts normally to 5 to 25 mg. per day. Nearly all of this, 94 to over 99 per cent, is in the feces, and most of this was not absorbed. The *normal urinary* excretion in dogs is 0.13 to 0.49 mg. per day. The urinary excretion was but little increased by feeding zinc oxide to dogs and rats and cats for three to fifty-three weeks and soluble zinc salts to rats. A part is excreted by the bile. The excretion returns to the normal level two weeks after the administration is discontinued. Practically none of the administered zinc is retained (K. R. Drinker *et al.*, 1927; normal children, Scoular, 1939). If radioactive zinc is injected *by vein* it disappears rapidly from the blood plasma and appears early in the red corpuscles, increasing during the 170 hours of observation. The maximal deposition is in the liver, which after two hours contains about a third of the injected amount. Considerable is excreted by the pancreatic juice and by the duodenal secretion, practically none by the bile. About a third of the injected dosage is eliminated by the feces in one or two weeks, 2 per cent or less by the urine (M. L. Montgomery *et al.*, 1943; G. E. Sheline *et al.*, 1943; human, R. A. McCance and Widdowson, 1942).

The *total zinc* of mice on normal diet averages 0.434 mg. (Bertrand *et al.*, 1935), which would correspond to about 1 Gm. in a human adult. The *distribution* of the normal zinc shows striking peculiarities. Its concentration is relatively high in the *pancreas*, where it probably forms a part of the *insulin* molecule. It is a constituent of carbonic anhydrase (0.3 per cent) (Keilin and Mann, 1940), and all the zinc in the red blood corpuscles is bound to this enzyme (Hove, Elvehjem and Hart, 1940). It is also high (80 to 450 ppm) in the *epidermal structures*, hair, finger and toe nails and feathers. It is about the same in pigmented and unpigmented hair (Eggleton, 1938).

Deficiency phenomena have been studied on rats and mice with synthetic diets low in zinc, but adequate in other factors. These show nutritional disturbance due to marked interference with intestinal absorption, especially of nitrogen; retardation of growth and subnormal body weight; and roughing of the fur, alopecia and eczema. The *skin* changes involve abnormal keratinization, thickening of connective tissue, and loss of hair follicles. There is vascularization and leukocytic infiltration of the *cornea*, similar to riboflavin deficiency. The *esophagus* is also affected (R. H. Follis *et al.*, 1941) The growth deficiency can be counteracted by transplantation of anterior pituitary. The deficiency symptoms occur if the daily zinc income of the rat is less than 40 gamma; with 22 gamma, the growth rate is retarded by half. All the phenomena are corrected by *adding* zinc (Hubbell and Mendel, 1927; Hove *et al.*, 1938). More severe withdrawal causes paraplegia and death of mice in fourteen to twenty-three days, of rats in two or three months (H. G. Day and McCollum, 1940). The average total zinc content falls to about half the normal (Bertrand and Bhattackerjee, 1934, 1935). In rats, Hove *et al.*, 1938, found the tissue Zn but little decreased by a zinc-deficient diet; the greatest reductions were in the bones, teeth and blood. The significance of zinc for living organisms was reviewed by K. R. Drinker and Collier, 1926. Zinc deficiency is not of clinical importance, as the ordinary income is adequate. Scoular, 1939, concludes that the diet of the preschool child should include 0.31 mg. per Kg. daily.

The **oral toxicity** of zinc compounds is low. Zinc oxide or soluble zinc salts in quantities considerably larger than those that could be introduced in food, *f. i.*, from zinc containers, appear to be innocuous. They cause no apparent symptoms or pathologic changes even when administered daily for a year to dogs and cats, or to rats for several generations, nor is the zinc content of the organs increased (Heller and Burke, 1927; K. R. Drinker *et al.*, 1927; C. K. Drinker and Fairhall, 1933). In drinking water, 30 to 40 mg. per liter is considered safe (D. M. Hegsted, 1945).

No effects result when 0.1 per cent of zinc carbonate is added to the diet of rats; but 0.5 per cent causes anemia and disturbed reproduction; and 1 per cent prevents reproduction (W. R. Sutton and Nelson, 1937). Dornick, 1938, reported food poisoning in a group of people who ate apples cooked in a galvanized iron kettle, so that apples contained 83 mg. of zinc per 100 cc., and the vomitus 17 mg. per 100 cc. The bacteriologic findings were negative, but other metals (cadmium?) were not excluded. *Chronic industrial zinc* poisoning has been reported for workers in galvanizing plants (McCord and Friedlander, 1926) and in processes employing zinc chloride (du Bray, 1937). The symptoms were chiefly gastro-intestinal (nausea and vomiting), but also hypochromic anemia. They were probably due to more toxic metals, Pb, Cd, As and Sb, which are common in zinc ores (Batchelor *et al.*, 1926).

Feeding zinc to rats produces hypochromic anemia and deficient growth (S. E. Smith and Larson, 1946).

Systemic effects of *intravenous injection* of soluble zinc salts are mainly paralytic. Consciousness is lost, but the motor areas are not involved. The blood pressure falls rapidly, probably by flocculation of the plasma protein. Blood coagulation is retarded for an hour after the injection of 5 to 50 mg. per Kg. in rabbits, probably by increase of antithrombin (Melon, 1926). Rabbits develop glycosuria and generally albuminuria after intravenous injection of zinc malate, also after larger doses hypodermically. The quantity of urine is either diminished or unchanged, rarely increased (Salant and Wise, 1918).

The movements of *excised intestines* are depressed by very dilute solutions, abolished by medium concentrations (Salant and Mitchell, 1916). Long-continued ingestion of zinc salts by cats results in fibrotic changes in the acinar portion of the *pancreas*, without affecting the islets (K. R. Drinker *et al.*, 1927). Zinc oxide has been used as a *nervous sedative*, in epilepsy, and so forth, but is useless.

Metal fume fever or "*Brass founder's ague*" is produced by the inhalation of the finely divided zinc oxide formed in the combustion of the metal, even of pure zinc (Lehmann, 1910), and of the vapors and fumes of all heavy metals and their oxides: brass, Cd, Pb, Hg, Hn, As, Sb, Cu, Sn, Ni, Ag, Fe; and also by magnesium oxide (Koelsch, 1923). After exposure of several minutes or hours, depending on the susceptibility and ventilation, there is slight irritation of the throat; but the main symptoms occur later, often after the patient has been in the air for some hours, and they are aggravated by cooling of the body. The attack resembles a malarial chill, which may last some hours, with ordinary febrile symptoms—lassitude, headache, nausea, muscle cramps and joint pains, constricting sensation over lungs, leukocytosis. The attack ends in twelve to twenty-four hours, with perspiration and rapid recovery. It is often diagnosed as influenza or pneumonia, and in animals severe exposure may result in bronchopneumonia (reviews, C. K. Drinker, 1937; R. R. Sayers, 1938).

The phenomena are presumably analogous to those of the inhalation of zinc stearate. Lehmann attributes the symptoms to the absorption of the remains of the respiratory cells destroyed by the zinc. The zinc oxide formed by burning the metal in air appears as branching needles under the electron microscope (L. C. Martin, 1942). This may partly account for the injury. The hypodermic injection of zinc salts also produces fever (Kisokalt, 1912); but so do other irritants.

Repeated exposure to zinc fumes leads to tolerance, which is soon lost if there is no further exposure. It may result in chronic lesions of the respiratory, digestive, excretory and nervous systems (Hayhurst, 1913; Chrometzka, 1936); but C. K. Drinker, 1937, asserts that these are not caused by pure zinc, but by contamination with more toxic metals.

Welding fumes may produce toxic effects by oxidation of the coating metal; zinc if galvanized, lead if painted. The oxides of the iron core are not toxic (B. D. Tebbens and Drinker, 1941; H. K. Sessions, 1944).

PREPARATIONS.—**Soluble Zinc Salts.**—***Zinc Sulfate,** U.S.P. (Zinci Sulfas; White Vitriol); $ZnSO_4 \cdot 7H_2O$. Small colorless crystals, odorless, metallic taste. Very sol. in water (1:0.6), with acid reaction. *Incompatible* with alkalis, carbonates, sodium borate. Dose, as emetic, 1 Gm., 15 grains. *Zinc Acetate*, U.S.P.; $Zn(C_2H_3O_2)_2 \cdot 2H_2O$; soft white plates; faintly acetous odor; astringent metallic taste. Freely sol. in water (1:2.5) with neutral reaction. *Zinc Chloride*, U.S.P.; $ZnCl_2$. White granular powder or porcelain-like masses or in pencils; highly caustic. Very sol. in water (1:0.5).

Insoluble Zinc Compounds—***Zinc Oxide,** U.S.P., (Zinci Oxidum); ZnO; a very fine amorphous, white or yellowish-white powder, without odor or taste. Practically insol. in water or alc. ***Zinc Oxide Ointment,** U.S.P. (Zinc Ointment), contains 20 per cent in white ointment, with 7 per cent of wool fat. *Lassar's Paste*, used in eczema, contains zinc oxide, 1 part; starch, 1 part; white petrolat., 2 parts. *Calamine*, U.S.P., is a zinc oxide tinted by a small amount of ferric oxide. *Calamine Lotion*, U.S.P., contains 8 per cent of calamine, 8 per cent of zinc oxide, and 2 per cent of bentonite in calcium hydroxide solution. *Zinc Carbonate, Precipitated,* is a basic zinc carbonate compound of somewhat variable chemical composition, corresponding to not less than 68 per cent of ZnO. Impalpable white powder, without odor or taste. Insol. in water or in alc. *Zinc Stearate,* U.S.P.; a zinc soap, is a white amorphous, insoluble powder.

CADMIUM

In contrast to zinc, which they resemble chemically, cadmium compounds produce acute toxic symptoms even on oral ingestion. They are responsible for some outbreaks of apparent "food poisoning" with violent gastro-enteritis, when acid foods had been in contact with cadmium-galvanized containers, or from cadmium carbonate silver polish (Sovet, 1858). Cadmium fumes are also toxic.

Serious clinical poisoning occurred from cadmium dissolved by acid foods (fruit juices) that had been in brief contact with containers coated with the metal. Very acute gastritis set in almost immediately after ingestion, affecting all who had partaken; but all recovered (S. Frant and Kleeman, 1941). The treatment consists in gastric lavage with sodium bicarbonate, to precipitate the cadmium (W. H. Lufkin and Hodges, 1944). The Sanitary Code of the City of New York prohibits cadmium articles in the preparation or storage of food or drink.

Continued ingestion of small doses (50 to 100 mg. per Kg. of food) by rats causes marked symptoms: bleaching of incisor teeth; severe hyperchromic anemia, stunted growth, and death after some months. The bone marrow is not materially altered. The toxicity is increased by low protein diet. Cadmium diminished the action of phosphatase (R. H. Wilson and De Eds, 1941; A. G. Fitzhugh and Meiller, 1941; J. T. Ginn and Volker, 1944). The chloride is a potent emetic (15 to 25 mg. per cat), and produces nephritis. Hypodermic injections are followed by local necrosis. Intravenously, it kills by arrest of respiration (Alsberg and Schwartze). Intravenous injection of cadmium salts induces ovulation in estrous rabbits, probably through pituitary stimulation (Emmens, 1940).

Inhalation of cadmium oxide fumes produces metal fume fever. The symptoms begin with irritation of the respiratory tract, and may end with fatal pulmonary edema between the fifth and seventh day, in about 14 per cent of the reported cases. Gastro-intestinal irritation may occur if the cadmium is swallowed. There may also be renal irritation. The lighter cases recover in seven to eleven days (P. Ross, 1944; review, L. W. Spolyar *et al.*, 1944).

COBALT

This is one of the indispensable elements. Its administration causes cutaneous vasodilatation and stimulates hematopoiesis to rapid and considerable polycythemia. Its absorption is limited. The local actions are similar to those of copper salts.

Foodstuffs from different parts of the United States contain 0.005 to 0.057 mg. per 100 Gm. of dry substance; leguminous seeds generally more than cereals (Ahmad and McCollum, 1939).

The excretion of cobalt occurs chiefly by the urine, somewhat by the bile and feces (D. M. Greenberg *et al.*, 1943). After intravenous injection of radioactive cobalt salt into dogs, about 5 per cent of the dose is eliminated by the bile in three days, practically none by the pancreatic juice (G. E. Sheline *et al.*, 1946).

Radioactive cobalt, administered to rats on a low mineral diet, shows 80 per cent excreted by the urine, 10 per cent by the feces. The liver retains small amounts for a few days (C. L. Comar *et al.*, 1946).

After oral administration of finely powdered metallic cobalt to man the urinary excretion amounted to 1 to 6 per cent (Penati and Ruata, 1940).

Deficiency Phenomena.—Bertrand and Nakamura, 1934, found that mice died in three weeks when fed on a diet free from cobalt and nickel. Rigg, 1937, reported from New Zealand that "bushsickness" of sheep can be cured and prevented by feeding 8 mg. of cobalt weekly. The liver of the affected sheep was poor in cobalt, averaging 0.002 mg. per 100 Gm., and this rose to the normal, 0.015 to 0.025 mg., when the cobalt was administered. W. M. Neal and Ahmann, 1937, also reported that calves fed on Natal hay free from cobalt develop malnutrition, with microcytic hypochromic anemia, and that this is prevented or cured by feeding 1 mg. of cobalt per day for cattle, 0.1 mg. for sheep. A relatively small excess is harmful. Iron and copper aggravated the cobalt deficiency.

Hematopoiesis.—Waltner and Waltner, 1929, observed marked polycythemia in rats following promptly on the administration of cobalt. Hypodermic injection of 0.1 Gm. of $Co(NO_3)_2$ increased the red count and hemoglobin 20 per cent in twenty-four hours. Addition of 0.5 per cent of cobalt to the food for a month raised the red count to ten or eleven millions, and the hemoglobin to 165 per cent. These gradually returned to normal on discontinuing. The polycythemia occurs in all vertebrates that have been tried, including birds and frogs (J. Sutter, 1934). Dogs require 10 mg. per Kg. daily to produce significant polycythemia (G. Brewer, 1940). The blood volume is increased chiefly by the volume of the cells (J. E. Davis, 1940). It accelerates the recovery of rabbits from the anemia induced by repeated hemorrhage or benzene (W. Kleinberg *et al.*, 1939), but has relatively little effect on x-ray anemia (A. S. Gordon *et al.*, 1942). The cobalt polycythemic animals give better work performance under anoxic conditions (S. S. Dorrance *et al.*, 1943). Orten, 1936, administered clinically 0.1 to 0.5 mg. daily as cobaltous chloride, by mouth or hypodermically. C. R. Baxter, 1939, reports mildly toxic reactions without any benefit, in hypochromic anemia patients.

Cobalt does not increase the anoxic polycythemia in rabbits (J. Goodman, 1947).

The polycythemia is caused by increased hematopoiesis, probably by hyperplasia of the bone marrow;

but its mechanism is not understood (C. O. Warren *et al.*, 1944). It occurs when the marrow is denervated (Q. D. Schubmehl *et al.*, 1943). It is preceded by a significant rise in the proportion of reticulocytes. The bilirubin concentration of the serum is slightly increased. Splenectomy may delay the increase of blood cells (Orten, 1935, 1936) and may prevent it (Berwald *et al.*, 1934). In rabbits, the addition of manganese heightens the action (Kleinberg, 1934). It does not occur if the diet is deficient in copper (J. M. Orten, Underhill *et al.*, 1932). In four dogs rendered anemic by milk diet, the feeding of 0.1 mg. of cobalt daily enhanced materially the utilization of added iron and copper (D. V. Frost *et al.*, 1941; review, M. O. Schultz, 1940).

Cutaneous Vasodilatation.—LeGoff, 1930, 1934, reported that hypodermic injection of 10 to 50 mg. of cobalt chloride, citrate or salicylate, in man dilates the vessels of the face and ear, beginning in three minutes and persisting for fifty minutes. The blood pressure falls about 10 mm. No toxic symptoms were observed. The effect occurs also on oral administration; it is not produced by similar doses of nickel.

Blood Sugar.—Bertrand and Macheboeuf reported that cobalt enhances the hypoglycemic action of insulin. Others have failed to confirm this on dogs (Magenta, 1927) and on standardized rabbits (Blatherwick and Sahyun, 1927).

Toxic Actions.—Intravenous injection of 0.5 mg. of cobalt salts into rabbits produces considerable fall of blood pressure (LeGoff, 1930). Canjolle *et al.*, 1944, report prolonged vasodilatation, chiefly by the diminished excitability and tone of the vasomotor center supported by direct action on arterial muscle. Respiration is increased by direct action and reflex stimulation of the center. Peristalsis is increased after transient inhibition. A. Stuart, 1884, reported that intravenous or hypodermic injection of cobalt or nickel salts affects the central nervous system directly, in addition to the usual metal action on capillaries, heart and kidneys. There are tremors, chorea and convulsions, followed by paresis. In frogs the medulla is stimulated before the spinal cord (A. Stuart, 1884). Some tolerance is acquired.

The urine is increased, and always contains sugar, often proteins. Cobalt salts act as antidotes to HCN poisoning, through the formation of cobalt cyanides. To be effective they must be introduced subcutaneously in doses which are not devoid of danger. They are therefore not used in man.

The toxicity of cobalt (and nickel) for rats is diminished by the sulfur aminoacids, especially by cysteine, but not by choline. This suggests that the cobalt produces its toxic effects by fixing the sulfhydryl group, analogous to arsenic (W. H. Griffith *et al.*, 1942).

◆

NICKEL

The pharmacologic significance of this metal appears slight. The metal is extensively used, but is not easily soluble, and the salts are not easily absorbed. They are astringent and irritant on local application. Nickel salts have been used as emetics, but are not to be recommended. Nickel cooking vessels give up a harmless trace of the metal to the food (Dzerzgowski and Schumoff-Sieber, 1906, 1908; Lehmann, 1909). Nickel platers are subject to eczema.

Du Bois, 1932, reported 80 per cent of the workers in nickel plants affected. Gaul and Stand, 1934, found 0.01 to 0.09 mg. of nickel per 25 mg. of fresh tissue in psoriasis lesions, in persons not especially exposed to nickel, and never more than 0.01 mg. in normal skin.

Intravenous injection of nickel salts produces fall of blood pressure and the usual flocculation phenomena. The nickel is *excreted* slowly, chiefly by the urine. The urine contains about two-thirds of the nickel of food (N. L. Kent and McCance, 1941). *Hypodermic* injection into mice and frogs is followed by paralyses (Yamagami, 1928). A. Stuart, 1884, described the same effects that he observed with cobalt salts.

With *excised intestine*, dilute solutions of nickel salts produce primary depression, which may be followed by stimulation. Higher concentrations abolish the movements. Nickel is much less toxic than zinc (Salant and Mitchell, 1916).

Nickel Carbonyl.—This gas—$Ni(CO)_4$—is formed by passing CO over finely divided nickel, as in the Mond process of obtaining pure nickel. The phenomena following its inhalation are serious. There is transient malaise, with quick recovery in fresh air; but after twelve to thirty-six hours the patient becomes dyspneic, cyanotic, febrile and delirious, with a blood-stained cough. Death occurs in four to eleven days, with hemorrhages (due to fatty degeneration of the vessel walls) in the lungs, brain and suprarenal glands, and pulmonary edema (Mond, Langer and Quincke, 1890; Armit, 1907, 1908; Brandes, 1934). It is not absorbed as such, but is decomposed by moisture and deposits absorbable colloidal metallic nickel on the respiratory epithelium.

Metal carbonyls in general are volatile liquids that may be absorbed from the skin. *Iron carbonyl* damages the liver severely.

◆

TIN

Absorption and Fate.—When soluble salts of tin are fed, a small quantity is absorbed and accumulates in the tissues. Of the normal tin income, 50 to 80 per cent is excreted by the urine. After intravenous injection the excretion is also largely by the urine (N. L. Kent and McCance, 1941). When soluble salts are injected hypodermically, elimination occurs slowly, mainly by the alimentary tract, but somewhat by the urine, producing marked injury of the kidneys. Considerable quantities are retained: 20 to 25 per cent in the skin, 5 per cent in the liver (Salant and co-workers, 1940).

The *acute toxicity* of the nonprecipitant stannic or stannous sodium citrate by intravenous injection into rabbits is of the order of sodium citrate, so that the tin salts as such are not acutely toxic. Animals with 25 per cent of the fatal dose recover completely. The tin leaves the blood rapidly. The organ distribution is similar to that of bismuth; the kidneys retain it longest (J. Seifter and Rambousek, 1943). Older observers reported *chronic effects* ranging from gastro-enteritis to ataxia and motor paralyses resembling chronic lead poisoning (White, 1880). Salzer, 1918, reports chronic poisoning resulting from a dental plate of "*Watt's metal.*" There were nervous symptoms and anemia. "*Stannoxyl,*" a proprietary compound advertised for oral and intramuscular administration in boils and styes, was found worthless by J. A. Kolmer *et al.*, 1931.

Tetramethyl tin, when inhaled, causes immediate aliphatic narcosis, followed by temporary paralysis and delayed encephalopathy. Tetra-ethyl tin has similar actions, but is less potent (J. Seifter, 1939).

Tin hydride, SnH_4, is highly toxic to mice and guinea pigs, producing pulmonary irritation and convulsions (F. Paneth and Joachimoglu, 1924).

◆

MERCURY

Mercury, particularly in the mercuric salts, has a strongly toxic action on protoplasm. Mercurial compounds are therefore potent antiseptic agents, but their usefulness is limited by precipitation, irritation and toxic systemic effects. The local actions depend on the mercury ions, and are absent in organic compounds that hold the mercury in molecular form. Intravenous injection of the mercury-fluorescein dyes (mercurochrome, and so forth) produces colloidal "reactions." The water-insoluble mercury compounds are fairly rapidly converted into soluble compounds, and these are absorbed, distributed through all the tissues and excreted by all channels, but mainly by the urine and feces. Traces remain in the body for many months. Acute poisoning presents chiefly the phenomena of local corrosion, followed later by the characteristic features of systemic poisoning, stomatitis, dysentery and nephritis. In chronic poisoning, nervous symptoms and cachexia appear. Calomel is comparatively insoluble, so that it may be employed as a cathartic and diuretic. The relatively nontoxic organic compounds, such as mercurophylline (mercupurin) and mersabyl (salyrgan), are injected intramuscularly or intravenously as active diuretics; this effect is also produced by small doses of inorganic mercurials. Mercury was the earliest and for centuries the only effective agent for the treatment of syphilis.

Local Actions and Uses of Mercurials.—The application of soluble mercury compounds produces antiseptic, stimulant, irritant and escharotic effects. These depend on the concentration of mercuric ions in the solution, and on the precipitation of proteins. The latter is not a simple function of the ionization, for the protein precipitates redissolve in excess of protein and in a variety of other substances, such as the halide salts of alkalis, especially the iodides; and in alkalis, amides, and so on. When these are present in or added to the mercuric salts, the precipitation of protein is diminished or prevented. Solutions that ionize weakly also fail to precipitate proteins, presumably because they always leave a sufficient excess of protein to prevent precipitation. Absence of protein precipitation diminishes local irritation and favors the penetration of the mercury. In the presence of proteins and in complex culture fluids, the ***antiseptic action*** of such nonprecipitant compounds may therefore appear equal to or greater than that of more highly ionized but more precipitant compounds. From the standpoint of local and antiseptic actions, the mercury compounds fall into three broad groups: (1) the soluble inorganic mercuric salts; (2) the water-insoluble mercury compounds, mostly mercurous, which are dissolved slowly on contact with the tissues; and (3) organic mercury compounds, mercury of which is attached to a benzene ring, and held more or less firmly, so that it ionizes but little.

Ionization of Mercury Compounds.—The following classification is similar to that of F. Mueller, Schoeller and Schraut, 1911, but also takes into account the antiseptic action on yeast cultures, as determined by J. Peterson, 1926. These also give a convenient index of ionization, the restraining effect for equivalent mercury content being expressed in terms of $HgCl_2$ as unit; for instance, "yeast restraint 0.1" signifies that the anti-yeast activity is one-tenth that of mercuric chloride, after making allowance for the difference in mercury content. The individual compounds are arranged according to this coefficient, in descending order. Those in square brackets were not investigated by Peterson, so that their position is conjectural.

Simple Highly Ionizable Inorganic Mercuric Salts.—Yeast restraint, 1.7 to 1; precipitate proteins, but redissolve in excess; greatest local irritation; rust metals; readily precipitated by H_2S = Mercuric chloride ($HgCl_2$). It should be added that the actual ionization of mercuric chloride is not high, but that it can apparently replace the ions readily, so that it behaves chemically as if it were highly ionized.

Moderately Ionizable Mercuric Compounds.—Yeast restraint, 0.6 to 0.35; protein precipitation, slight or absent; irritation relatively slight; rusting of metals slight; precipitated by H_2S = Potassium-mercuric iodide (K_2HgI_4) [or bromide]; mercuric succinimide; sublamine (mercuric sulfate-ethylenediamine); metaphen (aceto-oxymercuri-nitrocresol), requires alkali for solution [Mercurophen (sodium oxymercury-nitrophenolate), Schamberg *et al.*, 1917, 1919].

Poorly Ionizable Mercuric Compounds.—Yeast restraint, 0.06 to 0.01; protein precipitation absent; irritation slight; rusting of metals absent; H_2S precipitates slowly or imperfectly with the lower members = [Novasurol (sodium mercuri-chlorphenyl oxyacetatediethylbarbituric acid)]; mercuric oxycyanide ($Hg(CN)_2HgO$); mercuric cyanide ($Hg(CN)_2$); mercuric benzoate, mercuric salicylate (low yeast restraint because of slight solubility; dissolves on adding alkali); meroxyl (sodium hydroxymercuri-benzophenone sulfonate); mercurosal (sodium hydroxymercuri-salicyl oxyacetate).

Mercuric Fluoresceins.—As class III, but with fluoresceins which play a considerable part in the antiseptic and colloidal shock reactions, for which they are principally used = Flumerin (sodium hydroxymercuri-fluorescein); mercurochrome (dibromo-flumerin).

Insoluble Mercurials.—These become active only by their conversion into soluble mercuric compounds = Mercury iodides and oxides, ammoniated mercury, calomel and metallic mercury.

The **local irritant action** is most pronounced with mercuric chloride, and is especially important in acute poisoning. The coagulation gives an ashy color and cooked appearance to the *mucous membranes* that come in contact with the mercuric chloride. The tissues underneath are inflamed. Prolonged contact leads to necrosis and corrosion. *Intramuscular injections* cause severe pain and sometimes local necrosis. *On the skin*, concentrations of 1 to 5 per cent produce irritation, vesication and corrosion; sensitive skin may be inflamed by the more dilute solutions used in surgical operations. The absorption from the intact skin may be sufficient to produce systemic poisoning. Solutions of 1:1000 to 1:200 are used in the skin diseases (pityriasis, sycosis) for antisepsis and to produce exfoliation of the epidermis.

The local irritation is considerably mitigated by the formation of double salts, as in the potassium mercuric iodide. This may be injected intramuscularly, but not without pain. Its systemic toxicity is about the same as for mercuric chloride, on the basis of mercury content. The organic mercury compounds ordinarily cause little or no irritation in the concentrations in which they are used.

The *water-insoluble mercurials* do not produce immediate effects, but since they are gradually dissolved by the proteins and salts of the tissues, they develop some local irritation and antiseptic action. The latter may be considerable, because of the prolonged and continuous supply of mercuric ions, even though these are of low concentration (Schamberg and Kolmer, 1914). The irritation varies with the rapidity of solution, from practically nothing with calomel, to "stimulation" with mercuric oxide and ammoniated mercury. *Yellow mercuric oxide* is used especially in ophthalmology, as 1/10 to 1 per cent ointment, introduced by Pagenstecher, 1866, for phlyctenular corneitis. Hosford and McKenney, 1933, believe that it is more often harmful than useful. *Ammoniated mercury*, the complex "white precipitate" obtained by precipitating mercuric chloride with ammonia, is employed as 2 to 10 per cent ointment in eczema and parasitic skin diseases, especially pediculosis. It is used against impetigo contagiosa, the official 10 per cent ointment being diluted with zinc oxide ointment to 2 per cent for prophylaxis, 3 to 5 per cent for treatment. This concentration may irritate the skin of the face and neck. Absorption is insignificant, about as with calomel (O. S. Gibbs *et al.*, 1941). *Calomel* is used as dusting powder or ointment for sluggish ulcers, ulceration of the cornea, vesicular conjunctivitis, and so forth. It is nonirritant and may be applied in any concentration. A dusting powder of calomel 3, talc 2, zinc oxide 1 is used to prevent spread of contagious impetigo of the newborn (Swendson and Lee, 1931). A 33 per cent ointment is employed in venereal prophylaxis, and against pediculi. The *mild mercurial ointment*, which contains 30 per cent of finely divided metallic mercury, is used for the destruction of lice, but is liable to cause dermatitis when used on hairy surfaces, even with a single application, so that the calomel ointment is preferred. The *stronger mercurial ointment* (50 per cent) is used in syphilis. The *insoluble mercury compound should not be applied to the eye when the patient is using iodides;* the irritant mercuric iodide is formed on the conjunctiva and causes severe injury. Iodine compounds that do not ionize readily naturally produce but little reaction (Grumme-Fohrde, 1914). Bromides behave like iodides, but chlorides are harmless (Schloms, 1913).

Bacteriostatic Action.—Robert Koch, 1861, popularized mercuric chloride as a potent antiseptic. Geppert, 1889, confirmed that it has a high bacteriostatic potency, preventing the multiplication of many bacteria in dilutions of 1:300,000; but that it is not a reliable germicide, for the bacteria are not killed, but resume growth when the mercuric chloride is removed or further diluted. It is especially ineffective for sporulating organisms, such as anthrax, tetanus and gangrene; anthrax spores exposed to 3 per cent mercuric chloride for seven days are viable after washing with hydrogen sulfide (A. Müller, 1920). This is practically important, as spore-forming bacteria are present in 10 per cent of the knife blades after use in operations (Brewer, 1939). The bacteriostatic potency is therefore misleading and a source of danger. This holds true also for the organic mercurials. These are likewise highly bacteriostatic, but the results of J. H. Brewer, 1939, show that none can be relied upon to sterilize instruments when spore-forming organisms are present, even with the twenty-four hours' contact with the solutions advised by the makers; nor do they kill staphylococcus aureus in thirty minutes. Mercuric chloride is further objectionable by irritating and injuring the tissues; by its systemic toxicity; and by producing rapid corrosion of metallic instruments and gradual deterioration of rubber. The irritant and corrosive effects are somewhat decreased by the presence of an equal or double quantity of ammonium or sodium chloride, as in the commercial bichloride tablets. These form double salts which are less dissociated and therefore somewhat less active (Sabbatani, 1906). Hydrochloric, tartaric and citric acids have similar effects. The result is accomplished more effectively by using the *potassium mercuric iodide;* or the mercuric oxycyanide, cyanide or benzoate, which dissociate less; or the organic compounds.

Definition of Terms.—Much harm has probably resulted from loose conceptions of antibacterial properties. Properly speaking, *germicidal* means actually to kill bacteria; *bacteriostatic,* arrest of their growth and multiplication; *sterilization,* the absence or destruction of all micro-organisms; *antisepsis,* prevention of sepsis and putrefaction; *disinfection* renders an object noninfectious.

Antiseptic Dilutions of Mercuric Salts.—Mercuric chloride and the other inorganic mercuric salts are used outside the body as 1:1000 solution; on mucous membranes, 1:20,000 to 1:2000, with caution as to absorption. A 1 per cent alcoholic solution of mercuric chloride is used on corneal ulcers. *Spermatozoa* (of rats) are immobilized by 0.0003 per cent. [The equivalent spermicidal concentrations of other antiseptics are: permanganate, 0.004 per cent; phenol, 0.07 per cent; quinine, 0.6 per cent; alum, 0.8 per cent (Ishikawa, 1923; quoted by S. Loewe, 1926, in Handbuch der Praktischen Therapie, *1:* 796).] *Pediculi* are killed effectively by applying a 1:500 solution of mercuric chloride in diluted alcohol twice daily for several days in succession to the head, or a 1:2000 solution to the body; but there is some risk of dermatitis (Fantus, 1937). A 1:100 solution in alcohol is used against *bed bugs.* The vapor of metallic mercury at room temperature is highly toxic to insects (H. C. Gough, 1938).

The bacteriostatic action of mercury salts has been attributed to binding of protein *thiol groups* (P. Fildes, 1940). *Saccharase* is poisoned by mercury and silver salts in dilutions of about $1:10^9$, or approximately an atom of the metal per molecule of enzyme (Euler and Mÿrback, 1919). A similar relation holds for silver and urease (Sumner and Mÿrback, 1930).

Potassium mercuric iodide is formed by dissolving mercuric iodide or chloride in an excess of potassium iodide. Mercuric iodide is insoluble in water, but dissolves in the presence of potassium iodide in the molecular ratio of one HgI_2:two KI, forming a complex salt, K_2HgI_4. A slight excess of KI (20 per cent by weight of the potassium mercuric iodide) is required for permanent solutions. This is assured by using equal weights of HgI_2 and of KI (or NaI); but they are often used in the ratio of 3 Gm. of KI (or NaI) for each gram of mercuric chloride.

Mercuric oxycyanide, cyanide and benzoate produce little irritation and have been used as antiseptics on sensitive mucous membranes, such as the conjunctiva and urethra, as 1:4000 to 1:1000 solutions. They have been largely displaced by organic compounds.

Organic mercurial antiseptics were proposed with the hope of securing a better therapeutic index, a wider margin between antibacterial potency and injury. A considerable number of compounds has been introduced in which the local and systemic toxicity of mercury has been greatly reduced by binding it more or less firmly to a benzene ring, without materially decreasing the bacteriostatic power. As bacteriostatics, these compounds are useful for application to mucous membranes, but satisfactory germicidal potency has not been achieved.

The following are the principal commercial compounds of this type in alphabetic sequence, their approximate mercury content, and the dilutions in which they are generally employed: *basic phenylmercuric nitrate* (*merphenyl nitrate*), 63 per cent, 1:15,000; *merbromin* (*mercurochrome*), 25 per cent Hg, 1:100; *meroxyl,* 27.5 per cent, 1:200; *merthiolate,* 49.5 per cent, 1:1000; *nitromersol* (*metaphen*), 56 per cent, 1:2500.

Phenylmercuric ("*merphenyl*") *Compounds,* N.N.R., readily liberate the phenylmercuric radical $(C_6H_5Hg)^+$, which does not precipitate serum proteins or rust metals, but which combines with protein thiol groups to form poorly dissociated protein mercaptides (L. Hellerman *et al.*, 1943). It depresses cytochrome and various other enzyme systems (E. S. Cook *et al.*, 1946). The *basic nitrate* was introduced by L. A. Weed and Ecker, 1931, as a highly potent bacteriostatic agent, with low toxicity for man, ordinarily producing little local irritation. Brewer, 1939, ranks its bacteriostatic potency with the other compounds listed above. Like other mercurials, it is not effective against spores. It is employed as buffered solutions which are more stable and less irritating. It is applied to the skin and superficial wounds as 1:25,000 to 1:15,000 solution. It is marketed as 1:1500 solution which may be applied briefly, but should not be used for wetting dressings. It may liberate mercuric ions under some conditions and become caustic. The *borate, chloride* and *picrate* are also used. *Phenylmercuric acetate* appears to outrank all other contraceptives, experimentally and clinically (N. J. Eastman and Scott, 1944). Very little is absorbed.

Mercurochrome, merbromin, N.F., a bromomercurifluorescein derivative related to eosin, was introduced by H. H. Young *et al.*, 1919. *Eosin* itself is somewhat antiseptic (Noguchi, 1908) and shares many of the properties of mercurochrome.

Mercurochrome is used as a nonirritant *antiseptic.* Solutions of 2 per cent cause only slight and brief smarting of sensitive mucous membranes, such as the urethra. Prolonged contact with 5 per cent solutions, however, is injurious to cells. It is considerably more toxic for bacteria, especially in acid solution (urine of *p*H 6.), but its activity varies greatly for different organisms, even of the same group, and is materially reduced at the neutral point, more so at alkalinity, and by proteins and bile (Birkhaug, 1930, 1933). Altogether it does not rank high as an antiseptic, even in the test tube (Simmons, 1928). Mercurochrome practically does not penetrate normal living tissue, but only such as is dead and dying; it is fixed in the stratum corneum of the skin and of the mucous membranes; and penetrates mucus and wound detritus. A 2 per cent solution is advertised as a first-aid antiseptic, but is ineffective against spore-bearing organisms and against rabies. It forms a thin eschar on burns, but several instances of severe mercury poisoning have been reported (A. M. A. Councils, 1944). A 2 per cent solution in an acetone-alcohol-water mixture has been advocated for preoperative skin disinfection, but it is unreliable (von Oettingen *et al.*, 1931). Mercurochrome is *marketed* as iridescent green scales or granules, permanent in the air, freely soluble in water, soluble in alcohol, insoluble in chloroform or ether. Its aqueous solution is of a deep cherry color, and is stable. It is incompatible with acids, with most alkaloidal salts and with local anesthetics.

Intravenous injection of mercurochrome was introduced by Young *et al.*, 1926, to combat septicemias and certain localized infections, but has practically gone out of use. It produces a shock reaction which is sometimes followed by prompt improvement; but it is ineffective in many cases and not without danger. Positive results are presumably due to the flocculation shock, for the body fluids (blood, bile, knee joint) are not even bacteriostatic (Hench, Snell, Greene *et al.*, 1925). The drug is injected, in the dosage of 5 mg. per Kg. of body weight, as a freshly prepared and filtered 0.4 per cent solution in distilled water. It is self-sterilizing and should not be boiled

It generally causes a febrile reaction, with chill, nausea and sometimes also profuse diarrhea; but a single injection of this dosage is reasonably safe. Severe symptoms and occasionally serious collapse sometimes occur between 5 and 7.5 mg. per Kg. Stomatitis is also sometimes seen. *Rabbits* show severe but usually temporary renal damage with 5 mg. per Kg.; 25 mg. may be fatal. Their susceptibility is evidently greater than with men or dogs, but the margin of safety is not wide.

Excretion.—The mercurochrome leaves the blood stream rapidly. It is excreted mainly by the bile and stools, some by the urine (Hench *et al.*, 1925). However, gallbladder carriers of Bacillus typhosus could not be disinfected by mercurochrome, by vein or by mouth (K. F. Meyer *et al.*, 1926).

Sodium-p-hydroxymercuribenzoate was recommended by M. T. Hanke, 1940, as an oral antiseptic. It is relatively nontoxic (T. J. Haley and Edwards, 1947).

◆

ABSORPTION AND FATE OF MERCURY

Mercury compounds and metallic mercury are absorbed readily from all surfaces, even from the intact skin, and all these channels are utilized therapeutically. Chemical changes occur in the course of the absorption. Mercurous compounds and metallic mercury are oxidized; the mercuric salts from soluble compounds with the proteins, sodium chloride and alkalis (Voit, 1857). The absorbed or injected mercury leaves the blood rapidly, except for small traces. A part is excreted by the urine and feces (Welander, 1886), the fecal excretion being generally the less important. Variable traces are generally found in the bile, sweat (Tachau, 1911; Lambert and Patterson, 1915), gastric (Lieb and Goodwin, 1915) and intestinal juice and saliva (literature in Lomholt, 1928). The excretion declines rapidly and becomes insignificant within a week after the administration ceases (unless absorption depots are maintained), but traces may be excreted intermittently for six months or longer. A considerable proportion of the absorbed mercury is *retained* indefinitely in the body: 50 or 60 mg. with therapeutic courses of intramuscular or intravenous injections of soluble inorganic or organic compounds, and 200 to 700 mg. with intravenous injections of colloidal solutions (Cole, Sollmann and Schreiber). The excretion will be further discussed in connection with the clinical use. The *mercury concentration in the blood* falls rapidly, even after intravenous injection, to traces about equivalent to those in the urine. Similar concentrations exist in the other body fluids. The distribution in the organs is similar after the therapeutic use and in acute poisoning.

Normal Mercury Content.—Nearly all foods contain tangible traces of mercury, giving a normal income of about 20 micrograms daily. The daily urinary excretion averages 7.6; fecal, 4.8; total, 12.4 micrograms. Kidneys of men without history of mercury exposure contain about 50 micrograms, animals about 25 per 100 Gm. (O. S. Gibbs *et al.*, 1941).

After clinical *acute and fatal bichloride poisoning*, the quantity in the organ is surprisingly uniform, although dosage does have some effect. The concentration is always highest in the kidneys (average, 3.8 mg. per 100 Gm. of fresh organ); then comes the liver, with about one-half to two-thirds of the kidney concentration; the spleen with one-seventh, the intestines with one-ninth; the heart and skeletal muscle and lungs with one twenty-fifth (= 0.2 to 0.3 mg. per 100 Gm.) and finally the blood, with 0.015 to 0.12 mg. per 100 cc., about one-fortieth of the kidney concentration. Edema fluids are still lower. The bile is variable, but always higher than the blood. The total content of the liver is about three times that of both kidneys. From these data, the mercury generally retained in the entire body can be estimated as about 240 mg., which would be close to the intravenous fatal dose (Sollmann and Schreiber, 1930. The older analyses are reviewed by Lomholt, 1918). The amount stored in the kidneys and liver furnishes an index of the amount absorbed, for instance, from percutaneous application to rats (E. P. Lang, Vox *et al.*, 1946). In therapeutic administration, the mercury *level of the blood* is said to run between 0.4 and 2 mg. per liter, which approximates the concentration in the urine: 2 to 3 mg. per liter is rare, and is generally accompanied by toxic manifestation. Young and Taylor, 1929, claimed that mercury is bound in the bones similarly to lead. It passes through the placental circulation, and it is claimed that congenital syphilis may be treated by mercurial inunction of the mother (Jung, 1914). The concentration in the amniotic fluid was found of the same order, 0.2 to 0.6 mg. per liter. The data for cerebrospinal fluid (Young and Taylor, 1929) are contradictory and probably not reliable. In animals, the *colloidal forms* of mercury, including the dyes, are found chiefly in the liver, after intravenous injection. With mersalyl, intravenously, the highest percentage was in the bile, suprarenals, kidneys and large intestine (J. Müller, 1929). After sojourn of guinea pigs in an *atmosphere saturated with mercury vapor* (6 mg. per liter at 13° C.) for ten hours to four days, the highest concentration was also found in the kidneys, relatively little in the liver (Holtzmann, 1931).

Form of Mercury in the Tissues.—The slowness of the excretion indicates that this is firmly bound, and presumably insoluble. The black line, sometimes seen on the margin of the gums, consists apparently of mercuric sulfide (Almquist, 1912), but this is not typical of its general distribution. It indicates, however, that the circulating mercury is ionized at least in part, presumably as a mercuric albuminate: sodium chloride compound. Eckmann, 1896, described the histochemical tests. The *globules of metallic mercury* reported in necrotic bone and in the tissue of an aortic aneurysm (Kolmer and Martin, 1918) are a curiosity. Colloidal mercury compounds when injected intravenously are presumably retained by the reticular endothelium. The *forms in which mercury is excreted* are also not fully known, but the greater part of the urinary mercury can be deposited by electrolysis and is therefore ionizable (Lomholt, 1928). Young and Taylor, 1929, claimed that the mercury excretion is temporarily suspended by calcium lactate (6 Gm. by mouth), and increased by low calcium income and ammonium chloride administration and by sodium thiosulfate. Confirmation by other analytical methods appears desirable. Blumenthal and Oppenheim, 1911, claimed that potassium iodide diminishes the deposition in the liver.

Toxicology.—*Acute* mercurial poisoning occurs generally from mercuric chloride; ***sub-acute***, from therapeutic overdoses; ***chronic*** mercury poisoning may occur medicinally, but is seen especially in industrial poisoning (workers in mercury, manufacturers of thermometers, mirrors, electric lamp bulbs, felt, and so forth). A large proportion of those exposed to mercury are affected, because the adherence of the metal to the skin, and the inhalation of its vapor make protection difficult.

Phenomena of Acute Poisoning with Mercuric Salts.—The immediate effects are due to coagulation, irritation and superficial corrosion, to which mucous membranes are highly susceptible. There is an astringent metallic taste, salivation; burning, swelling and ashy discoloration of the mouth and pharynx; thirst, abdominal distress and pain, at first epigastric, then diffused; vomiting with white or often bloody mucous shreds; sometimes edema of the glottis. The primary symptoms generally yield to local treatment, including abstinence from food for thirty-six hours; and the patient may be fairly comfortable. The light cases are practically well on the next day. Signs of mercurial stomatitis usually develop in twenty-four hours, but are not especially marked. *Severe cases* give the general picture of serious illness, even in patients who recover: great weakness and prostration or excitement; weak, rapid heart; fall of blood pressure; cramps in the legs; dehydration; stupor; collapse. Death may exceptionally ensue in a few hours by circulatory collapse (Mering, 1880).

The *viscosity of the blood* (not of the serum) is doubled in mercurial, lead and phosphorus poisoning (Farmachidis, 1912). A neutrophile *hypoleukocytosis* is a constant phenomenon (Donzello, 1915), but in the cases which go on to colitis and nephritis this is followed in a few hours by a marked increase. Counts above 30,000 are unfavorable (L. A. Kohn, 1936).

Somewhat later, the large intestine and kidneys become involved. Within two or three days, the *urine* becomes scanty and shows protein and casts. Anuria may be complete, with death within a week by nephritic pulmonary edema or nitrogen retention, without uremic convulsions. In the event of recovery, the urine may resume about the fifth day. Early anuria augurs a bad prognosis. Cases that begin with polyuria generally recover. If the nephritis is not extreme, membranous *colitis* is likely to develop, with dysentery, tenesmus, ulceration and hemorrhage. These phenomena may only appear, and prove fatal, several weeks after taking the poison (Lambert and Patterson, 1915). There may be toxic anemia with complete lack of blood regeneration (R. Wankmüller, 1944). All but the local symptoms are similar, by whatever channel the mercury was administered. *Postmortem examination* shows the mucous membranes of the upper digestive tract of an ashy color, congested and corroded. The colon lesions are those of severe dysentery: hemorrhage, congestion, coagulation and black ulcerations. The kidneys show acute nephritis, often with calcification of the epithelium.

The gross and microscopic pathology was well described by Eckmann, 1896. It is similar in man and experimental animals, except that with herbivorous animals the chief site of the *intestinal lesions* is in the cecum and appendix, while in man the colon is most affected.

Mercurial Nephritis.—The kidneys are especially susceptible to irritation and injury by mercury. Acute poisoning is followed by severe acute nephritis, primarily tubular, but involving also the capillary endothelium, especially in the glomeruli. Severe poisoning may show hemorrhagic glomerular nephritis. In nonfatal cases, the nephritis tends to become interstitial and eventually cirrhotic. In milder and slower intoxication, the type is primarily interstitial. The susceptibility to nephritis varies considerably even experimentally (W. C. Hunter, 1929). Temporary albuminuria is not uncommon in the therapeutic course, and enjoins caution, although the damage is rarely permanent. In severe acute poisoning, the lumen of the tubules, and sometimes the epithelium, may contain crystals of calcium oxalate (Saikowski, 1866), which have not been explained. They may appear forty-eight hours after the administration (Schamberg *et al.*, 1915). The functional changes in severe acute poisoning consist in intense albuminuria, partial or complete suppression of urine, diminished phenolsulfonphthalein output, retention of urea, rapid reduction of alkali reserve (MacNider, 1917). Smaller doses produce polyuria (Schlayer and Hedinger, 1907), which is utilized therapeutically for diuresis. Renal glycosuria may result from intermediate doses (Franck, 1913).

The anatomical and chemical changes in acute clinical mercury nephritis are described by W. R. Campbell, 1917; those in the subacute form by Foster, 1915. The lesions involve the distal half of the proximal convoluted tubules in frogs; practically the entire tubules in cats; the entire tubules and the duct system in rabbits; and the ascending limb of Henle's loop in guinea pigs (J. G. Edwards, 1934). The usual lethal doses produce acute epithelial necrosis, almost exclusively in the central part of the proximal convoluted tubules (J. G. Edwards, 1942). There is no parallelism between the degree of renal injury and the mercury content of the kidneys (R. Müller and Scheiner, 1936). The *urine changes in acute oliguria* are those of nephrosis: high albumin content; high urea, to 2 per cent; high specific gravity, to 1.030; low chloride, down to 0.01 per cent. The blood plasma shows decreased chloride, and increased nonprotein nitrogen, ten or twenty times the normal. Such patients may recover or may die of nitrogen retention even though the urine flow returns. In favorable cases restoration is accompanied by greatly increased excretion of the retained chloride and urea. Renal epithelium that has regenerated after mercurial injury is more resistant (W. De B. Mac Nider, 1941). In *more prolonged poisoning*, the urea and specific gravity are low, as well as the chloride, although the blood nonprotein nitrogen is high (to 340 mg. of urea N). Uric acid and creatinine are also high in the blood. The alkali reserve is lowered (Leschke). *Hypoproteinemia*, produced by plasmapheresis, protects dogs against mercury injury, but only if it preceded the mercury administration (R. L. Holman and Donnelly, 1942).

Hepatic degeneration of moderate degree was reported in experimental poisoning by Morel, Mouriguand and Policard, 1912. In acute poisoning there may be *glycosuria* and disappearance of glycogen. MacNider, 1919, found that dogs poisoned by mercuric chloride, 15 mg. per Kg., by mouth, react with severe gastro-enteritis, but usually recover. The liver of these animals shows degenerative changes, beginning with deposition of fat in the cells around the central veins, then cloudy swelling and necrosis, the process extending toward the periphery. The intensity is parallel to the nephritis, rather than to the gastro-enteritis. Kunkel, 1889, reported that the *intestines* of rabbits poisoned with mercury show black markings which follow the course of the blood vessels. They are probably hemosiderin formed from the iron liberated by extravasation of blood in the intestinal mucosa (Eckmann, 1896). The rapid *destruction of blood* in mercury poisoning also leads to deposition of hemosiderin in many organs. If the animal recovers, the injured *hepatic and renal cells* are replaced by epithelium of less differentiated and more resistant embryonic type.

probably with eventual restoration of normal cells (W. De B. MacNider, 1942).

The *toxicity of mercuric chloride* varies according to the promptness of the emesis and the individual resistance to the colitis and nephritis, so that the fatal dose is inconstant even for intravenous injection. The prognosis is bad if 1 Gm. or more of mercuric chloride has been taken by mouth, unless vomiting occurs within a few minutes; 0.5 gm. causes severe poisoning, but is ordinarily survived even without vomiting. Other soluble mercuric salts, the double iodide, cyanide (Gettler, 1916), and so forth, have approximately the same toxicity.

Mercuric chloride taken by mouth in doses of 1 Gm. or more, in a series of thirty-eight cases (S. Goldblatt, 1928), produced little effect if vomiting occurred within three minutes; if this was delayed to five minutes, toxic phenomena set in, but generally ended in recovery; with a delay of ten minutes, the outcome was uncertain; with thirteen minutes, most patients died, and with more than fifteen minutes the result was invariably fatal. The dosage of 0.5 Gm. produced severe effects, but ended in recovery, even without vomiting. In the series of Peters *et al.*, patients who had taken less than 1.5 Gm. generally survived (nine fatal cases in thirty-seven); with more than 2 Gm. the outcome was generally fatal.

The toxicity of the *water-insoluble mercuric salts* varies with their solubility in the digestive tract. This is high with the mercury iodide, low with sulfide (Niklasson and Santesson, 1926); the oxide and ammoniated mercury are intermediate. The *insoluble mercurous compounds* are generally less toxic. *Calomel* ordinarily produces only diarrhea even with large doses, but severe and even fatal effects are recorded (for children with 0.4 Gm.; for adults with 2 to 3 Gm.). Fatalities have been reported from *intramuscular injections* of 0.22 Gm. of mercuric salicylate and 0.1 Gm. of calomel. *Metallic mercury*, when finely divided as in "gray powder" (mercury with chalk), is probably more active than calomel.

Metallic mercury, in bulk, formerly given in ileus in doses of 100 to 500 Gm., usually passes off by the feces with little effect; sometimes there is diarrhea and stomatitis; and exceptionally, severe and even fatal poisoning; "and then, a ride in the hearse" ("et postea vectio in curru"), was Archibald Pitcairn's dry comment on the use of mercury in ileus "ad uncias aliquot, vel etiam libras" (Elementa Medicinae, 1740). An attempted suicide by *intravenous injection of metallic mercury* is quoted by Leschke, 2 cc. (27 Gm.) being injected into the right cubital vein. There were no symptoms for three days; then moderate subacute mercurial symptoms which subsided completely. X-ray examination showed mercury globules through the base of the lungs and in a pool in the apex of the right heart. The patient survived ten years in good health, except for occasional diarrhea.

The *toxicity of the organic mercury compounds* is relatively low, increasing with the ease of ionization (Abelin, 1912; Tsungmig Tu).

E. Fourneau and Melville, 1931, found that the intravenous toxicity is not directly related to the chemical reactions of the compound toward NaOH or H_2S, and so on, but rather to the primary linkage of the mercury. The mercurial dyes run irregularly (Klages and Schreiber, 1914). Eight commercial samples of *mercurochrome* varied to 3.5 times in their toxicity to mice (Burn and Elphick, 1930). The *diuretic compounds* will be discussed under that heading. *Fulminate of mercury*, $Hg(CNO)_2$, which is used in munitions, causes local irritation of the exposed mucosae and of the skin, especially of the face and hands, producing sensitization (L. Schwartz, 1944) The volatile *alkyl mercury compounds*, dimethyl and diethyl mercury, are highly toxic. The symptoms are almost exclusively nervous. Inhalation of *methyl mercury compounds* produced tremor, ataxia, dysarthria, gross constriction of the visual field. Memory and intelligence were not affected. Histological damage of the central and peripheral nervous systems was observed in rats and monkeys exposed to methyl mercury iodide (D. Hunter *et al.*, 1940). Two deaths from exposure to the fumes of *diethylmercury* were reported by W. H. Hill, 1943. Serious nervous and circulatory symptoms, which may last for weeks or even months, follow rather slight and brief exposure to the vapor. It is claimed that symptoms may not occur until several months after the initial absorption, and run a fatal course.

Intravenous injection of small doses of mercuric chloride produces *emesis*, which Hatcher and Weiss, 1923, inclined to refer to reflexes from the heart. Larger doses cause flocculation shock. The heart develops pathologic rhythms (F. D. McCrea and Meek, 1929). Small doses of nonprecipitant mercury salts (succinate, 1 to 2 mg., cat) increase the excitability of the vagus to faradic stimulation, and antagonize atropine. Larger doses depress the vagus response. They also greatly increase the toxicity of potassium. Conversely, the administration of calcium alters the response of the heart to mercury (W. Salant, 1924; W. Salant and Nadler, 1927). *Glycolysis in extracts of frog muscle* is inhibited by low concentrations of mercuric chloride or phenylmercuric chloride. This is prevented by the addition of cysteine or glutathione (Gemmill and Hellermann, 1937).

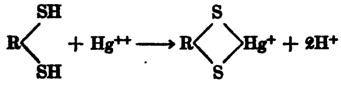
Treatment of Acute Mercuric Poisoning.—The absorption of mercury is prompt, or at least its fixation in the mucous membrane, so that the fate of the patient is practically decided within the first ten or fifteen minutes. If the stomach is evacuated in that time, usually by spontaneous vomiting, the prognosis is hopeful; treatment after this period accomplishes little, although gastric lavage must be tried as a routine. The customary antidotes (egg, milk, calcium sulfide, sodium thiosulfate orally or intravenously, or hypophosphite) are ineffective after this time (S. Goldblatt, 1928). Dimercaptopropanol (BAL) appears especially effective (A. M. Ginzler, 1946; W. T. Longcope and Leutscher. 1946), as it acts after absorption as well as locally. So also does sodium formaldehyde sulfoxylate, introduced by S. M. Rosenthal, 1934, 1946.

Colon lavage, or repetitions of the gastric lavage, and diuresis, do not remove significant quantities of mercury, and would be useful only against the irritation.

Removal of Mercury by Gastric and Colonic Lavage, Feces and Urine.—The impossibility of effective treatment along these lines is illustrated by the quantitative mercury determination of Sollmann and Schreiber, 1936, in four clinical cases of acute mercuric chloride poisoning, two light and two fatal, subjected to extensive and repeated gastric and colonic lavage. The total amount of poison recovered by all these washings, and by the stools and urines, amounted only to 23 to 164 mg. of mercury, 1½ to 3 per cent of the amount taken, and practically all of this was in the first gastric lavage. The colon lavage removed only 1.4 to 9 mg.; and the urine only a total of 1.5 to 9.7 mg. in the first five days. The severe cases had anuria, the mild cases polyuria, but in all the mercury concentration in the urine was within the range of therapeutic administration, indicating that the nephritis is not caused by mercury excreted into the urine, but by that circulating in the blood during the period of active absorption; for the low mercury concentration of the urine also indicates that the mercury disappears promptly from the circulation.

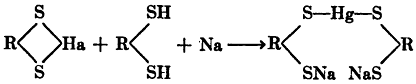
Chemical Precipitants and Adsorbents.—*Proteins* precipitate mercuric chloride, but the precipitate would redissolve, so that they would be useless, except as demulcents, unless they were administered immediately with the poison, to delay its absorption till evacuation. For this purpose, three raw *eggs* may be taken with a quart of *milk* (Sollmann, Barlow and Biskind, 1927). *Charcoal* (a tablespoonful) acts similarly, but by adsorption (Ferreira and MacBride, 1914). It is recommended by Leschke, who claims that 1 Gm. of animal charcoal binds 850 mg. of mercuric chloride. The stomach should be washed with a suspension of three or four tablespoonfuls of the carbon. *Potassium iodide and quinine* (a reversal of Mayer's reagent) was proposed as precipitant by Hall, 1914, but it would accomplish nothing more than the preceding (Barbour, 1915).

Dimercaptopropanol (*BAL*) reacts with Hg^{++} *in vitro* (Gilman, 1946) to form an insoluble mercury mercaptide.



$$\mathrm{R}{<}^{\mathrm{SH}}_{\mathrm{SH}} + \mathrm{Hg}^{++} \longrightarrow \mathrm{R}{<}^{\mathrm{S}}_{\mathrm{S}}{>}\mathrm{Hg}^{+} + 2\mathrm{H}^{+}$$

This reacts further with BAL to form a soluble compound which is probably nontoxic and is rapidly excreted:



$$\mathrm{R}{<}^{\mathrm{S}}_{\mathrm{S}}{>}\mathrm{Ha} + \mathrm{R}{<}^{\mathrm{SH}}_{\mathrm{SH}} + \mathrm{Na} \longrightarrow \mathrm{R}{<}^{\mathrm{S-Hg-S}}_{\mathrm{SNa\ \ NaS}}{>}\mathrm{R}$$

Reducing agents have been tried, on the basis that mercurous compounds are much less toxic than mercuric. They are effective in the test tube, and against whatever unabsorbed mercury remains in the stomach—but no more so than evacuation. Calcium sulfide and sodium thiosulfate were also tried intravenously, but even if they could act in the blood, which is doubtful, they would not be of much use after half an hour, when the mercury has gone into the tissues and the injury has been done.

Phosphite and Hypophosphite Reagents.—Sodium phosphite reduces mercuric chloride to calomel. Its use with sodium bicarbonate as an antidote was proposed by Linhart, 1917, although it is better known as "*Carter's antidote,*" a mixture of sodium phosphite and sodium acetate. Phosphite mixtures are quite successful if given within five minutes after the poison (Fantus and Hyatt, 1917). They are useless after it has been absorbed, even if the antidote is injected into the blood (Sansum, 1918).

Sulfides.—Wilms, 1915 to 1917, made the improbable claim that calcium sulfide is effective even when started twelve to twenty hours after the poisoning. He uses it by mouth (0.15 to 0.3 Gm. every hour) and intravenously (in quantity equal to that of the mercury) as a freshly made, boiled and filtered, 0.2 per cent solution. This is supposed to form mercuric sulfide. The advisability of the intravenous treatment is doubtful. Haskell and Courtney, 1917, found the benefits no greater than with simple saline.

Sodium thiosulfate has been suggested, both orally and intravenously. It acts not only as a reducing agent, but forms soluble double salts with mercurous compounds, which are probably quite toxic. It does not save dogs that have received a fatal dose of mercuric chloride (Melville and Bruger, 1929). J. G. Edwards, 1934, found that it diminished the renal injury, but did not prolong life.

Sodium formaldehyde sulfoxylate was introduced by S. M. Rosenthal, because it arrests the toxic action of mercuric salts promptly on contact, in the stomach and in the blood, but presumably not in the cells. It is ineffective after these have been injured by the mercury (H. Brown and Kolmer, 1934), but it is highly effective under suitable experimental conditions, against intravenous as well as oral administration of mercuric chloride. Injected intravenously shortly after hypodermic injection of mercuric chloride, it protects the kidneys completely against twice, and partially against three times, the fatal dose (Rosenthal, 1935). Modell *et al.*, 1937, find that this would be the limit of the protection against intravenous injection, since the compound that is formed has itself a toxicity of one-third to one-half that of mercuric chloride. Large doses of sulfoxylate increased the toxicity. Alkali injection increased its effectiveness against orally administered mercuric chloride. The *clinical usefulness* of the formaldehyde sulfoxylate is restricted by the delays incident to clinical poisoning. However, the cases in which it has been used generally had a favorable outcome. Rosenthal, 1934, advises the following routine: gastric lavage with 5 per cent of the salt, leaving about 200 cc. in the stomach; followed immediately by 10 Gm.

in 100 to 200 cc. of water (freshly prepared, or ampuls), by slow intravenous injection during twenty to thirty minutes. If necessary, another injection of 5 to 10 Gm. may be made in four to six hours. It is not toxic in the doses advised; animals tolerate 1 Gm. per Kg. intravenously, without symptoms.

The *acute and delayed shock* of mercury poisoning are due largely to dehydration from salt depletion (indicated by decrease of plasma chloride and protein), which is caused by the impaired absorption of fluid from the digestive tract, on account of the nausea, emesis and cell injury (Peters). This would suggest abundant intravenous injection of saline solutions, but administration of fluid beyond the excretory capacity of the kidneys entails risk of pulmonary edema and cardiac failure. It should only be pushed if the blood volume is diminished.

Saline Infusions, Alkalis, and the Like.—Sansum, 1918, determined the minimal fatal dose of mercuric chloride by intravenous injection for dogs as uniformly 4 mg. per Kg. This was not modified by the infusion of plain saline or by sugar solutions, alkalis, Fischer's solution, and so forth; *i. e.*, these were all unsuccessful against acute poisoning. Burmeister, 1917, claimed that *venesection and transfusion* diminish the renal changes. The use of *alkalis* is justified by the observations of MacNider that they protect the kidneys against metallic poisons. However, their success is probably limited.

Subacute phenomena develop in sequence to the acute symptoms; or independently of these if the mercury is introduced more gradually, with too intensive or excessively prolonged therapeutic administration, or in the course of chronic industrial or accidental poisoning. They consist in localized chronic inflammations, especially stomatitis, colitis, nephritis and more rarely dermatitis. The stomach and small intestines usually escape (review, Almkvist, 1928). The phenomena merge into those of the chronic poisoning and may be considered in that connection.

Chronic Mercury Poisoning.—Long-continued exposure to relatively small doses leads to a slow and insidious development of chronic poisoning, usually with some stomatitis and renal irritation, but with additional nervous and nutritional disturbances; especially characteristic tremors, erethismus (psychic irritability and restlessness) and other psychoses; cachexia with anemia, malnutrition and muscular atrophy; bone changes (decalcification) and more rarely neuritis or pareses. Abortion is common. It is doubtful whether *treatment* materially influences the course after the appearance of symptoms. Potassium iodide and hot baths are generally tried, with the intention of hastening elimination, but their effectiveness has not been established. Buchtala found that the iodide rather delayed the urinary elimination of mercury. Prophylaxis is therefore more important. Those who work much with mercury should be protected against unnecessary exposure (review, L. T. Fairhall, 1945).

Industrial chronic poisoning by mercurial solutions is illustrated by the study of Neal and Jones, 1937, on the cutting of fur for hat felting, where the workers are extensively exposed to mercuric nitrate. (It is being displaced by nonmercurial technics; P. A. Neal, Flinn *et al.*, 1941.) Of the 500 operatives examined, about a twelfth showed definite mercurial symptoms, especially nervous. All these had fine intention tremors and three-fourths had psychic irritability. Stomatitis and renal disease were not conspicuous and were indeed doubtful. The urine of two-thirds contained less than 0.01 mg. per liter, the other third, 0.01 to 0.79 mg.; only one above 1.2 mg. The incidence of positive Wassermann tests was 2.5 per cent, as against 3.5 to 4 per cent in other industries; but it is not certain that the difference signifies resistance to syphilitic infection. Acute and chronic poisoning in the *tungsten and molybdenum industry* was reported by L. Lewis, 1945. Leschke claims that the urinary excretion of mercury in exposed workers may exceed 20 to 80 mg. per day, with only moderate symptoms; but ordinarily it is about 0.1 mg. without symptoms.

Toxic Income.—O. S. Gibbs *et al.*, 1941, consider that continued absorption of 5 mg. daily is only occasionally deleterious. They incline to believe that chronic organ toxicity depends on the organ content, 0.1 mg. per 100 Gm. being harmless, while 0.8 to 1 mg. may be harmful. A. Stock, 1943, estimates the *normal daily urinary excretion* of mercury is 0.1 to 1 microgram.

Amalgam Tooth Fillings.—A few cases diagnosed as chronic mercury poisoning have been ascribed to copper amalgam (Fuehner, 1927; Fleischmann, 1928; A. Hertz, 1929); none to silver amalgam. Some doubt is justified as regards the copper amalgam. The symptoms were not particularly distinctive. Borinski, 1931, found the daily urinary mercury output in patients with copper amalgam fillings at most 1.6 mg. on the third day, and 0.02 mg. after a year, the latter about twice the output of persons without special exposure. Silver amalgam gave about half of these levels.

Mercury Vapor Poisoning.—Metallic mercury vaporizes at ordinary temperature, and more rapidly if heated. The heated vapor condenses on the respiratory mucous membranes and in the mouth, whence the mercury may be swallowed or oxidized in situ to absorbable compounds. These give rise to focal irritation, for instance in the lungs (Ricker and Hesse, 1914), and to systemic effects. Mercury volatilized at room temperature is absorbed directly, as such or after oxidation.

Mercury vapor poisoning occurs in various industries and was not uncommon among scientists. Stock, 1929, deduced from the biographies that Faraday and Pascal were so afflicted, without being aware of the cause. There are some indications that traces of mercury vapor diffuse through thin moist membranes as dissolved metal (it does pass in this manner through several centimeters of oil, and vaporizes again from the surface, so as to amalgamate a strip of copper suspended above the oil). It is also conceivable that the metal may circulate and be excreted in this form, since the urine does not give the mercury ion reactions until it has been oxidized. Henderson and Haggard give the following as the mg. of mercury in a liter of air saturated at the temperatures as stated: 20° C., 0.015 mg.; 30°, 0.034; 40°, 0.07; 100°, 3.26. (Multiplication by 1000 gives the mg. per cubic meter.) Such saturation would rarely be attained under working conditions. It should be remembered that the rate of volatilization increases with the surface exposed and with the subdivision of the mercury.

Concentrated mercury vapor may produce grave subacute poisoning, as with the crew of the British sloop Triumph, in 1810. In salvaging a mercury cargo, 200 sailors were severely poisoned, and three died (cited by Brouardel). The more dilute vapors, encountered in mercury mines, factories and laboratories, gradually produce the phenomena of chronic poisoning, tremors, stomatitis (rather uncommon, Merget, 1889) and some digestive derangements.

M. Shepard *et al.*, 1941, found up to 0.07 mg. per cubic meter in the *air of scientific laboratories* without any mercurial symptoms. They consider that there is little danger below 0.1 mg., and this is generally accepted as the *permissible limit.* Toxic symptoms are observed after two or three months or later, in men exposed for three to five hours per day to concentrations of 0.02 mg. of mercury per cubic foot of air (0.0007 mg. per liter), the daily absorption being estimated as 0.8 to 1.3 mg. (Turner, 1924). These dilute mercury vapors may be fatal to small animals, but not usually to man. The daily excretion may be fairly large, 2 to 7 mg. in men with therapeutic inhalations (Bürgi, 1906). *Dogs* exposed for eight hours daily to air with known concentrations of mercury (mg. per cubic meter of air) gave the following results (A. M. Fraser *et al.*, 1934) which are probably fairly applicable to man: 1.9 mg. for forty days did not produce recognizable mercury effects. The lowest concentration which invariably resulted in chronic intoxication was 3.05. When toxic symptoms appeared, the daily urinary mercury excretion was 0.5 mg. in a dog of 12 Kg., equivalent to 3 mg. for a man of 72 Kg. With air concentrations of 3 to 26 mg., about a fourth of the inhaled mercury was absorbed. *Guinea pigs* exposed ten hours daily for four days to 6 mg. per cubic meter showed marked hemorrhagic colitis and neurotic symptoms. The greatest storage was in the kidneys, little in the liver (Holzmann, 1931). *Rabbits* reacted unequally; some responded promptly with salivation, tremor and loss of weight; others showed no symptoms after several months of exposure (Kulkow *et al.*, 1932).

Tests for Mercury Vapor.—This can be visualized by interposing it between a mercury resonance lamp and a screen of anthracene (Leighton and Leighton, 1935). Other methods of detecting small amounts are reviewed by Goodman, 1938.

Stomatitis is usually the earliest symptom of excessive therapeutic use or of chronic poisoning. It occurs about as readily when the mercury is administered otherwise than by mouth. It begins with fetor, then metallic taste, soreness of the gums and some salivation (ptyalism). This is as far as the therapeutic use should go. If it is pushed further, the teeth loosen, the edges of the gums blacken and they, and later the tongue, become swollen and ulcerated. The irritation and infection cause severe salivation and progressive exhaustion and sometimes fatal ulcerative stomatitis. With a more chronic course of severe poisoning there may be loss of the teeth and necrosis of the jaw. The *susceptibility to stomatitis* varies greatly and is markedly influenced by the hygienic condition of the mouth and teeth and by other individual factors, as well as by the dosage of mercury.

The stomatitis is most effectively *prevented and treated* by hygiene and care of the teeth. Septic conditions about the gums are especially detrimental, and should be corrected before mercury is started. Hydrogen peroxide or potassium chlorate (a tablespoonful of the saturated solution to a glass of water) should be used as a mouth wash several times a day. The use of tobacco is said to be injurious.

The *mechanism of the stomatitis and colitis* is probably connected with the local precipitation of mercuric sulfide which occurs in the capillary endothelium in these situations, being formed by the interaction of putrefying material with the circulating ionic mercury. This sulfide is toxic to the cells with which it is in contact, and the injured and necrotic tissue furnishes a starting point for ulcerative micro-organisms, especially the B. fusiformis and the Treponema dentium in the mouth and the colon bacillus in the large intestines, the latter giving rise to different lesions. Analogous conditions arise also in necrotic tonsils. The ulceration is, therefore, an indirect effect, resulting from invasion of special micro-organisms through a nidus prepared by the precipitation of mercuric sulfide. This explanation, which originated with Almkvist (1906, 1912, 1916), accounts for the variations of susceptibility and for the exclusive location of the ulcerations in situations where putrefactive processes produce hydrogen sulfide. The stomatitis always starts as gingivitis, in "gingival pockets" which invite putrefaction. It does not develop in infants and old people without teeth. Bismuth and lead also form sulfides in the same manner, but these are less toxic, partly because they are less soluble. However, bismuth injections may also result in severe stomatitis.

The *actions of metal sulfides* were studied by Santesson, 1929 to 1934. *In vitro*, Hg, Bi and Cu sulfides are considerably more soluble in organ emulsions than are Pb and Zn sulfides. With hypodermic injection in rabbits, HgS is outstanding in causing violent local inflammation. Bi_2S_3 acts chiefly after absorption, on the intestines and kidneys, sometimes on the liver. CuS acts chiefly on the liver. PbS has insignificant local and distant actions. ZnS causes considerable local necrosis, but much less than HgS. Its effects on the liver and kidneys are intermediate.

The *mechanism of the salivation* is not definitely known. Since it may be diminished by atropine, it is probably partly a reflex response to the stomatitis; but this does not appear adequate. Histologic degenerative changes have been described in the parotid gland (Giani, 1913). These cannot be attributed to the concentration of the mercury in the saliva, for this is of the same order as in the blood (Lomholt found 0.05 to 0.06 mg. per 100 cc. in the saliva). The increased flow of saliva is not an immediate effect of mercury, for it is not produced acutely, as by intravenous injection. Toxic doses prevent the response to pilocarpine or stimulation of the secretory nerve (K. I. Melville).

Mercurial salivation has an interesting *history*. It was considered the effective modus operandi in syphilis, as a potent means for eliminating the materia peccans, the more the better, if not the merrier. On this theory of elimination salivation was also used in other conditions. Boerhaave and van Swieten made it a fashion so that it was taken several times a year as a general health measure, like the bleeding and purging then in vogue. A Dr. Chisholm asserted that yellow fever could be invariably cured if salivation were induced speedily, a few moments' delay in the exhibition of mercury being responsible for the deaths. Benjamin Rush advocated salivation in typhus, malaria and tuberculosis; the only trouble was that some patients, especially children, are difficult to salivate, so that he held "the greatest desideratum in medicine is to discover a mode of rendering salivation certain." John Hunter held that "no two fevers can exist in the same constitution," and that the salivation infection crowded out the venereal infection. This was the most widely received opinion at the beginning of the nineteenth century (from an inaugural dissertation of J. H. Camp, U. of Pa., 1804).

Hematopoiesis.—Small doses of mercury raise the blood count (Keyes, 1876; Schlesinger, 1884); higher doses decrease it by one and one-half to two millions (Noel Paton and others), especially in the chronic cachexia.

Metabolism.—The effects are imperfectly known, but appear to resemble those of arsenic, lead and phosphorus. Small doses, therapeutically and in animals, often cause considerable *increase of weight* (fat).

Nervous symptoms appear relatively early in the chronic poisoning, with tremor and emotional irritability. Serious mental disorders are exceptional.

The *tremors* begin as fine trembling of the fingers, interrupted by coarser movements, reinforced by excitement or intention, decreasing after the movement is started, generally ceasing during sleep except in advanced cases. They increase in intensity and extent, involving first the face, then the entire body, interfering with muscular control. The *emotional changes* (*erethismus mercurialis*) begin with lassitude, fatigue and nervousness, and progress to mental irritability and excitability and restlessness, insomnia, headache, diminished mental ability and a curious timidity, self-consciousness and embarrassment.

Calomel as Cathartic and Intestinal Antiseptic.—Mercury compounds produce intestinal irritation and therefore catharsis; but with the more soluble salts these effects are generally too violent. Calomel, the mercurous or "mild" chloride, dissolves so slowly and to so limited a degree that the irritation is mild, largely independent of the dose, and restricted mainly to the duodenum. Calomel is practically insoluble in water, and almost insoluble in the stomach and large intestine (Nemser, 1906), but in the small intestines it tends to be decomposed by the alkaline reaction of the pancreatic juice, bile and intestinal juice into mercury and mercuric oxide, and the latter dissolves slowly in the presence of proteins (T. W. Schaefer, 1910). This dissolved mercuric salt irritates the intestines to increased peristalsis and diminishes the absorption of fluid (Fleckseder, 1912). Indeed, Thiry-Vella experiments on dogs show that there is considerable secretion of fluid, some mucus, but no ferments (Sawitsch, 1926; also with metallic mercury). Radiologic examinations show that generally both small and large intestines are stimulated (Meyer, Betz and Gebhardt, 1912); but if the conditions are not favorable for solution, or with small doses, all the dissolved mercury may have been absorbed before the colon is reached, and the duodenal contents may be propelled into the colon without evacuation. Ordinarily, calomel produces dark-green semisolid stools in ten to twelve hours. The irritation is generally so mild that calomel may be used even in enteritis; but some patients appear to be hypersusceptible, and respond with marked griping and tenesmus. These also result from excessive doses. The catharsis is checked by opium or atropine. It is not influenced by the presence or absence of bile (Valeri, 1909). The *green color of the stools* is due to biliverdin. Numerous investigations with biliary fistulas have shown that calomel does not increase the flow of bile (Okada, 1915); but the antiseptic action of the dissolved mercury, and the rapid propulsion of the intestinal contents, prevent the ordinary destruction of the bile pigments. This may also be demonstrated *in vitro* (references, von Oettingen and Sollmann, 1926). Mercuric chloride and other oxidizing agents render bile more green, *in vitro*, by the oxidation of bilirubin to green and blue derivatives. The degree of this color change is a convenient index of oxidizing power (von Oettingen and Sollmann, 1927). The antiseptic action in the intestines is reflected by decrease of the urinary indoxyl. Larger doses of calomel may favor bacterial growth by diminishing intestinal resistance. Calomel is commonly used as a cathartic adjuvant to anthelmintics, but in itself is quite ineffective against the worms (Hall and Foster). The *dosage* is relatively unimportant, because the excess is usually expelled before it is dissolved. It is customary to give either a single dose of 0.125 to 0.5 Gm. (2 to 7 grains); or fractional doses of 15 mg. (¼ grain) every hour until 0.15 Gm. (2½ grains) have been taken. The divided doses insure better solution, because they are spread over a large surface, and because there is more opportunity for the coincidence of calomel and alkalinity. Formerly much larger doses were used, but they are superfluous; while usually harmless, they may become dangerous should conditions become exceptionally favorable to absorption. Calomel is not suited for long-continued use on account of its systemic actions. These may also be produced by a large single dose, if it is not expelled in the usual time. It is, therefore, advisable to follow the calomel in six hours by a saline; or it may be mixed with Resin of Podophyllum (5 mg.; 1/12 grain). Calomel should not be prescribed with iodides, nor mixed with alkalies or with many reducing or oxidizing agents.

Interaction of Calomel and Salt.—Mialhe attributed the solution of calomel to interaction with sodium chloride, forming mercury and mercuric chloride and complex double salts. Similar reactions were claimed by Joly to occur with hydrochloric and citric acids, alkalis, carbonates and sugar. The amount dissolved would be small (at most 1 to 4 mg. from 0.5 Gm. of calomel). However, mercuric chloride could not exist as such in the alkaline intestine, and the chloride can therefore not be made responsible for the solution of calomel (as was suggested, *f. i.*, by Carracido, 1906). Iodides, bromides, thiocyanates, thiosulfates, and the like, dissolve larger quantities of calomel. *Protein* (egg albumin) is distinctly solvent for calomel, and this is increased materially by sodium iodide, thiocyanate, bicarbonate and bromide, in descending order; not by chlorate, chloride, citrate or saccharose. In the absence of protein, calomel is not dissolved by moderate concentrations of any of these substances, although they may produce reduction or other changes (Sollmann).

Mercurial Diuresis.—Suitable doses of all mercury compounds increase the urine flow, especially in the presence of edema, by inhibiting the water absorption in the renal tubules. They are used to remove edema fluid in congestive heart failure, nephrosis, and hepatic cirrhosis, and have largely displaced other diuretics. They are contraindicated in acute renal disease and in advanced chronic nephrosis. Mercurial diuresis also causes marked and persistent lowering of the abnormally high venous and cerebrospinal fluid pressure of congestive heart failure (Volini and Levitt, 1940). The firm organic mercury compounds mersalyl (salyrgan), mercurophylline (mercupurin) and novasurol, which are soluble in water, practically nonirritant and ordinarily not toxic in the clinical dosage, are used intramuscularly and intravenously in preference to the older calomel, which causes objectionable diarrhea and is reliable, because of the uncertain absorption. Their activity is increased by rendering the urine acid; theophylline or theobromine is generally added to promote absorption and decrease irritation. The diuresis starts within three hours after the intramuscular or intravenous injection, reaches its peak in six to eight hours, and often continues into the next day, even after the visible edema has disappeared. During the first day, the urine volume may reach 4 or 5 liters, and sometimes 8 or 9 liters. (In *normal individuals*, the peak is reached within one or two hours, and the diuresis lasts only during the active excretion of the mercury. The median increase over the normal urine output on the day of injection is between 200 and 400 cc.; Sollmann, Mellon Lecture, 1931.) Patients have received over 600 injections of mersalyl and mercurophylline in the course of several years without evidence of damage and with continued diuretic response (M. Friedenson, 1944). However, the margin to toxicity is not wide, and the dosage should not be increased (B. J. Johnstone and Keith, 1928). Mercurial diuresis has little or no effect on *localized inflammatory edemas* (hydrothorax, pericardial effusion, tuberculous peritonitis).

Renal Damage.—Larger doses of all mercurial diuretics cause tubular nephritis, especially when the injections are frequently repeated (Lazarus-Barlow, 1928; Johnstone and Keith, 1928; Möller, 1930; Crittenden, 1932).

The failure to obtain diuresis on injection of mercuric chloride into the renal artery (Melville and Stehle, 1928) is probably due to the difficulty of keeping the concentration below the nephritic level.

Historical.—Mercurial diuresis appears to have been first recorded by J. D. Schlichting, 1741 (Proksch, 1895), and calomel was used as diuretic in cardiac dropsies by physicians in the latter half of the eighteenth century, *f. i.*, by Alex. Munro. It fell into neglect, however, and was practically rediscovered by Jendrassik in 1886–1891. Novasurol was originally introduced by Zieler, 1917, as an antisyphilitic. Its diuretic effect was described by Saxl and Heilig, 1920. References to the literature are given by Rowntree *et al.*, 1925. Salyrgan was introduced in 1924 by F. Brunn and by E. Bernheim; mercupurin by von Issekutz and von Vegh, 1928.

The *mechanism of the diuretic action* is renal, as proved by Goedert, 1928: Transplanting the kidney of a novasurol-treated dog into the neck of a normal dog, he found that the novasurol kidney excreted much more urine than the dog's own kidney; conversely, a normal kidney transplanted into a novasurol dog excreted much less than the dog's own kidneys, which had been exposed to the novasurol. Improved renal circulation is not an essential factor, for the diuresis does not go parallel to the changes in the kidney volume (primary decrease, followed by increase; Möller; W. E. Reed). Creatinine and urea clearance tests fail to show any increase of glomerular filtration, but do indicate *decreased tubular reabsorption* of water; and this is the only mechanism that has been established for the mercurial diuresis (H. Blumgart *et al.*, 1934). Rapid intravenous injection of dextrose after mercuric chloride may bring the urine volume up to the hypothetical rate of glomerular filtration (R. L. Stehle and Melville, 1943). Mercurial diuresis starts one or two hours after intravenous, two to four hours after intramuscular, injection of the organic mercurial diuretic. The diuresis is not preceded by increase of water or chloride content of the plasma, so that there is no "mobilization of tissue fluid." During the diuresis, the changes of plasma and blood volume are inconstant (Swigert and Fitz, 1940). In patients with congestive heart failure the decrease of plasma volume is roughly equal to the diuresis (D. B. Calvin *et al.*, 1940). The blood plasma concentration may increase through the loss of fluid, but the diuresis continues, nevertheless (Cipriani *et al.*, 1927; H. L. Hansen *et al.*, 1931; H. L. Schmitz, 1933; A. H. Bryan *et al.*, 1935). The injection of normal saline, which gives little diuresis in normal animals, increases the salyrgan diuresis (Möller). The increased output of the kidney involves the water and still more the sodium chloride (the latter even when diuresis fails). K and Ca are also increased. The excretion of urea, glucose, phosphate or ammonium is but little affected (Melville and Stehle, 1927, 1928; Blumgart *et al.*, 1934). The *oxygen consumption* of blood-perfused kidneys is increased by mercurial diuretics (Gremels, 1929). H. N. Wright and Bieter, 1930, reported changes in the *ultramicroscopic picture of the blood*, pointing to flocculation phenomena, which might entail diminished water affinity; but this is probably unimportant, since the flow of thoracic lymph is not increased (Yanagawa, 1916; Loria, 1912).

Synergisms and Antagonisms.—Mercurial diuresis is markedly increased by *acidification* of the urine, which may perhaps increase the ionization of the mercury. Administration of *bile salts* and their derivatives, decholine and dehydrocholate, increase mercurial diuresis (Engel and Epstein, 1931; Marengo and Massimello, 1935), and deflection of the bile by a biliary fistula prevents the diuretic response (Claussen, 1932). The mechanism is not understood. Mercurial diuresis counteracts *pituitary antidiuresis*, relieving the hydremia and oliguria. The antagonism is mutual (W. Raab, 1929). Mercurial diuresis may be suppressed by large doses of atropine (Fleckseder), ether or morphine (Schargorodsky, 1911). In *diabetes mellitus*, salyrgan produces a temporary retention of sugar, as also in phlorhizin glycosuria (Bix and Wechsler, 1931).

Mercurial diuresis is checked by certain thiols, especially by BAL (C. A. Handley and LaForge, 1947).

Toxic reactions occur occasionally with all mercurial diuretics. They take several distinct forms (review, A. C. De Graff and Nadler, 1942).

(1) *Sudden death during* or very shortly after intravenous, not after intramuscular, injection, attributable to ventricular fibrillation, probably from direct mercurial injury of the heart (J. Wexler and Ellis, 1944; L. F. Volini *et al.*, 1945). These are very few in relation to the total number of administrations. Most of the reports have been with mercupurin, but fatalities may occur with any of the mercurials. They are unpredictable; some of the patients had reactions from previous injections (G. Brown *et al.*, 1942), but the greater number had tolerated former injections without toxic symptoms.

(2) *Excessive chloride loss*, from the diuresis and not directly related to mercury, may produce the syndrome of acute chloride depletion; muscle pains, weakness,

apathy, delirium, occasionally coma. This may occur before the edema disappears. There is little if any change in the sodium and calcium level of the plasma. It has been suggested (but not proved) that the dehydration may mobilize toxic concentrations of tissue-bound digitalis in patients receiving this drug.

Tetany has occurred repeatedly in patients with low calcium levels of the blood, and was relieved by calcium administration. It appeared to be due to electrolyte imbalance, but set in before the diuresis (F. A. Marshall, 1947).

(3) *Toxicities of the ordinary mercurial types* may occur, but are rare. They are chiefly gastro-intestinal (stomatitis, salivation, hemorrhagic colitis); renal (degeneration of the tubular epithelium); cutaneous eruptions (A. Burrows and Stokes, 1945); chills and fever. Intramuscular injections may cause focal abscesses.

Toxic Effects on Animals.—The acute intravenous toxicity of the organic mercurial diuretics is fairly high. The fatal dosage of mersalyl for cats corresponds to about 15 mg. of Hg per Kg. of body weight, the same as for mercuric chloride. That of mercurin is equivalent to 30 mg. It is not materially affected by dilution of the solution or speed of injection (W. Modell and Krop, 1944). On the basis of weight, the toxicity in cats is greatest with esidrome, then, in descending order, mersalyl, mercurin, mercurophylline, mersalyltheophylline (A. C. De Graff and Lehman, 1942). Combination with *theophylline* decreases the toxicity of mersalyl to about half; it has no effect on mercuric chloride or mercurin (W. Modell and Krop). The acute deaths are due to *ventricular fibrillation*, following on changes of intraventricular conduction, and often preceded by tachycardia. It is not prevented by atropine (De Graff and Lehman, 1942). Ventricular fibrillation resulting from mercuric chloride injection into dogs was described by Salant and Kleitman, 1922, and D. E. Jackson, 1926. I. Pines *et al.*, 1944, report that the ventricular fibrillation is prevented by addition of 0.5 cc. of 20 per cent magnesium sulfate, so as to survive seven times the fatal dose.

R. A. Lehman, 1947, reports that the severity of electrocardiogram changes in cats decreases in the order of mercuric chloride, salyrgan-theophylline, mercuzanthin, and mercuhydrin (least).

Coagulation of the blood is markedly accelerated by intramuscular or intravenous injection of mercurial diuretics (not by theophylline, caffeine or theobromine without mercury). This may be a factor in the sudden deaths. The prothrombin and antithrombin times are shortened; the blood fibrinogen is increased (D. I. Macht, 1946).

Sublethal Effects on Animals.—With single intravenous injections of mersalyl into rabbits, 2 mg. per Kg. have no diuretic effect; 5 mg. give moderate diuresis; 6 to 7 mg., marked diuresis, albuminuria and acute tubular nephritis, which becomes chronic; 15 to 30 mg. produce anuria, complete necrosis of the tubules, and death in about ten days; with intermediate doses, the chronic nephritis terminates fatally in about three weeks. Dogs are rather less injured, so that 6 mg. per Kg. produce marked diuresis without albuminuria. The diuresis follows the same course as clinically, reaching its peak in about two hours and lasting about two hours. Novasurol is more toxic than mersalyl (Johnstone, 1931; Melville and Stehle, 1927; Möller, 1930). Lazarus-Barlow, 1928, considered cloudy swelling of the liver cells as the chief lesion. The addition of mersalyl to intramuscular injections of procaine, strychnine, picrotoxin and other *convulsants* materially diminishes their effect (R. Beutner, Landay and Lilberman, 1940).

Excised Organs.—The frog heart is weakened and arrested in diastole by salyrgan, 1:10,000. Excised turtle heart is depressed (R. L. Johnston, 1941). Perfused vessels are constricted by 1:25,000. Skeletal muscles go into fibrillary twitchings (Möller, 1930).

Comparison of Different Mercury Preparations.—Fourneau and Melville, 1931, found all the mercuric compounds examined by them to be diuretic, with quantitative differences related to the chemical structure. Clinically, also, the diuretic response is practically equal, but the effective dosage varies greatly, especially if it is judged by the concentration of mercury in the urine. For a given mercury preparation, the urine volume and its concentration of mercury run fairly parallel; but the concentration for the organic mercurials is about a thousand times higher than that of the inorganic, suggesting that the organic compounds are not directly diuretic, but act through dissociation of small amounts of inorganic mercury (T. Sollmann *et al.*, 1930). With the chloride excretion in dogs as criterion, mersalyl is about half as potent as mercurophylline (C. C. Roby and Pfeiffer, 1942).

The administration of organic mercurial diuretics is usually by intramuscular injection. Intravenous injection carries some risk; oral and rectal administration act more slowly, but may be used in ambulatory patients. The *intramuscular injections* produce some irritation. This is diminished (but not eliminated) by adding 5 per cent of theophylline to the 10 per cent solution of the mercurial. It acts as a buffer, materially hastens absorption and so increases the diuretic response. The amount of theophylline is too small to exert a direct diuretic action (A. C. De Graff *et al.*, 1938). *Intravenous injection* may be justified when the intramuscular is not absorbed sufficiently fast or if it produces excessive irritation. The total diuretic response is about equal to the same dose intramuscularly.

The efficiency can be materially increased by the administration of full doses of *acidifying salts* (N. M. Keith *et al.*, 1925; Modell, 1944), ammonium chloride, 6 to 10 Gm. per day, for a day or two days before a mercurial is injected. Smaller doses are ineffective. Alkalizing salts diminish mercurial diuresis (Hayman, 1936). The mechanism is not clear, but the acidification may help to liberate mercury ions in the renal tubules.

The clinical dosage is practically the same for the 10 per cent solutions of all these organic mercurial diuretics, intramuscularly and intravenously. The Injection Solutions contain, per cubic centimeter, 0.1 Gm. of the compound, corresponding to about 0.04 Gm. of Hg., with or without theophylline, 0.05 Gm. Injections of 0.5 to 2 cc. are made at intervals of three to five days. The first intravenous injection should not exceed 0.5 cc. to test for special susceptibility. The optimal dosage for continued use, as in congestive heart failure, should be adjusted by the change of weight. Smaller doses are relatively more effective than large; for instance, 2 cc. by vein is only 25 per cent more potent than 1 cc.; two doses of 1 cc. per week produce 20 per cent more weight loss than a single 2 cc. dose. Ammonium chloride increases the weight loss about 15 per cent (W. Modell, 1944).

Rectal suppositories of 0.5 Gm. of Mercurin (containing 0.2 Gm. of mercury) give diuresis approximately equal to that obtained by intravenous injection. They are administered in the morning, after a cleansing enema, repeated at three to five day intervals as needed. This causes some local irritation, generally only burning, rarely inflammation visible with the proctoscope; but it should not be used in case of diarrhea, ulceration, fissure, or congestion. Salyrgan suppositories, 0.4 Gm., are also effective, but cause much more irritation, sometimes even ulceration (De Graff *et al.*, 1939). *Calomel* has been administered orally as a diuretic in doses of 0.2 Gm. four or five times a day, until slight stomatitis appears, the bowels being meanwhile regulated with an opiate.

PREPARATIONS.—*Merbaphen* (*Novasurol*), the double salt of sodium mercuric chlorphenyloxyacetate with diethyl-barbituric acid (barbital), contains not less than 33 and not more than 34.5 per cent of Hg. A white crystalline powder. Sol. in cold water, the solution being slightly alkaline. Dose, 0.15 Gm., intramuscularly. This appears to be the most toxic and most irritant of the organic mercurial diuretics, and has only historic interest.

Mercurin, N.N.R. (*Novurit*), a complex organic Hg compound, derived from salyrgan by replacing the benzene ring with a camphoric nucleus, contains 40 per cent Hg. Dose, as rectal suppositories, 0.5 Gm., mornings, at intervals of three to five days. Local irritation indicates discontinuance. ***Mercurophylline Injection**, U.S.P., *Mercuzanthin, Mercupurin;* a watery solution of mercurin with theophylline. Usual sizes of ampul, 0.1 and 0.2 Gm. of the mercury compound with 40 or 80 mg. of theophylline in 1 cc. Average dose, 0.1 Gm. intramuscularly. Mercurophylline may also be used orally (Batterman *et al.*, 1944).

Mersalyl, U.S.P., *Salyrgan*, the sodium salt of salicylalbylamide-orthoacetic acid, containing about 40 per cent of Hg. A crystalline powder, gradually decomposed by light; freely soluble in water. Administered as ***Mersalyl and Theophylline Injection**, U.S.P.; 100 mg. of mersalyl and 50 mg. of theophylline per cubic centimeter. Average dose, 0.2 Gm. of mersalyl. *Mersalyl and Theophylline Enteric Tablets*, N.N.R., each containing 80 mg. of mersalyl; *dose*, 2 tablets after breakfast, repeated in four or five days.

Meralluride, N.N.R. (*Mercuhydrin*), contains equimolecular quantities of a mercury compound of allylsuccinyl urea, and of theophylline, with about 32 per cent of Hg.

The Place of Mercury in the Treatment of Syphilis.—Syphilis can be checked by mercury, but more slowly than by arsphenamine or even by bismuth. The treponemas disappear from the lesions, and the symptoms subside completely, at least in the early stage. As in other protozoan infections, however, and in a rather higher degree, the invasion recurs unless the treatment is continued for some time. The permanent clinical cure for syphilis requires continuous energetic medication during the greater part of two years. This is accomplished by the alternation of several remedies to avoid the chronic poisoning which follows the unintermittent intensive use of a single metal. When mercury was the only antisyphilitic drug, it was pushed to actual poisoning, and then stopped completely, or it was administered continuously in harmless but ineffective dosage, until Fournier introduced the "intermittent treatment," alternating fairly intensive "courses" of active medication with "rest periods" of about equal duration. This system was transferred to the arsphenamines, whose continued use may become even more toxic than that of mercury. The alternation of the two drugs gives this "rest" to the patient, without giving any respite to the parasites. It avoids the cumulative intoxication, but enhances the therapeutic effect, partly by permitting higher dosage, and probably also by attacking the parasites from several angles. Arsphenamine and mercury or bismuth are therefore given in alternating courses of four to six weeks' duration, stressing at first the arsphenamine, because of its more rapid action; and later the "heavy metals," which can be used more cautiously, and the effects of which appear to be more thorough and more persistent. Bismuth is intermediate between mercury and arsphenamine in rapidity and perhaps in kind; it has the practical advantage of causing less pain, and is less liable to serious stomatitis. The relatively high toxicity of mercury limits the use of effective quantities, and doses that are ordinarily well tolerated may in some cases prove toxic. For these reasons, bismuth has largely displaced mercury. Several other metals are also more or less antisyphilitic (Levaditi; H. Schlossberger, 1931; von Oettingen), but appear practically inferior. A number were tried during the antimercurial agitation in the early nineteenth century, but as they are less effective than mercury, they were properly abandoned. The chemotherapy of syphilis, including mercury, is more or less useful in all stages of the disease, except against the late sclerotic lesions. As with other protozoan infections, the response is the more satisfactory, the earlier adequate treatment is started. When the disease has become thoroughly established by the neglect of proper treatment, it is much more resistant. This holds also for experimental syphilis in mice (Schlossberger, 1931).

Contraindications to Mercury.—Caution should be exercised with weak or anemic individuals, with albuminuria, during digestive derangements, and with diseases of the mouth or teeth. Pregnancy is not considered a contraindication. It is safer to begin treatment with small doses, since some patients are hypersusceptible.

Antisyphilitic prophylaxis by calomel ointment has a questionable status. It was believed that it often prevents the primary and secondary lesions, if it is applied locally before the treponema has penetrated, *i. e.*, within four or at most eight hours after exposure; the site of the suspected infection being cleansed with soap and dressed with an ointment containing 33 per cent of calomel or 0.3 per cent of sublimate ("Neisser-Siebert Ointment"). However, Schlossberger, 1931, found that the prophylactics prevent the dissemination of spirochetes through the scarified skin of mice only if the application of the agents preceded that of the treponema; they were totally ineffective if applied even immediately after the treponema. This suggests that clinical prophylaxis does no real good, but rather harm by preventing the recognition of infection. It is conceded clinically that mercury should not be used locally, if twelve hours have elapsed.

Historical.—Mercurial inunctions were introduced by the Arabian physicians, about 1000 A.D., against chronic skin diseases, and became widely known through the popular medieval textbook, the "Canon" of Avicenna (980 to 1036). They were pushed to intensive salivation, to "depurate the humors." There are those who contend that the conditions which responded were syphilis, which had not yet been differentiated from lepra, variola, typhus and other eruptive diseases (Sudhoff, 1926; in contrast to the traditional view that syphilis was imported from America by the expeditions of Columbus). When syphilis was definitely recognized in 1495, it was at once met by this intensive mercurial treatment, through inunction and other methods of administration (reviews of the history of mercury in syphilis may be found, among others, in J. K. Proksch, 1895; Haeser, 1882; and in the Mellon Lecture of Sollmann, 1930). Until the discovery of arsphenamine in 1905, mercury remained, with some vicissitudes, the only effective treatment of syphilis. Originally, the administration was pushed energetically until profuse salivation occurred, so that the improvement must have been prompt and striking. The treatment was stopped, however, as soon as the secondary lesions were healed, since the latent course of the tertiary syphilis was not understood. When this was realized, the therapy had already been made less energetic to avoid the risks of severe stomatitis. Between the inadequate dosage and deficient persistence of treatment, the results were often imperfect. As this was difficult to recognize by the course of the symptoms alone, little progress was made until the recognition of the Treponema pallidum and the Wassermann reaction furnished more definite criteria, and the transfer of the disease to animals made experimental controls possible. The latter, however, have chiefly qualitative value; results with allied protozoan affections of animals (spirillosis, trypanosomiasis) do not go parallel with antisyphilitic efficiency. The prejudice against mercury led to the introduction of a number of vegetable "alteratives," such as guaiac, echinacea, phytolacca, iris, sarsaparilla, and others, as *vegetable antisyphilitics*, but their uselessness is attested even by eclectic practitioners (Hilton, 1909). *Mercury in tuberculosis* was advised by B. L. Wright, but Hartz, 1910, found the ultimate results detrimental and never beneficial.

The **effects of mercury on syphilis** appear analogous to those of arsphenamine and bismuth, but are rather slow and progressive: suppression or rather great diminution of the treponemas in the lesions and presumably in the body; clearance of the superficial secondary manifestations, the eruptions, mucous patches, and so forth; and gradual disappearance of the positive serologic reactions. The tertiary lesions are checked or arrested. If treatment is stopped too early, the disease again becomes active and perhaps more resistant to therapy. Sufficiently prolonged treatment with mercury alone may produce permanent cure in rabbits (Kolle), but it is not safe to rely upon it clinically. The *theories of the mechanism* of the antisyphilitic action are not supported by adequate evidence.

They include direct toxicity to the parasites (Neisser), stimulation of the production of immune substances (Finger), increased resistance by other factors, increased susceptibility of the parasites to the protective mechanisms, and combinations of these factors. Mercury solutions are directly fatal to the treponema *in vitro*, and also in the local prophylactic treatment; but the concentration of mercury in the blood, probably not over 1 mg. per liter, appears far too low for this effect. The *explanation of the relapses is also hypothetical*, as with other protozoan infections. It may be assumed that the main mass of the parasites is destroyed in the active treatment, but some escape, probably by assuming a less active but more resistant form; perhaps also by being in protected situations, such as occluded capillaries or impermeable tissues. The multiplication of these surviving treponemas is checked by the treatment, and they eventually succumb; but if the checks are prematurely withdrawn and the factors of body resistance weakened, they reawaken to activity. The increased difficulty of treatment may be due to persistent foci of resistant forms.

Objectives in Mercury Administration.—The relapses start rather promptly after medication is discontinued, and when there are still considerable quantities of mercury retained in the tissues. It is therefore evident that the stored tissue mercury is not antisyphilitic; indeed, its slow excretion indicates that it is in an insoluble and therefore inactive form, and the action must be due to dissolved mercury. This is in diffusion balance between the tissues and blood, and through the latter it is reflected in the urinary excretion. The therapeutic effects are presumably proportional to the concentration of active mercury in the blood. With all inorganic mercury compounds, the urinary concentration of mercury is between 0.4 and 3 mg. (median, 0.65) per liter, or 0.5 and 2 mg. per day, when the therapeutic effects develop; and the subtoxic phenomena, the stomatitis, may appear about the same level. Compounds with organically combined mercury (salyrgan and novasurol) give considerably higher concentrations, as reflected by the higher urinary excretion; from 8 to 40 mg. of Hg per day; but they have little antisyphilitic action and do not produce stomatitis; presumably their mercury is too firmly bound to be active, and the excretion curve indicates that the high concentration is of short duration. The slowness with which therapeutic effects develop even with the active preparations indicates that the Hg concentration must be maintained for some time; however, the gradual effects depend in part on the methods of administration, by which the amount of daily absorption increases slowly, partly because this is inherent in the methods, and partly because it is desired to test the tolerance of the patient.

The *objectives of mercurial treatment* therefore are to furnish a continuous supply of mercury in active form, at sufficiently high concentration, raising this gradually so as not to exceed the tolerance of the patient. In principle this may be accomplished by frequently repeated dosage with easily absorbable mercury, or by the establishment of depots of sparingly soluble mercury for continuous absorption. In fact, however, all clinical methods involve deposition, and the effects are therefore more or less continuous and outlast the administration, as may be recognized by the slow descent of the excretion curve, which remains high for a week or two after the course is ended. With inunctions a store of metallic mercury accumulates in the ducts of the skin; with oral administration, the insoluble or precipitated compounds must be retained between the villi. Intramuscular injections of sparingly soluble compounds, metallic mercury, calomel, salicylate, generally in oily suspension, form depots among the muscles. These cause irritation, however, and become walled off by fibrous tissue, so that a part of the mercury remains unabsorbed for weeks, sometimes indefinitely, as shown by radiography (Cole, Littmann and Sollmann, 1920). Watery solutions of mercury salts, for instance sodium mercuric iodide, are absorbed more rapidly and more smoothly from intramuscular injections, but as the sodium iodide diffuses rapidly, the mercury reacts with the proteins to form precipitation depots. Even intravenous injections are deposited, since they tend to flocculate with protein and are caught in the reticulo-endothelial system. This "depot" mercury must be distinguished from the "stored" mercury that has been absorbed in diffusible form, penetrated into the cells, and been fixed there. The long-continued excretion of minute traces of mercury shows that this is also gradually mobilized, at least with the death of the cells; but its concentration is too low for any appreciable action.

Clinical Excretion Studies.—The course of the urinary excretion of mercury indicates how far the objectives are fulfilled by the clinical administration. The fecal excretion is less useful for this purpose, because it involves other factors. It is indispensable for determining the total excretion, and through this the quantity of mercury retained in the body. In this, the amounts excreted by minor channels must be neglected; the retained mercury includes that which has never been absorbed as well as that which has been deposited in the tissues. The excretion data gathered by several investigators (Buergi, 1906; Buchtala, 1913; Lomholt, 1920; Cole, Schreiber, Sollmann and associates, 1926 to 1931) agree in their general features. The present summary is based mainly on the figures of the American work. The course of the urinary mercury excretion, and therefore the blood concentration and therapeutic action, ranges in the different methods from (1) periodic and completely remittent; through (2) incompletely remittent and therefore cumulative; to (3) continuous progressively increasing excretion. The (1) *periodic and completely remittent type* obtains for all intravenous injections, organic, ionizable and colloidal suspensions. The excretion rises and declines acutely, reaching its maximum in one to two hours, and ceasing practically in eight to twenty-four hours. This type applies also to intramuscular injection of several nonprecipitating organic compounds (novasurol, flumerin; with salyrgan the decline is not quite so acute, but it attains approximate zero in the clinical intervals). The (2) *incompletely remittent cumulative excretion* is illustrated by the salicylate suspended in oil: The excretion rises and declines promptly, as in the periodic type, but the decline is incomplete, so that the excretion of the successive injections becomes superimposed, cumulative and even somewhat potentiated. The (3) *continuous progressive excretion* is obtained when the absorption is nearly continuous, so that there is no opportunity for remission. This occurs when depots are established by inunction, and by intramuscular injection of difficultly soluble preparations, gray oil or calomel. The excretion in the after-period declines slowly, so that the therapeutic level is maintained for a week or two after the end of the course. Transitions between types (2) and (3) are furnished by oral administration, and by daily intramuscular injections of ionizable compounds, sodium mercuric iodide or bromide.

Quantitative comparisons of the various methods of administration should be based upon the median of a number of patients; for while the general features of the course of excretion are fairly uniform for a given method, the amount of the excretion varies considerably, especially with methods that involve absorption (Sollmann, Schreiber, Cole *et al.*, 1935). In view of the importance of maintained concentration, the therapeutic efficiency is probably best reflected by the daily urinary excretion, at the end of the fourth week, remembering that the effective level is between 0.5 and 2.5 mg. of active mercury per day. The level at the end of the first week reflects the speed of action. The urinary level attained during the period of maximal excretion may be higher than the level at the end of four weeks. The total cumulative excretion, *i. e.*, the total amount excreted in four weeks, is interesting chiefly in comparison to the amount of retained mercury. The latter is useless and potentially harmful.

The *fecal excretion* is variable and runs a more irregular course, partly because the intestinal contents are not necessarily expelled on the day when they are formed; and as they are not formed by filtration as the urine, their relation to the plasma concentration is less direct. Some is probably excreted directly into the intestines, but most through the bile, involving the activity and affinity of the hepatic cells, which is much higher for some compounds, such as *flumerin*, than for others. For other injections the median ratio of fecal to urinary mercury averages about 1:5. *Excretion* by the sweat is negligible under ordinary conditions; but 900 cc. of sweat collected in an hour after pilocarpine administered during a course of mercury salicylate injections contained 0.08 mg. of mercury. *Saliva* contained in one case 0.06 in 115 cc., in another, 0.08 mg. in 150 cc. (Lomholt).

The *form of mercury in the urine* is mostly inorganic, so that this part is precipitated directly on electropositive metals (Lomholt, 1928). The late excretion (three years after chronic poisoning) was entirely in the sediment (R. Probst, 1932).

Details of Administration.—The following paragraphs aim to give the principal facts that may aid in the choice and application of the various methods and preparations. Septic conditions in the mouth, particularly about the margin of the gums, should be treated before any form of mercury is administered, and oral hygiene should be painstakingly observed, employing hydrogen peroxide as mouth wash; the patient should be frequently examined for the first signs of stomatitis.

Inunction is a very effective method of administering mercury, with a minimum of undesirable local effects; the slow intensification of absorption makes it easy to avoid serious overdosage. On the other hand, it is time-consuming, dirty and disagreeable, difficult to keep secret and the dosage is uncertain. The excretion varies in individual patients from less than half to more than twice the median. The usual technic in the United States is to rub 4 Gm. of "Strong Mercurial Ointment," U.S.P. (*i. e.*, 50 per cent), vigorously into the skin for half an hour to an hour, until it appears entirely absorbed. The "rubs" are repeated every night on a different skin area, thus increasing the absorbing surface, making the tour of the body in six nights. On the seventh night, a hot bath is substituted, and so on. The course usually lasts for four to six weeks, unless the gums become definitely tender, which may occur after ten to twenty rubs.

In Europe, the milder mercurial ointment (25 to 33 per cent) is used, probably with more vigorous friction. The tell-tale excess ointment may be sponged off with benzene (Cole, Gericke and Sollmann, 1921; Cole, Hutton and Sollmann, 1924); but this reduces the excretion to half: The daily rotation may be replaced by a single weekly administration, rubbing 30 Gm. of a 30 per cent mercurial ointment into the entire skin for an hour. Although the quantity of mercury is but two-thirds of that of the rotation system, the absorption is fully as high, and practically a week is saved in attaining the effective level (Cole, Rauschkolb *et al.*, 1929).

Historical.—The early mercurial salves contained only 5 to 13 per cent of mercury, but they were applied much more intensively, by vigorous rubbing of the entire body with 2 or 3 ounces at a time, daily or on alternate days, so that three rubs or less sufficed to produce the severe salivation considered necessary to remove the syphilitic poison. This was still the opinion and practice of Sydenham (1624 to 1689), and of Boerhaave (1668 to 1738); the latter was not content with less than 3 or 4 pints of saliva per day. The absorption was intensified by preliminary sweating and the treatment rendered more exhausting by severe dietary restrictions. A reaction against the supersalivation was started early (Almenar, 1502), and the toxic effects led to opposition to the use of mercury and the substitution of the ineffective guaiac treatment (Ulrich von Hutten, 1519); but mercury proved indispensable and notwithstanding some further protests (Chicoyneau of Montpellier, 1718), its effect remained identified with the flood of saliva until about 1820, when another antimercurial movement (A. Mathias, "The Mercurial Disease," 1810), the spread of homeopathy, the decline of the humoral theory of disease, and particularly the influence of the practical syphilologist, Ricord (1800 to 1889), led to the final recognition that salivation is not necessary to the treatment.

The *median level of urinary excretion*, with the normal technic (4 Gm. of 50 per cent ointment per day, rotation, no benzene), is as follows at the end of each week: first week, 0.12 mg.; second, 0.33 mg.; third, 0.60 mg.; fourth, 0.83 mg.; and sixth, 0.98 mg. After discontinuing, the level remains unchanged for about a week, then declines slowly and logarithmically, by about a third at the end of four weeks. The cumulative urinary excretion (the total amount excreted during the entire time) at the end of the fourth week is about 11 mg., with the normal technic; 5.4 mg., with benzene washing; and 16 mg., with massive inunctions. The fecal mercury varies widely, from a ninth to ten times the amount of the urinary. The urinary excretion figures of foreign workers average two or three times higher, presumably because of more vigorous rubbing. This and the area of skin inuncted (paralleling the quantity of ointment), and the mercury concentration of the ointment, are the more important controllable factors. The excretion is almost proportional to the concentration of the ointment. The texture of the skin is also important. Cutaneous syphilides have no significant effect; but fatal poisoning has been reported from the inunction into the open surface of a fissured eczema (Sackur, quoted by Lomholt). The ointment base has no material effect (Sollmann, Cole and Schreiber, 1935).

Manner of Absorption.—The mercury is absorbed mainly from the upper portions of the hair follicles and from the gland ducts, into which it is forced by the rubbing, and where it is gradually converted into soluble compounds. The epidermis probably does not participate in the absorption (Zwick, 1925). A variable quantity of the mercury is also conveyed by the hands, from the skin to the mouth of the patient; for instance, the ratio of fecal to urinary excretion is five times higher with inunction than with intramuscular injection (Cole *et al.*). Some absorption occurs through inhalation (Schamberg *et al.*, 1918); this has been estimated as one-fourth to one-half of the total absorption, but the data are not convincing, as they are based either on animals with a different skin structure (Juliusberg), or on the excretion of noninuncted patients in inunction wards, with their extraordinary mercury-vapor concentration, and extensive opportunity for hand contamination.

In man and animals, mercury globules can be demonstrated in the hair follicles and sebaceous ducts to about two-thirds of their depths, but only in the orifice of the sweat glands. The surface of the globules becomes dulled by the formation of oxide and in a week may have disappeared, almost completely in four weeks. No mercury is absorbed from a skin free of hair follicles and ducts, so that it does not penetrate the dry epidermis. When the skin is macerated, however, as with mercurial plasters, some absorption occurs. Mercuric chloride in 1:1000 watery solution is absorbed from the intact skin sufficiently to be demonstrated in the excreta after twenty-four hours of immersion (Fuerbringer, 1880).

The *size of the mercury globules* is probably of less importance than their fluidity. Ointments of *colloidal mercury*, which behaves as a solid, give variable, but generally smaller, absorption.

Mercury Oleate.—Mercurial ointments generally contain small quantities of mercury soap, added as oleate to aid emulsification, or formed by rancidity of the fat. This led to the suggestion that the mercury is absorbed only in this form (Menschel, 1923); but the absorption of the oleate is little better than that of metallic mercury, and the quantity is too small to be significant. The oleate is inconspicuous and has the further advantage that it does not require prolonged friction. It may be applied as an ointment, of which 15 Gm. contain 1 Gm. of mercury, as the daily dose (Sollmann, Cole and Schreiber, 1935).

Mercury plasters were attempted early, but were soon abandoned. They cause considerable local irritation; and since they do not force the mercury into the ducts, they are not reliable.

Powdery triturations were tried (with lycopodium, Unna; with clay mud, Talge, 1920), but abandoned. No excretion studies are available.

Calomel Ointments.—Very little is absorbed from the inunctions, and these have proved ineffective clinically (Cole *et al.*, 1933). The absorption from the skin of rabbits and rats was studied by Laug *et al.*, 1944.

Oral Administration.—Effective quantities of mercury are absorbed without difficulty from the ordinary therapeutic dosage, as shown by salivation as well as by the urinary excretion, which is as high as with inunctions or injections. The excretion rises progressively with continued administration, and declines rather slowly in the after-period, though somewhat faster than with inunction. Judging by the excretion, the daily dose of 0.2 Gm. of mercury with chalk, or 0.064 Gm. of mercurous iodide, would be equivalent to inunctions with 4 Gm. of 50 per cent ointment; mercuric chloride, 15 mg., would be but a fourth to a third as potent, and therefore of doubtful efficiency (Sollmann, Schreiber and Cole, 1935). The gastro-intestinal irritation is a serious disadvantage which restricts the oral administration mainly to the less soluble preparations; but these also tend to produce diarrhea and they have the further disadvantage of variable absorption, according to the solution and catharsis. The most serious disadvantage of the oral method is, however, that the patient is under less perfect control. It has therefore been largely abandoned except for newborn infants. To these mercury with chalk may be given in doses of 0.015 to 0.03 Gm. three times per day.

For adults, the oral method was used continuously: beginning with a small dose, this is increased daily by about 10 per cent, to tenderness of the gums. The dose is then reduced to one-third or one-half and continued at this point till the end of the treatment. The usual preparations are, *Yellow Mercurous Iodide* ("protoiodide"), 10 to 50 mg.; *Mercury with Chalk*, 0.05 to 0.2 Gm. (introduced by Jonathan Hutchinson); *Mercuric Chloride*, 5 to 15 mg., prescribed in solution with an excess of potassium iodide and taken in milk, to prevent corrosion. All these doses are used three times daily, after meals. The daily dosage of *calomel* for adults is from 0.05 to 0.1 Gm.; for infants, 0.01 to 0.03 Gm.

The mercuric chloride should be prescribed in solution, with an excess of potassium iodide, and administered in milk, to prevent local corrosion.

Rectal Administration.—Suppositories containing emulsified mercury have been suggested as a convenient method; but the absorption appears insignificant; the daily urinary excretion after ten days of administration was only 0.03 mg. (Cole *et al.*, 1926).

Fumigation.—The inhalation of heat-volatilized mercury, mercuric sulfide, oxide, or calomel, and so forth, is properly obsolete. The dosage is indefinite and there may be serious pulmonary irritation (Cole, Gericke and Sollmann, 1922).

Inhalation of mercury vaporized at room temperature was advocated especially by Merget, 1894, and Welander, 1900' but has not become popular, because of the uncertain dosage and of the inconvenience. It is practically devoid of local action, and effective quantities may be absorbed, as indicated by the urinary excretion of 1 to 4 mg. per day (Farup, 1901).

Intramuscular injections have the advantage that they keep the patient under frequent observation by the physician. They are therapeutically effective and avoid the conspicuousness of the inunctions and the direct gastro-intestinal irritation of the oral administration. They are painful, however, and the capricious absorption of the poorly soluble preparations may cause serious poisoning. The effective mercury compounds are so irritant that injection into the subcutaneous tissue may result in sloughing. The injections are therefore made deep into the gluteal or lumbar muscles. They generally rupture the muscle bundles and follow the nearest fascia, so that the location of the mercury is interfascial as well as intramuscular. The spreading reaches its limits within a few minutes (L. W. Shaffer, 1929). The muscle fibers in the immediate vicinity degenerate (Gruhzit, 1929). This is of no practical importance in itself, but contributes to the inflammatory reaction. The ionizable preparations cause immediate pain, which lasts some hours; it may be diminished by injecting 1 cc. of 2 per cent procaine solution through the same syringe. With the insoluble preparations, the *pain* develops later, but may last for some days; calomel is the most, gray oil the least, painful. Heat and rest give relief. Small amounts of concentrated solutions are generally less painful, because fewer nerve fibers are involved; but this also diminishes the area for absorption (Lomholt). The slow absorption of the insoluble preparations is utilized with the idea of establishing depots so that weekly injections would furnish a continuous supply of mercury. However, if the absorption is not promptly completed, *the remaining mercury becomes encapsulated* with inflammatory and fibrous tissue, and this slows absorption to an incalculable degree. Roentgenographs (Cole, Littmann and Sollmann, 1920) show that the mercury salicylate is generally absorbed within a week and calomel in two weeks; the greater part of metallic mercury suspension ("gray oil") remains unabsorbed after four weeks. The mercury that remains unabsorbed at the time of the next injection is a source of danger; for if conditions should become more favorable for absorption, the multiplication of depots may give rise to serious cumulative poisoning.

Absorption from Intramuscular Injections.—The mercury, in whatever form it is introduced, acts on the proteins to form albuminates of mercury. These are strongly chemotactic, and attract leukocytes. Some of these are killed, but others take up the mercury, especially in their nuclei, and distribute it through the body; its final fate is the same as with other methods of administration (Lombardo, 1912). The quantitative excretion is capricious.

Water-soluble ionizable compounds by intramuscular injection cause considerable pain, which is especially objectionable, since they must be made frequently. Mercuric chloride (1 cc. of 1 per cent solution) is particularly painful, and is therefore not advised. The irritation is materially diminished by conversion into the "biniodide," by adding 2 per cent of sodium iodide to a 1 per cent solution of mercuric chloride; or the sodium or potassium mercuric iodide may be used directly, as 1 per cent solution, adding 0.2 per cent of sodium iodide. In either case, 1 cc. of the 1 per cent solution is injected every day or on alternate days. Salts with organic acids (the benzoate, succinimide, oxycyanide and cyanide) have also been used. Absorption starts promptly, but the compounds form poorly soluble precipitates with proteins, and the absorption becomes slowed and incomplete. The injections must be repeated almost daily, at least every two or three days, to maintain an effective concentration. This establishes multiple depots, and the absorption rises gradually to the effective level, the median excretion curve with daily injections of the double bromide, equivalent to 5.5 mg. of mercury, being practically identical with that of the 50 per cent simple inunctions; *i. e.*, 0.4 mg. of urinary mercury at the end of the first week and about 1 mg. at the end of the fourth week. With the clinical dosage of the benzoate the median urinary mercury maintained only 0.12 mg. per day, which is probably insufficient.

Water-Soluble Nonionizing Compounds by Intramuscular Injection.—These include novasurol, salyrgan and mercurosal. The antisyphilitic action of the first two is slight and practically unreliable; the same would be expected from mercurosal. They cause little local irritation and are not toxic in the clinical dosage, nor does stomatitis develop in the course of weekly administrations. The urinary excretion curve rises rapidly to a high peak, attaining 1 to 5 mg. per hour (twenty-five to 100 times the median of the intramuscular bromide and of the four-week inunctions); it then falls promptly, becoming insignificant in eight to twelve hours, with novasurol; but salyrgan and mercurosal maintain a slight excretion. The total urinary excretion of the first day is about 12 mg., for all these compounds, *i. e.*, about fifteen times that of the four-week inunctions. The absorption is therefore rapid and fairly complete, but with mersalyl and mercurosal, a small part is absorbed more slowly. The retention in the four weeks is one-third to one-half of the quantity injected. Although this ratio is considerable, it is less than with any of the other mercury compounds.

Mercuric salicylate (for intramuscular injections) is not a simple salt, as the name would imply, but a molecular compound, with one valence of the mercury united directly to the benzene ring. It is insoluble in oil and in water, but it dissolves in the presence of various salts, including sodium chloride and proteins. It is administered as weekly injections of 1 cc. of a 10 per cent suspension in oil = 60 mg. Hg. It is effectively antisyphilitic, and may produce stomatitis, but this is rarely serious. It has the advantage of causing relatively little pain.

The urinary excretion curve suggests a sequence of organic and insoluble injections. It rises promptly in two to four hours, to a peak of 0.13 to 0.87 mg. of mercury per hour, about a sixth of the novasurol level, but ten or thirty times that of the bromide. It then declines, at first rapidly and then more slowly. The daily excretion is from 2 to 10 mg. per day, on the first day, to the median of 0.34 mg. at the end of the week; in the next two or three injections, the excretion level rises somewhat, the daily median at the end of the fourth week being 2.3 mg. About two-thirds of the mercury is retained at the end of the fourth week (Cole, Gammel *et al.*, 1929). The excretion curve indicates that a part of the compound is promptly absorbed unchanged; *i. e.*, in molecular form, and therefore inactive, and that the remainder is decomposed into poorly soluble compounds, which establish absorption depots of effective mercury.

Difficultly soluble mercury preparations by intramuscular injection have been administered suspended in oil; especially calomel, 10 per cent, 0.5 cc. weekly to 1 cc. twice weekly; and metallic mercury, finely divided, as the "gray oil" (oleum cinereum), 40 per cent, ½ cc. weekly, not to exceed five injections. Although they are highly effective (calomel also in experimental rabbit syphilis, Döhring, 1915), they have gone practically out of use because it is not possible to control their absorption; they are liable to produce excessive stomatitis, especially the gray oil, which has caused several deaths. Calomel injections also produce severe local irritation; the gray oil but little. Their absorption is slow, since they must first be converted into soluble compounds; but when the injections are repeated, the absorption from the multiple depots become cumulative and uncontrollable. The urinary excretion was studied for gray oil by Lomholt and Christianson; for calomel by Lomholt and by Buergi. It increases slowly from about 0.5 mg. per day at the end of the first week, to 2 or 3 mg. by the fourth week; but it varies considerably from day to day, indicating capricious absorption which is probably responsible for the disproportionate toxicity. The absorption is greatly increased by the administration of haloids, especially by iodide, which forms soluble mercuric salts; bromide is also dangerous, and to a less degree, excessive chloride income (F. Garcia, 1928, fatality to rats). *Mercuric sulfide* also produces local irritation and systemic toxicity, so that it must be converted into soluble, ionized compounds. It is not irritant or toxic by mouth (in rabbits; H. Niklasson and Santesson, 1926).

Intravenous injections were introduced (by Bacelli, 1892) to secure the maximal concentration of mercury in the blood and to avoid the local actions of the mercurials. However, they irritate the veins at the site of the injection and tend to produce fibrosis, which precludes the use of the vein for further injections, a rather serious matter for syphilitic patients. They also present some danger of embolism and colloidoclastic shock, at least in inexperienced hands. Urinary excretion studies indicate that the high concentration in the blood is of too brief duration to be important in chemotherapy, and that the maintained level is generally too low, even with daily injections. The excretion is incomplete, the retention at the end of the fourth week of treatment amounting to half or more for the diffusible preparations, organic and inorganic, and from 97 to 99 per cent for the colloidal. The diffusible mercury is presumably bound in the tissues and remains inactive. *The colloidal compounds* are probably enmeshed in the reticular endothelium, forming depots from which active mercury is absorbed and circulated for long periods; but the absorption is capricious and uncontrollable. The mercurial dye flumerin occupies a peculiar position and probably produces flocculation reactions.

Ionizable mercuric salts, mercuric chloride, oxycyanide, benzoate or the double iodide have been administered by vein, generally in 1 per cent solution, 1 to 3 cc. daily or every second day, using a glass syringe and platinum-iridium needle (Crume, 1908). With mercuric chloride, it is advisable to add 3 per cent of sodium chloride to the solution. Similar injections have been tried in puerperal infections and other septicemias, influenza, and so forth (Barsony, 1909). Vecki, 1918, endorses this use, but reports severe poisoning, exceptionally from 3 mg. The therapeutic results in syphilis are probably not so good as with other methods of administration, certainly no better (A. Strickler, 1923). With the oxycyanide, 10 mg. = 8.5 mg. of mercury, twice a week for four weeks, the daily urinary excretion was 0.02 mg. at the end of the first week and 0.1 mg. in the fourth week, distinctly too low for therapeutic results. The excretion rose to a peak of 0.12 mg. per hour in one or two hours after each injection, which is about ten times the average level after intramuscular injection of the sodium mercuric bromide; but it fell rapidly and was insignificant by the next day.

Organic Mercury Compounds by Intravenous Injection.—The urinary excretion of novasurol, salyrgan and mercurosal rises in one to two hours to a high peak, and declines promptly, leaving an insignificant level within eight hours after the injection. With injections of 1 cc. of the 10 per cent novasurol and salyrgan solutions (= 34 and 38 mg. of mercury), weekly, and of 0.1 Gm. of mercurosal (= 34 mg. of mercury) every second and third day, the hourly urinary excretion at the peak was 4 to 8, 10 to 27, and 21 to 30 mg., for the respective compounds. At the end of the first week, the median daily urinary excretion had fallen to 0.03, 0.04 and 0.3 mg.; these levels would be quite ineffective even if they represented active mercury. Mersalyl did not cause any untoward symptoms; but novasurol and mercurosal produced bloody diarrhea in some of the patients. Novasurol and salyrgan have been injected clinically with arsphenamine, which would disguise their inefficiency.

Flumerin, **N.N.R., is derived from sodium fluorescein, with the mercury united to the benzene ring. Like other dyes, it tends to form colloidal adsorption products with proteins. Promising results were reported in experimental syphilis of rabbits; in man, 3 mg. per Kg. have been injected every second day, with gradual therapeutic effect (White, Hill, Moore and Young, 1922), but probably not better than with ordinary mercurial treatment. This dosage produces subtoxic phenomena in a considerable proportion of patients (stomatitis in a third, renal irritation in a fifth, gastro-intestinal disturbance in a fifteenth of the cases); but these are temporary and generally not dangerous. The *fecal excretion* surpasses by far all other mercurials that have been studied, attaining 1 mg. on the day of the injection, indicating a biliary excretion of the unchanged compound. The *urinary* excretion is intermediate between the organic and the colloidal compounds, inclining rather more to the latter. It starts promptly, attaining the fairly high peak of 0.45 mg. per hour, in the second hour. The daily excretion is 2.6 mg. on the first day, 0.4 mg. on the second and 0.25** at the end of the week. The latter is still below the therapeutic level, but it is about five times as much as with the organic compounds, indicating the deposition of colloidal depots, probably in the liver.

Spinal injection of mercurialized serum was introduced by Byrnes, 1914, and endorsed by Ireland and Wilson, 1915, against cerebrospinal syphilis, as being about equally successful and safe as the Swift-Ellis serum, but it did not become established. Swift, 1916, believed that repeated injections of mercurialized horse serum render the membranes hypersensitive and tend to produce chronic meningitis.

Mercury Mobilization by Iodide and Other Halogen Salts.—The impression prevails clinically that the administration of iodide mobilizes the mercury stored in the body from previous treatments. This has not been investigated adequately by modern methods, but Ludwig, 1929, claimed that a double iodide is formed which breaks down the mercury-protein compound in the tissues; Young and Taylor, 1929, believed that mercury is deposited in the bones, similarly to lead, and as the latter is mobilized by iodide, this might also happen with mercury. Garcia, 1928, reported that administration of halogen salts increased the toxicity of subcutaneous injections of insoluble mercury salts in rats, by accelerating absorption; the order of efficiency being I > Br. > Cl.

PREPARATIONS—METALLIC MERCURY.—*Mercury with Chalk,* U.S.P. (Hydrargyrum cum Creta; Gray Powder), contains about 38 per cent Hg, dispersed in chalk. A light gray, rather damp, sweetish powder. Used especially to secure the constitutional effect of mercury in infantile syphilis. Dose, 0.25 Gm., 4 grains, equivalent to about 0.1 Gm. of metallic mercury, in powders or capsules. *Mercury Mass* (Blue Mass, Blue Pill) contains 33 per cent Hg. Dose, 0.2 Gm., 3 grains; used similarly to calomel. ***Strong Mercurial Ointment,** U.S.P. (Unguentum Hydrargyri Forte), contains 50 per cent Hg, emulsified by 8 per cent of mercury oleate, in wool fat, white wax and petrolatum. Used for inunction. *Mild Mercurial Ointment,* U.S.P. (Ung. Hydrargyri Mite; Blue Ointment, Diluted Mercurial Ointment), contains 10 per cent Hg (formerly 30 per cent!). Used against cutaneous parasites.

INSOLUBLE MERCUROUS COMPOUNDS.—***Mild Mercurous Chloride,** U.S.P. (Hydrargyri Chloridum Mite; Calomel, Protochloride of Mercury); HgCl; a fine white powder, odorless and tasteless. Practically insol. in water or alc. Incompatible with alkalis; oxidizing acids; iodides and bromides; and with a mixture of sod. bicarb. and antipyrine (J.A.M.A., *56:* 287, 1911). Dose, laxative, 0.12 Gm. (0.03 to 0.2 Gm.), 2 grains (½ to 3 grains), as powder or tablets; intramuscularly, 30 to 60 mg. *Yellow Mercurous Iodide,* N.F. (Hydrarg. Iodidum Flavum; Protoiodide of Mercury); a bright, yellow, odorless, tasteless, amorphus powder; almost insol. in water. On exposure to light, it darkens by decomposition into mercuric iodide and metallic mercury. Incompatible with oxidizing agents, alkalis and carbonates, chlorides, bromides and iodides. Dose, 10 mg., ⅙ grain (maximum, 1 grain). "*Green Iodide*" is an analogous salt prepared by a different method. It is said to be less potent.

INSOLUBLE MERCURIC COMPOUNDS.—***Mercuric Salicylate, U.S.P. (Hydrargyri Salicylas); containing about 57 per cent Hg; a white, slightly yellowish or slightly pinkish powder. Nearly insol. in water; sol. in alkalis,** forming a double salt. Dose, intramuscularly, 60 mg. as suspension in oil, twice a week. *Mercuric Salicylate Injection*, U.S.P., a suspension in fixed oil, usually available as 0.06 Gm., 0.1 Gm., and 0.12 Gm. in one cc. *Ammoniated Mercury*, U.S.P. (Hydrargyrum Ammoniatum; White Precipitate); NH_2HgCl; a white, amorphous, insol. powder, obtained by precipitating $HgCl_2$ by ammonia. Represents about 79 per cent Hg. Irritating and not used internally. Employed externally against eczema and parasitic skin disease, especially pediculi, as dusting powder, but chiefly as *Ammoniated Mercury Ointment*, U.S.P., 5 per cent (formerly 10 per cent). Its absorption from the ointment is reported by O. S. Gibbs, Shank and Pond, 1941. *Yellow Mercuric Oxide*, U.S.P. (Hydrarg. Oxidum Flavum; Yellow Precipitate); a light orange-yellow amorphous powder, turns darker on exposure to light. Odorless; somewhat metallic taste. Nearly insol. in water or alc. Incompatible with acids. Maximum dose, 0.03 Gm., $\frac{1}{2}$ grain. Applied chiefly as *Ointment of Yellow Mercuric Oxide*, U.S.P., 1 per cent. It is used in ophthalmology against inflammations of the lids and conjunctiva, diluted with petrolatum so as to contain $\frac{1}{12}$ to 1 per cent of the oxide. "Pagenstecher's Ointment" contains 4 per cent. *Oleate of Mercury*, U.S.P. (Oleatum Hydrargyri), is made by dissolving 25 per cent of yellow mercuric oxide in oleic acid.

SOLUBLE MERCURIC SALTS.—***Mercuric Bichloride**, U.S.P. (Hydrargyri Bichloridum; Corrosive Sublimate, Bichloride or Perchloride of Mercury); $HgCl_2$; occurs as heavy, colorless crystals or white powder of acrid metallic taste. Slowly sol. in water (1:13.5), freely sol. in alc. (1:3.8), sol. in glyc. (1:12) or eth. (1:22). Its solubility in water is increased by ammonium or sodium chloride and tartaric or citric acid ("Sal Alembroth" = 2 parts of $HgCl_2$, 1 part NaCl). Incompatible with alkalis and carbonates; iodides; many alkaloids and other organic compounds and reducing agents. Dose, 2 to 4 mg., $\frac{1}{32}$ to $\frac{1}{16}$ grain. The discovery of mercuric chloride is attributed to the Arabian alchemist Geber, of the seventh century. Rhazes and others employed it against skin eruptions ("leprosy"). ***Large Poison Tablets of Mercury Bichloride**, U.S.P. (Toxitabellae Hydrargyri Bichloridi; Corrosive Sublimate Tablets, Bichloride Tablets). In order to guard against accidents, the U.S.P. directs these tablets to be of a distinctive color and of an angular, not disk shape. Each tablet contains about 0.47 Gm. of $HgCl_2$, and about 0.5 Gm. of NaCl. These tablets should be dispensed in securely stoppered glass containers on the exterior of which is placed a red label bearing the word "Poison" and a statement of the amount of corrosive chloride in each tablet. One tablet to 1 pint of water makes an approximately 1:1000 solution.—*Small Poison Tablets of Mercuric Chloride*, U.S.P., are similar, but contain about 0.125 Gm. of $HgCl_2$. One tablet to 4 ounces of water furnishes an approximately 1:1000 solution. *Red Mercuric Iodide* (Hydrarg. Oxidum Rubrum; Biniodide); HgI_2; is a scarlet red, odorless and tasteless powder. Nearly insol. in water; rendered soluble by the presence of four-fifths its weight of KI and NaI. Incompatible with alkalis and carbonates and alkaloids. Dose, 2 to 4 mg., $\frac{1}{32}$ to $\frac{1}{16}$ grain; maximum, 20 mg., $\frac{1}{3}$ grain. *Potassium Mercuric Iodide*, N.N.R., K_2HgI_4, is usually made as extemporaneous solution, by dissolving HgI_2 or $HgCl_2$ in excess of KI (1:4). For intramuscular injection, the corresponding sodium salt is preferred (HgI_2 = 1; NaI = 3; Water = 100). Dose, 0.4 cc. = 4 mg., $\frac{1}{16}$ grain. *Mercuric succinimide*, U.S.P., about 50 per cent Hg, soluble in water (1:20). Average dose, 15 mg., intramuscularly.

LEAD

The lead salts precipitate proteins and therefore act as local astringents. Their acute toxicity is low, as they are absorbed rather slowly; but they tend to produce cumulative effects. Chronic lead poisoning is a common disease with characteristic symptoms: the "lead line" at the margin of the gums; marasmus and anemia; paroxysmal colic and arthralgias; "wrist drop" and other peripheral motor paralyses; central motor stimulations (tremors and convulsions); psychic changes (encephalopathia), and so forth. The mechanisms and relations of these effects are not definitely known. On withdrawal from the lead, the phenomena generally recede more or less completely; but the patient may remain in bad health and over-susceptible to lead, for some time. Prophylaxis against lead poisoning is more important than treatment.

The root growth of *plants* is retarded by dilutions of 1:100,000 in the nutrient solution (Hammet, 1929), probably by combining with *sulfhydryl groups* and so interfering with enzyme processes. Very small amounts decrease the oxygen consumption of *excised tissues*. Concentrations higher than 1:20,000 inhibit the germination of *frog spawn* (Dilling, 1926) and of *chick embryos*.

Astringent Actions.—Lead acetate and subacetate ("lead water") produce more astringent and less irritant effects than other soluble metallic salts. They are effective against diarrhea and catarrhal inflammations; but they are so liable to produce chronic poisoning that they should never be used internally or on open surfaces. Their use should be avoided even on the skin and in any case should not be long continued.

Lead subacetate solution should not be used on the eye, for in the presence of corneal ulcers it leads to persistent white incrustations which interfere with vision (Fantus). "*Lead and opium wash*" was used on superficial contusions. Saturated alcoholic solution of lead acetate was employed in Rhus ("Ivy") poisoning. Emplastrum Plumbi, "*Diachylon plaster*," acts as a mild irritant.

Acute lead poisoning is uncommon. It is generally produced by the acetate or subacetate, sometimes by the carbonate (white lead). The phenomena are at first local and not immediately dangerous, but they are often followed by chronic poisoning. Application to the skin (lead wash, Diachylon plaster) has rarely if ever caused acute poisoning (Paessler, 1804). Diachylon pills (as abortifacient) have proved toxic (A. Hall and Ransom, 1906; W. F. Warner, 1907).

The *acute symptoms* start with the taste, which for the soluble salts is at first sweet, then disagreeably metallic and astringent, with dry throat. This is followed in fifteen or thirty minutes (rarely after several hours) by thirst; burning abdominal pain (not to be confused with "lead colic") and vomiting, which often appears milky from lead chloride; this is followed by diarrhea, more rarely by constipation. The stools are black from lead sulfide. The urine is often scanty, with albumin and casts. Colic may occur in two or three days, especially if the administration is continued. It is generally accompanied by constipation; rarely by diarrhea. The patients are debilitated. There may be muscle cramps. Severe cases of acute lead poisoning develop collapse with slow pulse and finally coma, which is probably uremic. Convulsions may or may not appear. Death occurs usually within thirty-six hours. Most patients *recover* in two or three days from the acute effects, but the convalescence is slow; after a few weeks they show the phenomena of chronic poisoning (also animals, Dauwe, 1907).

Pathology of Acute Lead Poisoning.—The local effects are quite superficial. The gastric mucosa is somewhat blanched (astringent action), sometimes with ecchymoses or slight erosions. These changes may extend into the intestines; but the lower intestines are tinted black by the lead sulfide.

Of *soluble lead salts*, 10 Gm. are said to have produced death; and 30 Gm. may be survived (Kunkel). Fifty Gm. of lead acetate are probably always fatal. Formerly, lead acetate was used therapeutically in doses of 1 to 4 Gm.; but 2 to 3 Gm. have produced toxic effects. Of *lead carbonate*, 40 to 50 Gm. are said to have caused death (Brouardel). Of *lead chromate* a few centigrams are fatal, but this is attributed to the chromic acid (Brouardel). The toxicity of various lead pigments is reviewed by A. Hamilton, 1913.

Treatment of Acute Poisoning by Soluble Lead Salts.—The stomach must be emptied, preferably by lavage. This may be preceded by the administration of a soluble sulfate (sodium or magnesium). Animals are thus saved from several times the fatal dose (Dauwe, 1907); 1 per cent sodium sulfate may be used in the lavage. Milk, eggs or tannin are useful. A cathartic should be given after the stomach has been emptied. Subacute colic is treated as in chronic plumbism. Iodide is commonly given in the after-treatment.

Subacute lead poisoning is produced by repeated administration of acutely toxic or slightly subtoxic doses, with criminal intent, or in food contaminations, or therapeutically.

With large doses, each administration is followed by the gastro-intestinal symptoms of acute poisoning; dyspepsia and anorexia in the intervals. With subtoxic doses, the gastro-intestinal symptoms develop more slowly. Typical phenomina of chronic poisoning may start in a few days, with the lead line, headache, cramps, paralysis, especially of the upper extremities, nephritis and uremic coma and convulsions, ending in death (Brouardel, 1914).

Intravenous injections of soluble lead salts produce enteritis (through paralysis of capillaries). This does not involve the stomach (Orfila). If death is delayed, nephritis develops. Thouvenet also described liver changes (Brouardel). The intravenous toxicity of various compounds is reported by F. Bischoff *et al.*, 1928.

Lead Injections in Cancer.—W. Blair Bell, 1922, claimed that the intravenous injection of colloidal lead is beneficial in clinical cancer, both directly and by increasing the efficiency of x-ray treatment. Others have reported variable results. Sometimes there is apparent temporary improvement, which has been attributed to necrosis of the tumor in consequence of blocking of its capillaries by lead particles. Arrigoni, 1930, found necrobiotic changes in the blastomatous tissue, but also toxic actions on normal parenchyma, especially in the liver and kidneys. The injection may cause serious plumbism and appears scarcely advisable. The *fate of colloidal lead* was studied by Dilling and Haworth, 1929, in cats and rabbits.

Acute Toxicity.—Colloidal lead as such has no immediate effects; but it passes readily into salts, and the intravenous injection of such solutions causes marked fall of blood pressure and heart block. The solution should therefore be tested for this action (Dilling, 1929).

Mouse and *rat tumors* have been treated with lead and a variety of organic lead compounds, including tetraethyl lead. McMarsh and Simpson, 1927, and H. E. Eggers, 1934, obtained negative results; Datnow, 1935, tested twenty-seven organic lead compounds on the Brown-Pearce strain in rabbits and considered the results rather promising.

Absorption of Lead.—All lead compounds (with the possible exception of the silicate) are absorbable from all mucous membranes and exposed tissues. Absorption from the intact skin has not been definitely proved, but could probably occur to a limited extent through the cutaneous glands and hair follicles. The digestive and respiratory tracts are the principal avenues of entrance; their relative importance is difficult to judge, since inhaled lead fumes or dust or paint spray are largely swallowed. There is no doubt, however, that abundant absorption occurs directly from the nasopharynx and from the respiratory tract (Blumgart, 1923). Lead on the hands generally reaches the mouth with food, and is therefore absorbed from the digestive tract. The lead must be in solution before it is absorbed; but even the most "insoluble" lead salts and metallic lead if finely divided are somewhat soluble in the digestive juices and tissues; the "soluble" salts are to a considerable extent precipitated. The greater part of the ingested lead, soluble as well as "insoluble," is not absorbed. A quantity harmless as a single dose may be toxic when divided into smaller doses and thus spread over some days (review, A. S. Minot, 1938).

The *solubility of lead compounds in the digestive tract and tissues* is independent of their solubility in water. In the stomach, lead carbonate and even lead sulfate are dissolved fairly readily, being converted into chloride, by the aid of gastric juice. The solubility corresponds to that in HCl of corresponding strength. Peptone (0.2 to 1 per cent) facilitates the solution of lead salts; bile does not. Alkalis, including milk, diminish the solution (Carlson and Woelfel, 1913). Alkalis of the concentration of the pancreatic and intestinal juices convert lead sulfate into carbonate and lead carbonate into a mixture of neutral and basic carbonate (Auerbach and Pick, 1913). In the large intestine a part of the unabsorbed lead is converted into sulfide, as indicated by the black color of the stools; but this is prevented or diminished, as the sulfide may be redissolved, if an acid reaction prevails. Lead is also rendered soluble on the bronchial mucosa, presumably as protein combinations. The *sulfide* was supposed to be inabsorbable, but Woelfel and Carlson, 1914, showed that it is absorbed sufficiently, even from ores, to be dangerous. Lead *silicate* appears to be unabsorbable (Shie, 1921). The solubility of lead salts in balanced physiologic saline solutions was investigated by L. C. Maxwell and Bischoff, 1929.

The sulfate is less toxic than the more soluble carbonate; but both produce poisoning in adequate doses; for instance, 0.1 Gm. per Kg. per day (Carlson and Woelfel, 1913). The toxicity of a variety of inorganic and organic lead compounds is reported by J. S. Buck and Kumro, 1930; that of various lead pigments is reviewed by A. Hamilton, 1912.

Absorption from Respiratory Tract.—Lead may enter the respiratory passages as dust, in white lead works; as spray, in painting; and as fumes from heated lead. Molten lead volatilizes below its ebullition temperature (Shie, 1921). The fumes are converted into oxides (Teleky). The greater part of inhaled lead is caught in the nasopharynx and swallowed (Carlson and Woelfel, 1913). Lead poisoning often develops more rapidly with inhalation than with other methods (Aub, 1935), because inhaled lead is likely to be more finely divided (Teleky). However, it has been shown by ligation experiments that lead compounds are readily absorbed directly from the lungs (Tanquerel des Planches, 1839; Minot, 1924) and from the nasopharynx (Blumgart, 1923).

Absorption from Conjunctiva.—Poisoning has been produced by the long-continued use of a lead eye wash.

Absorption from Skin.—The application of lead washes or ointments to the skin may lead to poisoning; but the positive results may be referred to transfer of the lead to the mouth, or to injuries of the skin, so that absorption from the intact skin has not been established. The coloring of hair by lead indicates, however, that this may penetrate at least into these structures, and therefore presumably also into the epidermis; metallic lead and finely powdered compounds could perhaps be rubbed into the hair follicles and then be dissolved and absorbed analogous to mercury and calomel inunctions; but the amount of this absorption appears to be negligible (P. O. Sussmann, 1922). Some absorption occurs from diachylon plaster (R. Schmid, 1942). Canuet and Drouet found that dogs or rabbits may be poisoned by baths of lead acetate, but Potain showed that poisoning does not occur if the animals are prevented from licking the skin (Brouardel); Beresina and Engling, 1887, found blood changes in guinea pigs after two days of inunction with 10 per cent lead carbonate ointment. The changes were greater when a lanolin base was used than with petrolatum base. *Absorption from denuded skin* may be an occasional source of poisoning in workers, whose skin is often thinned, macerated or chapped.

Absorption from Hypodermic Injections of Lead Carbonate.—Straub and Erlenmeyer, 1913, utilized this for the production of experimental plumbism. In cats, the lead was absorbed from the hypodermic deposits at the rate of 0.1 to 1 mg. per Kg. per day.

The excretion of lead occurs mainly by the feces and urine. The fecal lead is partly unabsorbed, partly excreted directly into the intestines, with small quantities by the bile and pancreas (Bricker, 1926). Insignificant traces of lead may occur in milk (Baum and Selig, 1895), saliva (Pouchet, 1880), sputum (Meillere, 1903) and sweat (after pilocarpine, Spillman). The excretion by the skin is negligible. The application of sulfur and sulfides to the skin of lead workers often gives a black color, which indicates exposure to lead, but this is due to adherent nonabsorbed lead, and not to excreted lead (Miura). Lead passes into the fetal circulation (Annino, 1893) and this may be a factor in the frequent abortions.

The *fecal excretion* is generally greater than the urinary, but the proportion varies. During the ingestion of lead, a large part of the fecal lead may be unabsorbed lead sulfide. After the patient has been withdrawn from exposure for some time, the ratio of fecal to urinary lead averages about 2.5:1 (Aub *et al.*). Normal feces contain about 0.08 mg. of lead per gram of ash (Kehoe and Thamann, 1929).

Time of Excretion in Urine.—After 0.02 Gm. of lead, taken by mouth, Riva, 1913, found demonstrable quantities in the urine only after three or four days. The excretion continued for a considerable time after the administration had ceased.

Compounds Excreted.—Unabsorbed lead occurs in the feces largely as sulfides; but absorbed lead is said to be excreted entirely as organic compounds (Erlenmeyer, 1913).

The *daily lead excretion* has been studied especially by Kehoe *et al.*, 1928, 1935, 1940. Under average conditions of American life the total excretion amounts to about 0.25 mg. (0.2 to 0.4) per day, of which 0.24 mg. is in the feces. This is practically equal to the ordinary food intake of lead, 0.32 mg. (0.1 to 2 mg.) in various regions of the United States, so that income and output are in equilibrium and there is little if any retention and accumulation. Under more primitive conditions, as in rural Mexico, the excretion is about half of this amount (0.12 mg.). In patients with lead poisoning it amounts to 0.3 to 1 mg. or more; in patients recovering from chronic plumbism, Aub *et al.* found an average of 0.4 mg.

The *urinary concentration*, per liter, averaged 0.014 mg. under primitive conditions; 0.04 mg. under ordinary conditions; 0.1 to 0.2 in lead poisoning, to 1 mg. in severe cases. The daily urinary output is normally between 0.02 and 0.08 mg.; in the convalescent group it ranged from 0 to 0.32 mg.

Diagnostic Significance.—The demonstration of more than 0.05 mg. of lead per liter of urine, or 0.15 mg. per day, indicates that abnormal amounts are circulating in the blood and are a warning, although concentrations of 0.05 to 0.15 mg. per 100 cc. of urine, or 0.06 to 0.07 for blood, may exist for months without deleterious effects (Kehoe *et al.*, 1940). Fecal lead beyond 0.6 mg. daily also indicates excessive exposure. The concentration is not necessarily proportional to the severity of the symptoms, for these depend largely upon the cumulative injury; moreover, the concentration may vary from day to day by the mobilization of the lead deposited in the bones; and finally, the lead nephritis may interfere with the urinary excretion, so that it may fail to reveal lead, although the blood contains 0.05 to 0.1 mg. per 100 cc. Diuresis does not materially affect the daily urinary output (S. H. Webster, 1941).

Retention of Lead.—If the income of absorbable lead exceeds the normal, the elimination also increases so as almost to balance the intake, but a part is retained and laid down in insoluble form, to a slight extent in the soft tissues as with other metals, but chiefly in the trabecular bone, analogous to calcium. The total amount so retained is not large; Aub estimates that an adult dying of chronic lead poisoning would probably not contain more than 1 gram altogether, and most of this would be in the skeleton. As the bone is reabsorbed, the lead is remobilized, and partly excreted, partly redeposited. The excretion is therefore slow, intermittent and prolonged, traces appearing in the urine and feces for months and even years after the absorption has stopped.

With *intravenous injection* of lead, the greater part is stored (Aub, 1935). *With oral ingestion*, the *amount* retained varies directly with the level of the intake and with the duration of this level; but the *percentage* retained is greater for low levels and short duration (Cowgill and Horwitt, 1938; Calvery *et al.*, 1938). The storage varies inversely as the *calcium of the diet* (Calvery *et al.*, 1938), owing to the interference of calcium with the absorption of lead, presumably by forming a less soluble salt (Lederer and Bing, 1940). Retention of calcium is inverse to that of lead. Lead retention is also increased by low phosphate income; but calcium or phosphate does not protect rats against excessive lead income (J. B. Shields and Mitchell, 1941). Calcium storage is increased by the administration of vitamin D (Sobel *et al.*, 1939). Growing animals store relatively more than adults (Shields *et al.*, 1939). Addition of 0.2 per cent of *ferrous sulfate* to the diet of rats tends to prevent lead acetate anemia and stunting in rats, presumably by interfering with lead absorption (Heppel and Kornberg, 1946).

"*Normal Lead.*"—Small amounts of lead are present in normal individuals, not as a necessary element, but because exposure to lead is universal. The difference from that found in lead poisoning is merely quantitative (human, W. Cone *et al.*, 1934; animals, Dankworth and Höll, 1934; fowl, Ciurea, 1931).

The **distribution of lead in the organs** is approximately the same for various compounds, including tetraethyl lead, and for different methods of administration, but it undergoes a change with time: Early after the absorption, the greater part of the lead is in the kidneys and liver; after several days it shifts toward the bones, and in chronic poisoning these contain a third to nearly the whole of the lead (A. S. Minot, 1924). Next comes the liver, which accounts for 0 to 28 per cent of the lead; then the kidneys (0 to 14 per cent). Only small quantities are contained in the other parts. These figures are from experimental animals (H. P. Morris and Long, 1939; radioactive isotopes, Lomholt, 1930, Behrens, 1934); but the concentrations in human cases indicate that the phenomena are strictly analogous. Lead passes across the placental circulation into the *fetus;* the quantity in the newborn is proportional to the amount ingested by the mother (E. P. Lang, Morris *et al.*, 1937).

Human hair contains considerable lead, normally 0.5 to 4 mg., averaging 1.7 mg. per 100 Gm. In lead industries the content is 16 to 230 mg. after thorough washing (H. Kraut and Weber, 1944. These workers deny any relation to the color of the hair, which had been asserted by K. N. Bagchi *et al.*, 1940).

The *concentrations in the more important organs of human lead poisoning*, under a variety of conditions, ranged as follows, mg. per 100 Gm. of moist tissue (Aub): Teeth, 5 to 20; skeleton, 2.2 to 15 (total, 200 to 800 mg.); liver, 0.1 to 5; kidneys, 0.1 to 1; central nervous system, 0 to 0.36; muscle, 0; blood, trace to 0.27; cerebrospinal fluid, to 0.1.

In rats receiving lead compounds the concentration was in the sequence: Femur > kidney > brain > liver;

and with higher intake it changed to kidney > femur > liver > brain (H. P. Morris and Long, 1939). Chronic administration of radioactive isotope to rats and mice gave the sequence: Bone > liver > kidney (confined to cortex) > spleen > pancreas > intestines > heart > lung, brain (Lomholt, 1930; Behrens, 1934).

The *blood concentration* is of diagnostic significance: The normal average, mg. per 100 cc., is 0.03 (Kaplan and McDonald, 1938); 0.06 (Kehoe *et al.*); 0.054 (Thompsett and Chalmers, 1939). Concentrations above 0.06 suggest lead poisoning. J. N. Chalmers, 1940, found 0.03 to 0.09 in seventy normal people in England; and 0.06 to 0.19 in forty-four lead workers without symptoms. Kaplan and McDonald found 0.1 to 0.6 in early clinical lead poisoning; and 0.4 to 0.6 in fatal encephalitis.

Distribution between Cells and Plasma.—The average lead concentration of the blood is ten to fifteen times higher than the average concentration of the urine, but about 90 per cent is contained in the cells, in clinical lead poisoning and in normal individuals (K. Bambach *et al.*, 1942). The plasma level is not far different from the urine concentration. F. L. Smith *et al.*, 1938, found the lead concentration of normal persons to range from 0 to 0.01 mg. per 100 Gm. for serum and 0.02 to 0.11 mg. for the cells. After intravenous injection of radioactive lead, up to 99 per cent of the lead in the blood is in the cells, within a few minutes (K. A. Mortensen and Kellogg, 1944).

BAL Mobilization of Erythrocyte Lead.—A single intramuscular injection of 5 mg. per Kg. of body weight into workers exposed to lead results in a prompt decrease of the lead concentration of the blood cells, demonstrable within a few minutes, maximal in eight hours, and returning to the previous level in twenty-four to forty-eight hours. This effect is much greater than is producible by any other agency. The cycle is repeated with further injections. The lead concentration of the plasma is not materially changed so that the released lead must leave the plasma rapidly, presumably into the tissues and urine. The urinary lead is distinctly increased, reaching a peak in one to two hours and returning to the previous level in eight to twenty-four hours. The extra amount of lead eliminated by a single injection is too small to have therapeutic significance, and sufficiently repeated injections are precluded by the toxicity of the BAL (H. W. Ryder, Cholak and Kehoe, 1947).

Form of Lead in Blood.—The lead of the erythrocytes is not diminished by washing with isotonic saline (H. Blumberg and Scott, 1936). The quantity in the plasma is so small that its combination has not been identified with certainty. It was generally assumed to exist as albuminate, but according to elecrometric measurements and other considerations, it exists most probably as tri-lead phosphate, $Pb_3(PO_4)_2$, which is formed when any lead salt meets with sodium phosphate. This is soluble in water only to the extent of 0.13 mg. per liter, and therefore probably in part in colloidal solution (Aub). In acid reaction, the tri-lead phosphate is changed into bi-lead phosphate, $PbHPO_4$. This is nearly a hundred times more soluble in water than is the tri-lead phosphate, and therefore exists presumably in true solution and ionized. It could not exist at the *p*H of the blood; but Aub believes that it could be formed by local acidosis, and that this transformation is connected with the lead actions, as well as with the mobilization of lead from the bones, the latter along with the similar mobilization of the calcium salts. Other theories of lead combination have been proposed. L. C. Maxwell and Bischoff, 1929, suggested that it is carried as a diphosphoglycerate; Jowett, 1932, believed that it forms a complex inorganic phosphate with calcium and chloride. If lead ions are added to blood serum in concentrations not over 1:10,000, they disappear from the solution almost immediately by adsorption on the protein colloids (Teisinger, 1935). Serum dissolves 12.5 to 33 mg. of lead carbonate per liter, *in vitro. Cerebrospinal fluid* contains lead in about the same concentration as blood (Aub *et al.*, 1926; Rabinowitch *et al.*, 1933; A. J. Hyman, 1934).

Lead deposition in bone and teeth is closely parallel to that of calcium, as was recognized by A. Gusserow, 1861. Lead is in no way necessary to bone formation, but accumulates passively as the insoluble tri-lead phosphate, apparently by its similarity to the calcium phosphate of the bone, perhaps incorporated into the apatite pattern. It is therefore deposited when and where calcium is laid down in the bone, in the trabeculae and in the actively growing epiphysis; and remobilized when and as calcium is mobilized (Aub *et al.*, 1932). The amount deposited varies directly with the income (Calvery *et al.*, 1938) and therefore increases with age; but the rate of deposition for a given income level is greater in the young than in the mature (Calvery *et al.*, 1938; Kasahara and Nosu, 1934). The age difference is greater in compact than in spongy bone (H. P. Morris, 1940). The total amount deposited is not large, even in pronounced clinical lead poisoning, scarcely ever above 150 mg. per Kg. of fresh bone, or 0.2 to 0.8 Gm. in the entire skeleton (Aub, 1935). Bones of normal individuals without special exposure contain 0.5 to 10 mg. per 100 Gm. of ash; the higher concentration in older people, the lowest in infants. The lead of soft tissues does not increase with age (review, A. S. Minot, 1938). Lead in old age amounts only to 0.003 per cent of the bone ash, and a fifth of this in infancy (Barth, 1931).

The *distribution of lead* in the bones can be followed grossly and microscopically by decalcifying with formic acid and exposing to hydrogen sulfide. The deposition occurs on all surfaces exposed to the blood, in the periosteal and endosteal layers, in the Haversian and Volkmann canals, in the lacunae and bone canals, in the outer layers of the trabeculae and in the ossifying areas of the epiphyseal zones (E. Sieber, 1936), but not in the cartilage (Kasahara and Nosu, 1934). It is first laid down as dispersed colloid, then as crystalline masses (L. T. Fairhall, 1943). The lead content of the trabeculae averaged 80 per cent higher than that of the solid bone (Aub *et al.*, 1932); the ends of the femur 60 per cent more than the shaft (Calvery *et al.*, 1936). In children with serious lead poisoning, the epiphyses and kidneys were richest in lead (A. J. Hyman, 1934). Radioactive lead isotope (thorium 13) administered to mice and rats was more abundant in the subepiphyseal portion of long bones and subperiosteum of the ribs. Marked lead deposition occurred in young callus; rickets diminished the deposition of the lead, as did also overdosage of vitamin D. Lead was also deposited in pathologic calcifications (Behrens and Baumann, 1933). The concentration of lead *in fresh whole bone* of human adults not especially exposed to lead was stated by A. S. Minot and Aub, 1924, as not more than 2 mg. per 100 Gm. Tompsett, 1936, found in nineteen autopsies, 0.34 to 1.75 mg. in the ribs and vertebrae, 1.5 to 10.8 mg. in the femurs and tibias. In the *teeth*, the lead is chiefly in dentine, traces in the enamel (Pfrieme, 1934). The *bone formation* itself is altered when growing children are exposed to chronic lead poisoning, the roentgen shadows being similar to those produced by overdosage of viosterol, with transverse lines of greater density behind the diaphyses. Similar changes were produced in growing dogs, but not in full grown dogs (J. Caffey, 1931; Kasahara and Hiroshima, 1934). The bones are softer and more fragile than normal (Calvery *et al.*, 1938). The blood calcium decreases in the early stages and rises later in chronic lead poisoning (Pavloff, 1927).

Mobilization of lead from the bone occurs in man and in animals by the same agencies that mobilize calcium, notably acidosis as result of disease or the administration of the drugs that acidify the urine, such as ammonium chloride; lead is also mobilized by administration of sodium bicarbonate, probably because the carbonate is more soluble than the phosphate; and by potassium iodide. The iodide effect is as large as that of the acidosis, but its mechanism is obscure. All these increase the fecal excretion of lead to two or three times; the urinary excretion is not much altered. The effect of magnesium sulfate is doubtful (Aub *et al.*, 1932). Rise of the blood level of lead can be demonstrated (Teisinger, 1938). Low-calcium diet also mobilizes lead and raises its concentration in the blood, while this is lowered by high-calcium diet (Tompsett and Chalmers, 1939). Acidifying doses of calcium chloride produce mobilization (F. Schmitt and Basse, 1937). Parathyroid administration mobilizes lead in animals, but not clinically (Teisinger). Vitamin D in moderate doses promotes the storage of lead. Administration of neutral ammonium phosphate, lactic acid, sodium citrate or potassium chloride had no effect (Aub).

The following doses produce the mobilization clinically: ammonium chloride, 1 Gm. in a glass of water, ten to twelve times per day; dilute phosphoric acid (10 per cent), 20 cc. in a glass of sweetened water every hour, about ten times daily; sodium bicarbonate, 20 to 40 Gm. per day; potassium iodide, 0.5 to 2.5 Gm. per day.

Accidental or incidental mobilization of lead is credited with the periodic acute exacerbations of symptoms in chronic plumbism, especially in the acidosis of pneumonia, surgical operations and alcoholism. Iodide or bicarbonate is sometimes used to provoke lead excretion for diagnosis, but may bring on an acute symptomatic attack. Carefully managed mobilization is used for the removal of stored lead in the quiescent intervals (Aub).

Chronic Lead Poisoning (Plumbism; Saturnism).—Daily absorption of small quantities of lead occurs in numerous industries that employ lead or its compounds, and sometimes also from contaminated water or food. Chronic lead poisoning (plumbism, saturnism) is therefore common. It is especially dangerous because it develops insidiously, and is often not recognized until it is far advanced.

The symptoms involve the nutrition, the blood, and nervous and muscular structures, apparently independently. Eventually there may be degeneration of the kidneys and other organs. The effects are arrested if the patient is withdrawn from exposure to lead, usually with fairly prompt and apparently complete recovery, aside from anatomic lesions.

Animals are also subject to chronic lead poisoning, and show practically the same symptoms. Some of the phenomena may be produced acutely by the injection of organic compounds; but it is questionable whether these are identical with those of chronic poisoning.

Sources of chronic lead poisoning are found in many industries, especially through the use of paint; in food or drink contaminated by lead-containing vessels or pipes, by insecticides, and by other accidental sources; by cosmetics and sometimes medicines; by leaden bullets, and so on. Artisans working with paints are the most common victims. The manufacture of storage batteries is also an important source of poisoning. However, the metal is so widely distributed that everyone is to some extent exposed. The hazards of tetraethyl lead will be considered in a special section.

Industrial Lead Poisoning.—In 1921, Shie reported that about 200 American industries use lead, and the number is constantly increasing. Prophylaxis has become increasingly effective, however, so that lead fatalities decreased from 2.5 per million in 1910, to 1.1 in 1928 (F. L. Hoffman, 1930). The hazard at present is greatest in smaller establishments where adequate precautions are not enforced (review, L. T. Fairhall, 1945; "Occupational Lead Exposure," Am. Pub. Health Assoc., N.Y., 1943).

The more important lead trades are: Production.—Roasters of lead ore; manufacture of lead pigments and paints (white and red lead; lead chromate). The smoke and fumes of lead smelters may contain considerable lead which is harmful, not only by direct inhalation, but also by being deposited on vegetables cultivated in the vicinity. Animals grazing in such localities are often affected. The determination of lead in metallic fumes is discussed by R. G. Keenan and Fairhall, 1944. *Pigments.*—Painters, enamelers; varnishers; automobile work; glazers; dyers; paper; silk; artificial flowers; rubber goods; potters. Among *painters*, about 40 per cent show active symptoms. Less than half of those who have passed the age of forty years are free from plumbism. The heaviest incidence is among those who have been painters for ten years or longer (Harris, 1918). The spraying method of painting presents special dangers (Hamilton). Poisoning has been caused by the smoke from burning painted wood. *Children* may be severely poisoned by gnawing the lead paint of their toys or beds (Blackfan, 1917). *Metal.*—Plumbers; printers (handling type); file cutters; glass and gem cutters; storage batteries.

Lead in Food and Drink: Leaden water pipes and lead, tin and pewter vessels were prolific sources of danger, which have been largely but not completely eliminated. The use of lead paint for tightening pipe joints presents some danger (H. B. Williams, 1939).

Water pipes are especially treacherous because the solubility of lead varies greatly with circumstances. If perfectly pure water is allowed to flow through bright and clean lead pipes, poisoning results invariably. The surface of the lead is changed into a hydrate (Clowes, 1902), and this is sufficiently soluble to cause the intoxication. The danger is much less with old lead pipes; these become lined with a layer of lead oxide, PbO + Pb. This is quite insoluble, and does not readily form a hydrate. The solubility is increased by oxygen and salts, especially by nitrates (Fortner, 1905), but even by sulfates; it is diminished by carbonic acid and carbonates (Paul, etc., 1906). Hard water is therefore much less dangerous than soft water. (Details and older literature in Wolffhuegel, 1887.) Old lead pipes with hard water present relatively little danger; but should the water stand in the pipes for a time, some solution will occur. The use of lead pipes should therefore be avoided.

The actual lead content of water delivered from lead pipes has been found as 0.5 to 12 mg. of Pb per liter (Kunkel). In the Leipzig epidemic of 1930 it was 5.3 mg. per liter in the morning and 3.5 mg. per liter during the day. In two lead epidemics it was 14 mg. per liter (Brouardel). Angus Smith considered 0.35 mg. per liter as dangerous. From data to be quoted later, there is reason to believe that even 0.05 mg. is not indifferent. The U. S. Treasury Department sets 0.1 mg. per liter as the limit of lead in drinking waters. Fish have a high resistance to lead in water and thrive in a saturated solution of lead carbonate.

Lead, Tin and Pewter Vessels.—Leaden cooking utensils and containers for food or drink should be entirely discarded. Tin plate (cans), solder, pewter and tin foil usually also contain some lead. If the percentage does not exceed a certain limit (1 per cent for tin plate; 10 per cent for solder), the lead is held so firmly in the alloy that it is dissolved by moderately acid fluids, such as vinegar. These are deemed harmless. Evaporated milk bought from open shelf stock contained only the lead of the milk, allowing for the concentration (Fairhall, 1937). Higher proportions give up their lead and are dangerous. Some enamel ware contains soluble lead; but this is now believed to be exceptional. Earthenware and porcelain are glazed with lead silicate, and this is contained in varieties of glass; but if the lead is present only as silicate, it is harmless.

Millstones repaired with lead have contaminated *flour and bread.* The use of lead shot for cleaning bottles is dangerous. Clarification of wine with lead acetate is also dangerous.

The lead content of meat and fish was reported by O. Jones, 1946.

Spraying of fruit and vegetables with lead arsenate as insecticide is now extensively practiced and may leave considerable residue on the surface. The lead is generally the more toxic component. U.S. government regulations set a limit of 2.56 mg. of lead per Kg. of food, 0.018 grains per pound, which would correspond to 3.55 mg. for 3 pounds of daily food (the limit was formerly 2 mg. per Kg., 0.014 grains per pound). This limit is quite feasible if proper precautions are taken and fruit is washed in dilute acid.

The limitation was needed, as severe acute arsenical poisoning resulted from eating three apples from a sprayed orchard (Heeren and Funk, 1917), and even death has been reported (Hayhurst, 1920). The present limit appears to be safe, considering that sprayed food constitutes only a fraction of the diet. However, if even a third of the food contained the permitted maximum, this would amount to 1.025 mg. of lead, which would presumably become dangerous (Calvery, 1938). Further data are needed as to smaller amounts, in view of the cumulative nature of lead poisoning. The fear has also been expressed that continuous spraying may poison the soil itself.

The spraying of orchards with lead arsenate was introduced in 1894. Five or more sprays are applied in the season. Forty-four million pounds are used annually in the United States. An epidemiological field study of over 500 workers in sprayed apple orchards revealed only six cases with definite laboratory and clinical findings, but the latter were below "incipient plumbism." The urines almost always contained measurable amounts of arsenic and lead, even when there was no direct exposure. In exposed workers the urinary concentration of lead ranged from 0.068 to 0.123 mg. per liter; arsenic from 0.06 to 0.22 mg.; the blood concentration of lead from 0.039 to 0.052 mg. (P. A. Neal *et al.*, 1941). Fairhill and Neal, 1938, administered 10 mg. of lead arsenate, $PbHAsO_4$, per day to man for ten successive days without apparent untoward effects, but the period is too short for lead poisoning. Animal experiments indicate a greater degree of tolerance than it would be safe to transfer to man: Horwitt and Cowgill, 1937, raised three generations of normal rats on a diet containing 100 mg. of lead per Kg. of food, near forty times the official limit, and puppies also throve on 50 mg. per Kg., twenty times the official limit. Lead arsenate is sufficiently soluble in gastric juice to account for its absorption. When shaken with serum, dilead orthoarsenate forms soluble arsenates and insoluble pentalead chlorarsenate (Fairhall, 1939).

The *toxicity of lead azide* is discussed by Fairhall, Wendell *et al.*, 1943.

Cosmetics.—Lead carbonate, used as face powder or pomade, has caused plumbism. Kasahara and Hiroshima, 1934, reported bone changes characteristic of lead in 115 Japanese infants, caused for the most part by lead cosmetics on the skin of the mothers. Lead and sulfur hair dyes present at least a theoretical danger; although serious poisoning by them must be uncommon.

Medicines.—The internal use of lead is not advisable, although it may be harmless if it is temporary. Brief use of lead washes is safe, but prolonged application, especially to the denuded skin, is dangerous. This probably applies also to lead plaster. The plaster has been taken as abortifacient, with toxic results (Pope). The treatment of cancer by intravenous injection of colloidal lead has given rise to serious lead poisoning.

Lead Poisoning from Imbedded Bullets.—Projectiles left in the tissues do not readily give up their lead to the circulation, so that they may be harmless. Exceptionally, however, they produce severe and sometimes fatal plumbism, sometimes after a latent period of months or even years (Machle, 1940). Leschke, 1934, states that lead has been demonstrated in the blood ten years after the lead was imbedded, 0.01 mg. per 100 cc., increased to 0.175 mg. by bicarbonate treatment. The chances of intoxication are greater when the lead offers a large surface, as with small shot (Curtillet and Lombard, 1912). The possibility of eventual plumbism renders the removal of bullets advisable, even when they are not causing mechanical injury. However, in Curschmann's case an encephalitis saturnalis was precipitated by the manipulation of the scattered lead in the wound during the operative removal.

Swallowing of leaden bullets and shot usually produces plumbism, depending, however, on the time of sojourn in the digestive tract. Brouardel states that shot was formerly administered in volvulus, but that this was strongly condemned by Van Helmont and other masters of that period. He also describes some modern cases, in man, cows, dogs, and so on. *Birds* are especially subject to this form of plumbism, as the shot is picked up with food, and remains indefinitely in the gizzard or crop, where it is slowly ground and macerated. Six No. 6 shots are fatal to a duck (Wetmore, 1919). Hanzlik, 1921, found that ducks and pigeons die in two to three weeks, when 0.16 to 0.6 Gm. of lead per Kg. of bird has been absorbed. Other birds are similarly susceptible. When the total absorption averaged 0.01 Gm. per Kg. per day, the survival averaged eighty-three days. The symptoms consist in progressive anorexia and emaciation, starting in a few days, and proceeding to a loss of 40 per cent of the body weight at the time of death. The birds show visible crop peristalsis with regurgitation of fluid; diarrhea; paresis of extremities, with a "wing drop" simulating the "wrist drop" in man. The animals also develop dyspnea. Metallic lead is more toxic than its compounds when fed to birds (Hanzlik and Presho, 1923), doubtless because its softness permits it to be ground to a more colloidal powder, which can be more rapidly dissolved. *Other metals* are much less toxic to pigeons and do not produce the characteristic phenomena of the lead poisoning (Hanzlik and Presho, 1923).

The **susceptibility to lead poisoning** varies greatly, in the first place according to the precautions against exposure; but even when these are apparently the same, with men working side by side, some may be attacked in a few weeks, others may continue to work for forty years without notable symptoms (Shie). Wide variations in the time of onset and severity of symptoms occur even in animals selected and treated with a view to uniformity. Differences may depend on absorption and excretion, on the acid balance, the character of the food, digestive disturbances, starvation, anemia, infections, alcoholism and nephritis, and so on, and may therefore be important factors. Patients who have had an attack appear to be more susceptible to subsequent exposures; but this may only mean that the attack has revealed the susceptibility. Several observations, clinical (Legge and Goadby, 1912) and experimental (Weller, 1926), indicate that some individuals may acquire a degree of tolerance. Negroes are said to be more susceptible to encephalopathia.

The *quantity of lead required to produce chronic poisoning* can not be accurately stated, as it involves the time of exposure and other conditions, but it is generally considerably more than the average normal intake. There is some evidence that definite lead symptoms may result from the continued ingestion of 0.2 mg. per day, in addition to the normal dietary income which averages 0.25 to 0.35 mg. (H. B. Williams, 1939), but Kehoe *et al.*, 1940, found no deleterious effects on ingesting 1 mg. of lead, as acetate, daily for three and a half years, or 2 mg. one year.

The opinions of forty writers on the subject, compiled by Calvery, 1938, show that practically all consider 1.3

mg. per day as dangerous; 1 mg. is so considered by three-fourths, 0.65 mg. by half, and 0.325 mg. by a fourth. Epidemics of severe lead poisoning have been produced by water containing lead in quantities corresponding to the ingestion of 4 to 20 mg. per man, per day. This would be a maximal figure, and much smaller quantities are probably harmful. Brouardel believes that poisoning may result from 1 mg. per day; others place it much higher. W. Wright *et al.*, 1944, report that lead poisoning is common when the drinking water, over a period of years, supplies 1.5 mg. per day. Telekys, 1931, found that 1 to 2 mg. daily produced poisoning after some months, 10 mg. after some weeks. Gaertner claims that symptoms occur in man only after several months with a daily ingestion of 4 to 7 mg.; in three to four weeks, if the daily dose is 60 mg. (Fluegge and Heffter, 1912). In cats, 0.1 mg. per Kg. (corresponding to 6 mg. for man) may be absorbed daily for weeks without lead symptoms. Fatal lead poisoning requires the daily absorption of 1 mg. per Kg. or the daily ingestion of 12 to 30 mg. per Kg. Interference with appetite and growth may occur in rats with much smaller doses (Sollmann, 1921).

Time of Exposure.—The time required for the onset of noticeable symptoms varies greatly: in animals, from a day to several months; in man, from a few weeks to many years; in general, inversely to the dosage. The delay was formerly attributed to the gradual accumulation of effective concentrations of lead in the body; but as has been explained, the retained lead is practically entirely in inactive form in the bones. Straub, 1913, and Erlenmeyer, 1913, suggested that the cumulative action is due to the progressive accumulation of injuries, produced by the "stream" of circulating "active" lead, in course of absorption and excretion. The continuous mobilization of stored lead, with its periodic exacerbations, is doubtless an important factor in providing the active lead.

Characteristic Symptoms of Chronic Lead Poisoning.—These have a slow and vague beginning and run an irregular and intermittent course, with paroxysmal symptoms and recurrences. They may develop only some months after stopping work with lead. They are quite independent of the channel of introduction.

They begin generally with rather indefinite manifestations of ill health; digestive disturbances, especially anorexia and constipation; gingivitis and "lead line"; anemia, stippling of the corpuscles, disproportionate pallor; progressive loss of weight and of strength; rheumatic pains. Nephritis, gout, hypertension and arterioslcerosis, sterility, tuberculosis, and other chronic diseases are frequently associated with long-continued exposure to lead, probably mainly as secondary consequences.

A second group of phenomena occur as acute paroxysmal attacks of colic or sometimes arthralgias. A third group consists of motor paralyses, especially the "wrist drop." A fourth group are cerebral and bulbar phenomena, caused probably by hemorrhagic encephalitis, which are fortunately rare and confined to the most severe poisoning.

Frequency of Individual Symptoms.—Harris, 1918, found the named symptoms to occur in the following percentage of active cases among painters: Digestive disturbances are frequent. Loss of weight and of muscular strength are common complaints. Constipation, 72 per cent; backache (generally lumbar), 56 per cent; arthralgias, 56 per cent; anemia, 53 per cent; colic, 51 per cent; headache, severe frontal, 46 per cent; lead in urine, 46 per cent; hypertension (above 140 mm.), 39 per cent; pain in chest, 35 per cent; metallic taste, 18 per cent (this has no connection with the lead line); lead line, 14 per cent; stippling, 12 per cent; Wassermann test, negative, except in luetics.

Diagnostic Features.—The chief points may be recapitulated as: the history of exposure; lead line; ammonium sulfide reaction on the skin; black stools; especially the chemical demonstration of lead in the stools or urine; pallor, anemia, stippling, pinched features, asthenia, rheumatic pains, digestive symptoms, colic, obstipation, wrist drop, recovery when removed from exposure to lead. The concurrence of most of these signs is highly characteristic; but none of them is absolutely constant, and most may be simulated individually by other conditions (Linenthal, 1914).

Symptomatic Diagnosis.—With ordinary industrial poisoning, the *early symptoms* are not distinctive, but their absence tends to rule out lead poisoning. They consist chiefly of subjective complaints of poor health; exhaustion, ready fatigue, emotional irritability, anorexia, nausea, colic and constipation. Early objective phenomena are: skin pallor, blue line on gums, punctate basophilia, hematoporphyrinuria, flexor weakness. If any of these is present together with the subjective complaints, the patients should be removed from lead exposure. If they do not develop within a few weeks after starting the work, they will probably not develop at all; if they are absent after six months, the worker may be considered practically immune, provided that the conditions are not materially altered. Workers who have developed the minor manifestations, including the pallor, gum line and flexor weakness, may sometimes continue the exposure for years without developing more violent symptoms. Colic and epileptiform encephalopathy indicate recent and intense absorption of lead, generally superimposed on the more chronic symptoms, but occurring sometimes before these have had time to develop.

Experimental plumbism may be produced in mammals by *feeding* with lead compounds, especially the carbonate, either rapidly (Carlson and Woelfel, 1913) or slowly (rats, Weller, 1915; Sollmann, 1921); by scattering the carbonate on the sawdust of the cage (Wassermann, cats, 1916); in birds, by shot placed in the crop (Wetmore, 1918; Hanzlik, 1921); *hypodermically*, with lead carbonate (cats and guinea pigs, Straub, 1911 and 1914; Erlenmeyer, 1913). These methods require some weeks for the development of the typical symptoms. They resemble the human symptoms closely. *Dogs*, for instance, that received lead salts in their food, developed three grades of poisoning (Calvery *et al.*, 1938). *Mild:* apathy, loss of appetite, slight weakness of hind legs, loss of energy, early fatigue. *Intermediate:* paralysis of the hind legs, muscular incoordination, pain when handled. *Severe:* convulsions, severe pain, erethismus, tremors, impaired vision, muscular incoordination. The effects on *rats* were not so characteristic (E. P. Lang and Morris, 1938). Diets low in calcium increased the toxicity of the lead; the phosphate content had little effect (Calvery *et al.*, 1938). The phenomena in *birds* were described under the etiology. Somewhat similar symptoms may be produced acutely by the cautious *intravenous injection* of lead salts (Hirschfelder), but these acute effects probably have a quite different mechanism from the phenomena of chronic plumbism. Exposure of guinea pigs to the inhalation of lead oxide dust results in pneumonia (Ehrismann, 1939).

The *mechanism of the lead action* is obscure, but may conceivably involve several quite distinct factors. Some of the paroxysmal phenomena resemble flocculation reactions and could be connected with the unstable trilead and bilead phosphate system. Lead also alters the calcium level of the blood, decreasing it in the early stages, leading to increased sympathetic excitability, and lowering the calcium in the later stages with increase of parasympathetic excitability (Pavloff, 1927).

Details of Effects.—*Digestive disturbances* are among the earliest and most common phenomena. They begin with mild stomatitis, foul breath, sweet, metallic taste, anorexia and nausea. Diarrhea is frequent in the early stages; later there is usually obstinate constipation; or the two may alternate. The abdomen may be tender. These effects are based partly on mild inflammation of the whole alimentary tract, which later on is complicated by the colics. The anorexia is mainly responsible for the emaciation (sunken cheeks) and partly for the anemia, pallor, malaise, headache, insomnia, lethargy, weakness and tremors. Chronic parotitis sometimes occurs, perhaps as a part of the stomatitis. The lead line is a slate-colored margin of the gums where they meet the teeth. It is one of the earliest and most constant signs, and occurs also in animals. It shows that lead has circulated at some time, but not whether it is circulating at the moment. It is due to the precipitation of lead sulfide in the vascular subepithelial connective tissue. This is formed when the lead in the circulation comes in contact with hydrogen sulfide formed by putrefaction around unclean and carious teeth. The lead line therefore depends on the condition of the mouth, and may be prevented by oral hygiene. Its presence shows that the patient has absorbed notable quantities of lead, but it need have no relation to the lead symptoms. The buccal mucosa opposite carious teeth may also be blackened (Oliver's sign). A similar black line is given by bismuth, silver, mercury, iron and perhaps other metals. It may also be simulated by charcoal tooth powders. *Malnutrition, i. e.*, loss of weight, or checking of growth, is the earliest and most constant objective sign, and an almost quantitative index of lead poisoning.

In rats it is an inconstant feature, sometimes marked (Sollmann, 1921); sometimes slight (K. P. Morris and Laug, 1938); sometimes none, even with large doses (Horwitt and Cowgill, 1937). The difference has not been explained. In mice, Busch and Berman, 1927, found effects similar to those of thallium: Cessation of estrous cycle, alopecia, arrest of growth and occasionally cataract formation.

The *blood changes* in industrial plumbism begin early with polycythemia and polychromatophilia, rise of reticulocytes to double, and increase of the platelets. The red count and hemoglobin then return to normal, with further increase of reticulocytes. Basophilic granules, staining with methylene blue, appear in 500 to 1000 per million of the erythrocytes. This "stippling" is an important early diagnostic sign (van Emden and Kleerkoper, 1904), although the basophilic granules may occur in other anemias, and are sometimes absent in lead poisoning. With definite plumbism the proportion of basophilic cells increases, the total red count and the hemoglobin decrease below normal, poikilocytes and nucleated red cells appear, the percentage of large mononuclear cells increases, polymorphonuclears may be decreased, the platelets decrease (reviews, R. R. Jones, 1935; W. Machle, 1947).

In clinical cases the anemia is usually moderate, the count rarely falling below four millions. The color index is variable. Many corpuscles are destroyed, producing icterus and widely distributed "hemosiderin," and the appearance of hematoporphyrin in the urine. In animals, the erythrocytes often drop rapidly, from the first or second day, to about two-thirds of the normal, and remain at this level till death. If the lead is removed, the count rises rapidly. This severe anemia is probably due in part to inanition.

The *bone marrow changes* correspond to those produced by mercury, iron, phosphorus, and many infective and wasting diseases. They are perhaps secondary to anemia. At first there is marked increase of leukoblastic cells with disappearance of fat, and sometimes with moderate hyperemia; then, gelatinous degeneration and atrophy of the whole marrow tissue (R. Stockman and Charteris, 1903). The blood changes as a whole indicate increased destruction of the corpuscles, with consequent stimulation of the bone marrow to increased production of young cells. The resistance of the corpuscles to laking is increased, and this is somewhat diagnostic of lead poisoning. It is also seen when corpuscles are exposed to dilute lead solutions *in vitro;* it has been suggested that the lead hardens the surface, and so renders the cells less elastic and therefore more vulnerable to mechanical injury, and at the same time more resistant to chemicals (Aub). The *genesis of the basophilic granulations* is not clear. Their occurrence varies in individuals and especially in species. It has been suggested that they represent coagulation of the basophilic substance of young red cells by the lead; at least they are preceded by basophilia and reticulocytes and are more or less parallel to these (Aub *et al.*, 1925, review). They were described by Grawitz and Homel, 1900, and are found also in other conditions associated with anemia, but in no other disease in such numbers and in the absence of other major blood changes. They may be among the first signs of acute lead poisoning. In chronic lead poisoning they generally parallel the amount of lead exposure and the lead excretion, but not the symptoms. They are therefore a fair index of lead absorption, but not necessarily of lead poisoning. A ratio of 100 per million of erythrocytes is considered normal; 100 to 300, suggestive; 300 to 1000, diagnostic; 200, indicative of danger (J. P. Leake, 1927).

Prolonged immersion of the amphibian *Necturus* in dilute lead acetate solution leads to extensive phagocytosis of its mature erythrocytes, chiefly by mononuclear leukocytes. This appears to be connected with physical changes in the erythrocytes shown by their adherence to glass (A. B. Dawson, 1930).

The *hematoporphyrin* (protoporphyrin), which generally appears in the plasma and urine and feces fairly early in lead poisoning, is presumably formed from the destroyed erythrocytes. H. J. Kark and Meiklejohn, 1942, attribute it, and the stippling, to inhibition of hemoglobin formation. Toxic porphyria may also result from barbiturates and sulfur preparations, but lead is the most frequent cause, so that it is a valuable diagnostic criterion (Curschmann), if the urinary porphyrin exceeds 0.5 mg. per day. It tends to increase as the poisoning advances and to decrease with its improvement, but it does not parallel the symptoms. It may be high in "healthy" lead workers (Franke and Litzner, 1935; E. Roth, 1935; Carrie, 1936; K. Salomon and Cowgill, 1942).

Lead Pallor.—The color of the skin and mucous membranes is conspicuously pale and often slightly icteric in nearly all victims of lead poisoning exposed at least eight weeks. This lead complexion ("Bleikolorit") is of diagnostic value; it is too subjective to be decisive, but it should lead to the search for other signs. The pallor is greater than would correspond to the blood count, and the combs of roosters grow cold and shrink. It is usually attributed to vascular spasm, but this is improbable, since it does not vary periodically, as do the other lead spasms. It might be due to diminished blood volume, a suggestion that has not been tested.

The *blood pressure* is not affected by lead poisoning, except during the colic attacks when it rises (Riegel and Frank, 1874), largely by the compression of the intestinal vessels (Welch and Mall), partly by the pain reflex. The pulse is often slowed to 50, sometimes even to 20. In the absence of actual colic, the systolic and diastolic pressures average normal (Belknap, 1938). Pressures above 140 are rather exceptional. Chronic hypertension and arteriosclerosis do not appear to be more common in lead workers than in others (M. R. Mayers, 1927); nor can they be induced by long-continued lead administration in rabbits (Dominguez) or dogs (Adler, 1914).

Occasional attacks of spasmodic contracture of the *retinal vessels* may occur, perhaps analogous to the colic attacks, and cause temporary or permanent blindness

Constriction of excised or perfused arteries by the direct addition of lead salts (Siccardi, 1913) is an entirely different phenomenon.

Nephritis in acute and subacute lead poisoning involves direct tubular damage. In chronic clinical lead poisoning, contracted kidney develops only after long exposure, by sclerosis of the kidney vessels, followed by epithelial degeneration, deposition of calcium phosphate and finally cirrhosis (Bright, 1827).

The uric acid and nonprotein nitrogen of the blood are increased (Folin and Denis, 1913). During the colic the urine flow and chlorides are diminished; increased after the attack (Nistico, 1913); the urinary nitrogen increases during the acute attacks; the uric acid is said to be diminished during attacks (Goetze, 1892). *Intranuclear acidophile inclusion bodies* were demonstrated by S. S. Blackman, 1936, in the tubular renal epithelium and also in the liver cells, of lead poisoning, in children and in animals. Rats and dogs fed with lead for six or seven weeks develop marked hypertrophy of the kidneys and spleen, with irregularity of the tubular epithelium, intranuclear inclusion bodies and enlargement of the nuclei of many of the tubular cells (Calvery *et al.*, 1938).

Other Visceral Changes.—The long-continued administration of sublethal doses of lead carbonate to guinea pigs produced severe degenerative and necrotic change in the renal and hepatic epithelium, hemorrhagic edemas and chronic pleurisy (Ophüls, 1915). *Liver damage* is rare, although the reticular endothelium retains lead and excretes it by the bile. *Hepatic cirrhosis* may be produced in animals by lethal or slightly sublethal doses of lead (McJunkin, 1915). Von Glahn and Flinn, 1939, investigated the effect of *yeast* on the incidence of liver necrosis and cirrhosis in rabbits ingesting lead arsenate.

Gout is of fairly frequent occurrence in lead workers. The urate tophi are said to be rich in lead. There may also be periodic attacks of acute flocculatory arthritis, more or less similar to gout. *Arthralgia* occurs in about half the patients. After some preceding muscular weakness there are sudden paroxysmal attacks, generally at night, of violent remitting pains and disturbed functions of joints and groups of muscles, especially those of the shoulder and the flexors. Pressure gives some relief. The attacks last generally from five to eight days and often recur. They bear a resemblance to attacks of gout, and it is possible that they are due to a similar cause, perhaps precipitation of lead phosphate about the joints. Or they may be neuralgic, neuritic or central. *Other occasional sensory nervous phenomena* are: neuralgia, anesthesias and other hyperesthesias occurring in attacks of eight to eleven days' duration; amaurosis, amblyopia, deafness.

Intestinal colic is preceded by continued minor digestive disturbances; pressure sensation in the epigastrium; anorexia; obstipation; and some abdominal tenderness. Constipation is generally attributed to local astringent action. The acute attacks consist in paroxysms of intense pain, radiating from the umbilicus, and relieved by pressure. The patient therefore retracts the abdomen so that this often appears boat-shaped (scaphoid); he may lie on the face with the fists pressed against the painful region. The skin is pale and dry; the temperature low; the blood pressure high; the pulse hard, wiry and slowed, often to 40 or 50. The colic is sometimes accompanied by dyspnea (spasm of the bronchial muscles), and sudden severe muscular pains, especially in the flexors of the legs. After some hours the pain disappears completely, but the constipation lasts some days. Nausea and vomiting are frequent. Relapses are the rule and the whole attack may last ten days. The colic is very painful and wholly incapacitates the patient, but it is not dangerous.

Analogous effects may be produced in animals; except that with these diarrhea may be more common than obstipation. Radiography shows either increased peristalsis (producing diarrhea) or extreme tonic spasm (obstipation), so that the intestines appear like a cord (Herz; Wassermann, 1916). These effects are peripheral, since they are not prevented by section of the vagi (Harnack). They may sometimes be arrested by atropine, but this may fail clinically, and also in animals (Hanzlik). They are probably provoked by active mobilization of lead. The action appears analogous to barium and allergic stimulation, and is probably independent of the innervation. Intestinal spasm may also be produced acutely by intravenous injection of lead acetate (Hirschfelder, 1915) and in excised intestines (Siccardi, 1915), but it is questionable whether these effects are analogous.

Nervous phenomena include a variety of manifestations, some quite distinct, others more or less confused. The greater part may be reproduced in animals. They generally develop rather late, tend to spread, and are difficult to localize sharply. They involve probably direct peripheral actions on the sensory and motor elements; neuritis; and meningitis.

Wrist Drop and Other Muscular Paralyses.—Special groups of muscles, most commonly the extensors of the forearm (distribution of musculospiral below supinator longus) or others most exposed to fatigue (Mellon, 1913) become gradually paralyzed. The condition generally begins with weakness, tremors and disturbed sensation and passes through progressive paralysis, with the "reaction of degeneration" (muscles responding to galvanic and not to faradic stimulation, Eulenberg; Erb). Finally there is muscular atrophy and contracture. The contracture begins usually at the metacarpocarpal articulation of the two middle fingers, then the two outer fingers and the thumb and then the wrist. The onset is sometimes sudden. There is no pain. Restoration may occur even from advanced stages. The paralysis sometimes involves the recurrent laryngeal nerve (change of voice); and rarely the phrenic, with fatal termination. It has not been definitely decided whether the palsy is neuritic, spinal or muscular. The nerve trunks in clinical cases generally show interstitial neuritis, which is probably the primary feature (S. Moritz).

Harnack reported that methyl lead compounds affect skeletal muscle directly, rendering it more subject to fatigue. This has not been fully confirmed, and would in any case be more probably attributable to the onium structure than to the lead. Steinman, 1939, found that lead poisoning of frogs increases the hydrolysis of phosphocreatine, which would tend to prevent the development of full tension and delay recovery.

General asthenia, lassitude and neurasthenia are common. They may be early manifestations of the paralysis, or they may be merely the consequences of anemia and malnutrition. *Tremors* of the fingers, tongue, lips and eyelids are nearly always present. They may be due to weakness, or to neuritis, or early manifestations of encephalitis. *Sensory phenomena*, numbness of the hands and especially of the feet, were the chief symptoms in the slow poisoning observed by H. B. Williams, 1939.

Encephalopathia Saturnalis. — Cerebral symptoms are relatively rare. They occur especially in the rapid, severe cases, particularly with the easily absorbable tri- and tetraethyl lead; but also experimentally with hypodermic injections of lead carbonate in cats and clinically with oral administration. They are seen much more frequently in children than in adults. Negroes are said to be especially susceptible. The phenomena are the same in man and animals (Harnack, 1878; Erlenmeyer, 1913, cats; Calvery *et al.*, 1938, dogs). They set in rather suddenly after a latent period of variable duration, usually some weeks, with restlessness, hallucinations, delirium, melancholia, ataxia, pareses and pseudoparalyses, coma and epileptiform convulsions. *Children*, in the acute stage, have convulsions, with meningeal irritation and increased intracranial pressure; often with permanent sequels of convulsions and other cerebral symptoms (review, Haverfield *et al.*, 1940). All but one of twenty children who had been poisoned in infancy did not progress satisfactorily at school, and three had recurrent convulsions (R. K. Byers, 1943). Cats show significant changes in the electroencephalogram (Steinman and Therman, 1939). The prognosis is grave. The symptoms have an anatomic basis in meningitis with hemorrhagic edema and widely disseminated morphologic nerve changes, central and peripheral.

The *histologic lesions* of the nervous system in acute, subacute and chronic experimental lead poisoning involve the centers, peripheral nerves and muscles. They consist chiefly in diffuse degenerative encephalopathy without inflammatory changes. The nerve cells of the cortex and midbrain, less so in the cord, show all stages of degeneration, from acute swelling and chromatolysis to complete disintegration and liquefaction. Muscle cells exhibit fatty degeneration (A. Ferraro and Hernandez, 1932; Ewserowa, 1929; F. F. Grünberg, 1930; Erlenmeyer, 1913).

Sex functions and progeny are seriously affected by chronic lead poisoning.

Menstrual disturbances, dysmenorrhea, menorrhagia and amenorrhea are rather common. Lead always exerts an unfavorable influence upon *pregnancy*. The number of miscarriages in women affected by lead poisoning is large; of the children borne, by far the largest proportion die during the first year of life (Legge, 1901). In rabbits, lead poisoning injures the chorionic epithelium and causes coagulation necrosis and hemorrhages, with death of the fetus, which is sometimes retained for a long period (Datnow, 1928; Mitsui, 1934). Rats appear resistant to this effect; feeding of fairly large doses of lead acetate over long periods had no effect on the fertility or fecundity (H. P. Morris, 1937).

Plumbism of Father on Offspring.—The clinical evidence is slender. Sterility, stillbirth and early death of the children are common clinical occurrences. If the children survive, they are particularly liable to various nervous affections (Adami). Experimental feeding of lead acetate to male rabbits and fowl also results in smaller offspring of low vitality (Cole and Bachhuber, 1914). Weller, 1914 to 1916, confirmed this on male guinea pigs fed on lead carbonate, finding sterility or reduction of birth rate, early death of the fetus, and especially retarded development (underweight), which persists through life. In most of the lead-fed guinea pigs there are no demonstrable histological changes in the testes; a few, however, show complete aspermatogenesis, with atrophy and vacuolar degeneration of the germinal epithelium. Gradual recovery occurs if the administration of the lead is stopped, indicating that the deleterious action is confined to the maturing cells.

Lead Prognosis.—Slight, acute or subacute lead poisoning can be cured completely without any permanent disability, but the lighter grades of chronic poisoning are likely to decrease resistance indefinitely; severe grades are incurable and tend toward complete disability.

Prophylaxis.—The public, and especially the artisans, should be thoroughly educated to the insidious dangers of lead, and to guarding against the chances of poisoning. The sources of danger—lead pipes and so forth—should be eliminated. Proper precautions are essential in exposed trades and should include periodic health examinations, with especial emphasis on the lead characteristics. Lead-laden dust is especially dangerous. Since the main channel of poisoning is by the mouth, meticulous cleanliness should be enjoined and made possible by liberal facilities for washing. Sulfates are useless (see absorption). Food should not be permitted on the premises, and the clothing should be changed before leaving the works.

Ascorbic acid has no effect on the development of chronic lead poisoning or on the symptoms, in controlled experiments (Ecker *et al.*, 1940) or clinically (Dannenberg *et al.*, 1940; E. E. Evans *et al.*, 1943), nor does lead affect the utilization of ascorbic acid or complement activity. However, guinea pigs on diets deficient in ascorbic acid develop more severe nervous symptoms (paralysis and convulsions) in chronic lead poisoning; but if these symptoms have started, they are not relieved by administering ascorbic acid (Pillemer, Seifter *et al.*, 1940). *Pectin* diminishes the absorption of dietary lead (H. K. Murer and Crandall, 1942). The toxicity of lead chloride is affected by the quantity and quality of protein consumption (H. D. Baernstein and Grand, 1942).

The treatment during the active attacks consists in rest, symptomatic measures and attempts to lower the lead concentration by *deposition*. To this end, the diet should consist chiefly of milk, vegetables and potatoes; and the administration of calcium gluconate, 0.5 Gm. in milk, every three hours. All the mobilizing measures (including sodium bicarbonate) should be avoided (Aub *et al.*, 1926). The *symptomatic treatment of the colic attacks* consists in hot stupes or bath; magnesium sulfate, an ounce in half a glass of water (acting chiefly by the magnesium ion); morphine as needed. Half a pint to a pint of olive oil may be given as enema or by mouth. Amyl nitrite gives some relief (Riegel, 1878), but it is not sufficiently lasting. Atropine is ineffective. Irritant cathartics (castor oil, senna, calomel) should not be used. Slow intravenous injection of 10 cc. of 20 per cent calcium gluconate or chloride solution is reported to arrest the colic and shorten the attack (Aub *et al.*, 1926; Schretzenmayr and Baur, 1936). Thiosulfate has been suggested as antidote, but is ineffective in animals and even *in vitro* (Linguerri, 1933). In the acute lead encephalopathy of children, surgical decompression relieves the symptoms and prevents sequels (Haverfield *et al.*, 1940). *Mobilization of the lead* after and between the active attacks is advised by Aub, to hasten the removal of the depot-lead from the body. Belknap, 1935, urges that the de-leading be started before there are active symptoms. There is some risk, however, of provoking an attack (fatal, in animals; Schachnowskaja); and Kehoe, 1935, points out that the amount mobilized at the rate of 1 to 3 mg. per day in a ten day course does not make much impression on a store of 200 to 800 mg. This objection also applies to BAL (H. W. Ryder *et al.*, 1947). A diet low in calcium and high in phosphate would be safe and somewhat helpful in promoting the excretion of mobilized lead as the insoluble phosphate (Shelling, 1932; I. Gray, 1935).

The *measures commonly employed for therapeutic mobilization* are sodium bicarbonate, 20 to 30 Gm. per day; or ammonium chloride, 5 to 10 Gm., five times daily for three days; or sodium iodide (first recommended by Melsens, 1849), 0.75 Gm. per day for three days. Weyrauch, 1932, contends that lead excretion is not increased by ammonium chloride or by meat. *Sodium citrate,* 15 Gm. daily, materially increases the fecal and urinary excretion of lead, decreases its concentration in the blood and markedly improves the symptoms (S. S. Kety and Letonoff, 1943).

TETRAETHYL LEAD

The addition of this compound, $Pb(C_2H_5)_4$, increases the efficiency of gasoline motors, by preventing premature explosion (Midgeley and Boyd, 1922). It is highly toxic, being readily absorbed by the lungs and skin, and producing the phenomena of acute or subacute lead poisoning. Its combustion with gasoline results in lead chloride, bromide and sulfate, in the form of fine dust, which would therefore also be highly toxic (A. Hamilton *et al.*, 1925). Acute fatalities occurred in the manufacturing and blending, until proper precautions were taken. The danger to the public appears to be insignificant. Even attendants at filling stations dispensing large quantities of ethyl gasoline do not show any increase of lead level (Kehoe *et al.*, 1936), nor any lead symptoms (G. Lind, 1936).

Tetraethyl lead is a clear, heavy oily liquid of peculiar odor, somewhat volatile at ordinary temperature. It is practically insoluble in water, soluble in alcohol and fat solvents. The *annual consumption* in 1937 in the United States amounted to over 42 million pounds of lead, a third of a pound per capita.

Fate.—Tetraethyl lead is *absorbable* from the lungs, skin and digestive tract. Its immediate distribution in the organs presumably differs from the water-soluble compounds, but it is rapidly decomposed by the tissues and is then distributed as is water-soluble lead, and acts as such. The *excretion* occurs as inorganic compounds and may reach 8.4 mg. of lead in the daily urine (Kehoe and Thamann, 1931). It is rapidly destroyed in the body. The concentration of 11.4 mg. per Kg. of tissues is fatal (R. A. Mortensen, 1942).

Phenomena of Tetraethyl Lead Poisoning.—Application to the skin causes some irritation and local epilation (Templeton *et al.*, 1938). The systemic effects are similar to those of other lead poisoning (Kehoe, 1925). They occur usually by a combination of skin absorption and inhalation of vapor over considerable periods, but may set in after a few days if high concentrations of the vapor are inhaled, or large skin surfaces have been covered. Nervous symptoms tend to predominate. Insomnia and mental irritability and instability are among the earliest and most constant features. Other subjective symptoms are nausea, anorexia and vomiting; vertigo and headache; asthenia, and itching of the skin. The most constant objective phenomena are pallor, due to subnormal blood pressure, with subnormal temperature; loss of weight; and tremor. Relatively infrequent and unimportant are colic, lead line and stippling. The hemoglobin is usually normal. In severe acute cases the nervous irritability culminates in maniacal delirium. Such patients usually commit suicide if unrestrained, or die with cerebral symptoms. Inhalation by animals also results in acute lead poisoning (Demel *et al.*, 1933). Treatment could be attempted by calcium administration (Aub *et al*).

Experimental Poisoning by Organic Lead Compounds; Relation to Chronic Lead Poisoning.—Harnack, 1878, aimed to hasten the actions of lead by introducing it as a soluble and nonprecipitant organic compound, with the expectation that this would penetrate as such into the cells and be there decomposed, with the liberation of lead in active form. He experimented with triethyl lead acetate $(C_2H_5)_3Pb.C_2H_3O_2$. Intravenous injection caused immediate effects (which were probably due to flocculation): signs of agony; salivation and vomiting; psychic disturbances; distress and arrest of respiration. The course is rapid, so that the animal may be dead or completely recovered in a few minutes. Then, after one to several hours, phenomena gradually develop which resemble the symptoms of ordinary lead poisoning, including direct depression of striped muscle; peripheral stimulation of intestine; central motor stimulation. These differ relatively in different animals. Frogs and rabbits show mainly the muscular paralysis, whereas dogs die from the central effects before the muscles become paralyzed. Cats are intermediate. The intestinal phenomena occur with all the mammals. These delayed actions are attributed to the liberation of lead ions from the compound. This is based partly on the complete decomposition of the compound in the body, partly on the latent period, and partly on the close resemblance of the symptoms to those of chronic lead poisoning.

Triethyl lead chloride was studied by E. C. Mason, 1921, on dogs, but the identity of his preparation appears rather questionable.

THALLIUM

Thallium acetate has been used in children as a temporary depilatory in favus and ringworm of the scalp. Its therapeutic use has repeatedly caused severe poisoning and does not appear justified. The toxic phenomena resemble those of other chronic metal poisoning, but develop more rapidly, with malnutrition, epilation, polyneuritis, encephalopathy and degenerative changes in the ductless glands. It is also toxic to plants.

Historical.—Thallium was discovered by Crookes, 1861, through its characteristic green line in the spectrum. It is obtained as a by-product in the purification of cadmium and in the manufacture of sulfuric acid from iron pyrites. It is related to gallium and indium, and forms monovalent and trivalent salts; Tl_2O, thallous; Tl_2O_3, thallic. The thallous alone have been extensively studied, as the acetate and sulfate, chiefly because they are more stable. The relation of valence and action has been investigated by Iljin *et al.*, 1938. The toxic effects were shown by Lancy, 1863, and investigated by Blake and Luck, 1891, and Luck, 1895. It was tried in *syphilis* by S. Pozzi and Courtade, 1883, but was soon abandoned; later experimental studies showed it to be ineffective (Buschke, 1911, monkeys; Levaditi, 1921, rabbits). Combenale, 1898, introduced the therapeutic use of the acetate (5 to 10 mg. per day) against *night sweats.* It was effective (Buschke and Peiser, 1923), but its clinical use was abandoned because it was often followed by toxic manifestations, including temporary loss of hair. Sabouraud tried it clinically for *depilation* in 1897 and 1898, both internally and externally (1 per cent ointment, not more than 2 grains of wheat, to a limited area). He did not publish until 1912, because the results were rather unsatisfactory; the oral dosage was too low, and the thallium does not act locally (Dixon, 1927). The depilation formed the starting point of a series of studies by A. Buschke and co-workers, beginning with 1900. Successful internal use was first reported by Cicero, 1919, in a series of children with ringworm of the scalp. The clinical treatment was also developed independently by Buschke, Langer and Scheyer, 1926. The literature was reviewed by Peter, 1926, and by Buschke and Peiser, 1931.

Fate.—Thallium acetate is very soluble in water, and is readily *absorbed*, even from the skin. It reacts to form the sparingly soluble chloride, so that death is delayed even with intravenous injection (Sapiema, 1904). It is, however, *distributed* through all the organs (Dixon, 1927). In chronic poisoning its concentration is highest in the liver, brain and skeletal muscle, relatively low in the kidneys, none in the fat. It is *excreted* chiefly by the urine, beginning two and a half hours after its oral administration. In dogs, 62 per cent of the amount administered orally was excreted in the urine in thirty-six days (P. A. Shaw, 1933) in rabbits, 70 per cent in thirty days and 14 per cent in the feces (Testoni, 1933). It appears in the gastric juice of rabbits in a few minutes after hypodermic injection, but the concentration is less than in the blood; it increases materially in the intestines, owing to biliary excretion. It is somewhat reabsorbed in the digestive tract. It passes into the fetus (J. Frey and Schlechter, 1939). The milk in fatal cases may be toxic to the sucklings (K. Ehrhardt, 1927).

Etiology of Poisoning.—Thallium is more treacherous than lead and nearly as toxic as arsenic, and is used for homicide in place of the latter (Steidle, 1939). Alopecia is the only distinctive symptom, and as this takes several weeks to develop, it is absent in the acute and many subacute cases (A. O. Gettler and Weiss, 1943). Neuritis and other serious effects have been produced by a proprietary hair-removing *ointment* ("Koremlu"), containing approximately 7 per cent of thallium (reports in J.A.M.A., 1931; similar reports from Italy, Ciambellotti, 1929). Poisoning has resulted from its therapeutic use internally, especially by adults; from its employment in rat poisons, and in the industries—the latter generally chronic. More than twenty-three deaths were on record in 1931, and extensive series have been reported since then (Munch *et al.*, 1933; bibliographies, Swain and Bateman, 1910, including the older literature; Buschke and Langer, 1927). The toxicity is believed to be distinctly lower before puberty (Buschke and Markus, 1929).

Course of the Acute Poisoning.—Thallium poisoning develops slowly. With large overdoses, death occurs in twenty-four to forty hours, chiefly by hemorrhagic gastroenteritis, with terminal dyspnea (O. Gessner, 1931). Generally, the course is much slower. The group reported by Ginsburg and Nixon, 1932, involving a family of eleven, of whom six died, is illustrative. The symptoms within the first twenty-four hours consisted of tingling and pain in the hands and feet, severe paroxysms of abdominal pain and vomiting without diarrhea; then weakness of the extremities; traces of albumin and some hyaline casts in the urine; marked stomatitis and salivation, some with a "lead line"; blebs forming on lips. Within two to five days, all developed encephalopathy with cranial nerve palsies, disturbed sensorium, myoclonic movements of the extremities and head. The more toxic patients passed into convulsions, then marked delirium, coma, and death by respiratory failure. The temperature rose to 103° F. within twenty-four to forty-eight hours before death, with signs of pulmonary edema and bronchopneumonia.

With continued administration of smaller toxic doses, the symptoms ordinarily become perceptible in about a week and reach their acme by the end of the second or third week, and in favorable cases begin to retrogress about four weeks later. If the dosage was not too large, or too long continued, the recovery may be complete. In fatal cases, death generally occurs after several weeks, with severe nervous symptoms and gradual decline (Heinichen, 1931). The *phenomena of the slow poisoning* include stomatitis and hemorrhagic gastroenteritis, with diarrhea, but without the spastic constipation of lead poisoning; loss of hair and dermatographia; marked hyperexcitability of the sympathetic system; peripheral neuritis, pain in the extremities, tremors of the hands, weakness of the muscles; sometimes optic atrophy; glomerular nephritis, with polyuria and persistent albuminuria; inhibition of growth and sexual development, with degenerative changes in the endocrine glands, thyroid, parathyroid, gonads and suprarenal, and of other viscera; alterations in basal metabolism, blood sugar level and calcium; rickets and gray cataract; swelling of the reticulo-endothelial cells of the liver and spleen; restlessness, obstinate insomnia, depression, dementia and other neuroses, with degenerations in the basal ganglia, optic nerve and cerebellum.

The **treatment** in acute cases would consist in gastric lavage. Various antidotes have been proposed, such as iodide, thiosulfate, pilocarpine, calcium salts (Munch, 1934), but their value has not been demonstrated and their rationale appears doubtful.

Clinical Depilation.—Thallium acetate is, or was, used only in children younger than ten years, in a single dose of 8 mg. per Kg. of body weight, exactly measured, by mouth, generally in water. The hair becomes brittle in about a week and comes out more or less completely for the following two weeks, generally with some minor toxic manifestations. It is restored in about six weeks, perhaps even more abundantly than before. If the dosage is too large, the alopecia may be permanent. Biopsies show distinct lesions in the hair bulb and sheath, with later regeneration, but some of the follicles undergo sclerosis (Traffi, 1928).

Experimental studies of the depilation have been made especially in rats and confirmed on other animals (Buschke, 1911). The susceptibility varies in different individuals. It may be obtained with a single dose of 14 to 18 mg. per Kg. (Cooper and Engmann, 1931), or daily doses of 0.5 mg. per Kg., of thallium acetate (Buschke and Peiser, 1926), by mouth or hypodermically, or local application of 0.1 to 1 per cent ointment. The phenomena correspond exactly to those of the clinic, in kind and in time (Buschke and Peiser, 1926). Smaller doses may stimulate the growth of hair (Dixon, 1927; Cooper and Engmann, 1931, a single dose of 5 mg. per Kg.). *Histologically*, the depilation stage shows the hairs split and broken, the hair follicles often enlarged, changes in the keratinization of the epithelium and scaling (F. Hecke, 1928; Buschke and von Vasarhelyi, 1932). The perifollicular nerves show degeneration (Cortella, 1933). Petechiae and eruptions are sometimes seen clinically (Prokoptchouk *et al.*, 1930). The suppression of sweating is probably due to these skin changes. The depilation includes all the body hair, which is innervated by the sympathetic; while the sensory hairs, which have a cerebrospinal innervation, escape. On this basis, Buschke and Peiser, 1926, attributed the depilation to sympathetic stimulation, and Dixon, 1927, described increased excitability of sympathetic nerves to electric stimulation; but H. C. Chang, 1931, showed that the alopecia involves also denervated autotransplants. The change of susceptibility with age might suggest an endocrine action; for instance, administration to lactating rabbits may cause alopecia of the suckling without affecting the mother (Vasarhelyi, 1928); but excision of the thyroids and ovaries has no effect in either direction (Chang, 1931).

Internal Organs.—Thallium produces destructive changes, especially in the sexual glands, but also in other endocrine glands, in the lymphatic system and in the other viscera. The gastro-enteritis has been mentioned. These all progress and retrogress coincident with the general course of the poisoning and of the depilation. The most marked changes are in the spermatogenesis; namely, disintegration of the spermatic cells, azoospermia, suppression of mating. Corresponding suspension of *estrous cycle* is observed in mice (Buschke and Markus, 1929), but not in rats (A. J. Cox and Rodgerson, 1935). The *adrenal cortex* shows marked vacuolization (Hecke, 1928); Buschke and Markus, 1929, and Koyanagi, 1930, connect this with increase of the *blood cholesterol*, which occurs at the same time. The *thyroid* also shows changes, which may be connected with a decrease of the *basal metabolism*, described by Mu and Hu, 1930. The blood sugar level rises during the first ten days, then falls below the normal (Mamoli, 1926); with intravenous injection, hypoglycemia precedes the hyperglycemia (Koyanagi, 1930). The serum calcium is lowered, with softening of the bones and rachitic changes in prolonged poisoning (Buschke and Markus, 1929; Koyanagi, 1930). These suggested parathyroid deficiency (Buschke and Markus), but Mamoli, 1926, did not find any changes in this gland; he was inclined to attribute the *cataract*, which may also occur, to the hyperglycemia. Young rats regularly develop cataract in both eyes, differing from other toxic cataracts, naphthalene, diabetic and tetany (Donski, 1932). The *blood picture* shows leukocytosis and erythropenia, with normoblasts (Mamoli, 1926), but no stippling (Testoni, 1930; Viola, 1933). Pathologic changes in the lymph nodes and thymus, liver, pancreas, lungs and kidneys were described by Hecke, 1928, and Prokoptchouk *et al.*, 1930.

The *histopathology of the central nervous system* was described for a human case and for apes by E. Scharrer, 1933. The changes involved the olivary and dentate nucleus and Goll's columns and the anterior and posterior horns of the cord, and are similar to those of lead. Rats and cats show marked degenerative changes in the cells of the central nervous system, in the myelin sheath, axis cylinder, neuroglia and neurofibrillary reticulum, and degeneration of the peripheral nerves (Cortella, 1930, 1931, 1933; Delfini, 1934).

Vegetation.—Thallium prevents the germination of seedlings (Dilling, 1926). Ground on which thallium sulfate is sprinkled will not bear vegetation for years (S. C. Brooks, 1932). The amount which adheres to thallium-poisoned grain, however, is not injurious to the soil (Horn *et al.*, 1934).

Antiseptic Action.—Thallium salts are somewhat antiseptic, but only in the presence of air (Buschke and Jacobson, 1922; Buschke, Jacobson and Klopstock, 1925).

APPENDIX-BIBLIOGRAPHY OF PAPERS APPEARING SINCE JANUARY 1926*

Names of Authors.—If there are more than three authors of a given paper, only the first two names are listed and the others are indicated by *et al.* The names of the other authors are listed only if they are necessary for subsequent clarity of arrangement.

In general, if an author has more than two initials, only the first two of these are given.

Articles and Books.—Under a given author the subjects are arranged alphabetically; when reference is made to several papers on the same subject by the same author, the references are arranged under the subject according to year.

Full titles of papers are not recorded; the bibliography title indicates the material in the paper significant from the standpoint of pharmacology. Thus the bibliography title is not necessarily found in the author's title.

The abbreviation *Diss.* indicates *Dissertation.*

Journal Abbreviations.—The abbreviations used in this bibliography are, for the most part, those used in the Second, Series of the *Index Catalogue of the Library of the Surgeon-General's Office, U.S. Army,* Washington, D.C., and in the *Quarterly Cumulative Index Medicus,* American Medical Association, Chicago.

Because of the numerous references to the *Journal of the American Medical Association* and to the *Journal of Pharmacology and Experimental Therapeutics,* these are abbreviated respectively *J.A.M.A.* and *J.P.E.T.*

Abstracts, References, and Proceedings.—In all abstract references, such as those of the *Chemical Abstracts* and the *Biological Abstracts,* the page on which the abstract appears is recorded rather than the code number.

An abstract of a paper presented at a meeting is recorded as on the page of the journal in which the proceedings of the meeting appear.
